Siphons are pipes or conduits under pressure connecting sections of sewers. They are used to carry sewers under rivers, across valleys, and in other places where the continuous grade cannot be maintained. Siphons have ordinarily smaller areas than the sewers with which they are connected, so as to increase the velocity in them and diminish the tendency to form deposits. At the same time, some extra slope or head must be allowed for siphons, both to give the added velocity and to overcome resistance due to partial silting up of the channels.

Siphons serving large sewers in which the flow is very variable are best made of twin or triplicate pipe lines. Low flows then pass thru one line of pipe, the other lines being brought into service automatically for the flood flows. Siphons should be so designed that the maximum velocities thru them will be sufficient to scour out even considerable deposits of sand. Maximum velocities can sometimes be provided artificially by flushing when they would not occur otherwise. Siphons of considerable length and drop are best made of cast-iron or steel pipe. Small siphons with but little drop may be made of tile pipe, and large siphons with but little drop of reinforced concrete.

Manholes are masonry structures reaching from the channel of a sewer to surface of the ground, closed at the top with a cast-iron frame and cover, and affording access to the sewer for inspection, cleaning and repair. Manholes are usually placed at all street intersections, and frequently at intermediate points with small sewers. Manholes are provided in larger sewers wherever laterals enter, and in general not more than three to five hundred feet apart. If the sewer is large enough so that it can be inspected by passing thru on the inside readily, there is less necessity for frequent manholes.

Inlets for Storm Water are provided for combined sewers or storm drains on each of the four corners at street intersections, and in the middle of long blocks. Rain water is carried to these points by the gutters.

Catch Basins are masonry pits built in connection with, and frequently directly under, the inlets, thru which the storm water flows, and in which the coarser mineral matters from the street wash are deposited. Catch basins require to be cleaned at intervals. They should be used on all sewers except those having very steep slopes and where the discharge of coarse-grained

mineral matter at the outfall is not objectionable. The idea of the catch basin is that it is easier and cheaper to remove heavy matter collected from it than from the bottoms of the sewers.

Outlets are the ends of sewers, where the sewage is discharged into streams or other bodies of water. Outlets for small sewers are most conveniently made of cast-iron pipe of sufficient length to be well anchored into the bank. Larger sewers have outlets of masonry built on stable foundations, and sufficiently massive to resist the action of ice and logs or other material carried by floods.

Sewer outlets are best placed so as to discharge directly to the thread of the stream, so that the sewage will always mix directly with flowing water. With streams having great range in flow and elevation it is often impractical to carry the main outlet to such a point of discharge. In such cases a cast-iron pipe sufficient to carry the low-water flows may be laid under the bed of the stream, reaching the main channel, the pipe being connected with the bottom of the sewer back of a low dam. The low flows will then pass thru the pipe, while storm and other large flows will overtop the dam and find their way directly to the river.

In very cold climates, cold air enters the sewer outlets, chilling the sewers and their connections to an objectionable extent. In some cases sewer outlets are filled with straw in winter to protect them from extreme cold. This is safe because any flood requiring the capacity will force out the straw, making a channel for itself.

Where size is increased the axis of the sewer may be continued thru such increase, or the bottoms may be brought flush, an offset being made at the top, or the tops may be brought flush, the offset being made at the bottom. Where the slope is not steep it is always best to bring the bottoms flush, because this gives the greatest velocity for self-cleaning.

Intercepting Sewers do not carry storm flows. They are often much longer than lateral and trunk sewers, and are most frequently built after other parts of the sewer system and to correct defects, and especially to change the point of discharge or to allow other disposition of sewage to be made. The areas involved are often large, and it would be so difficult as to be almost impossible to build intercepting sewers large enough to carry all sewage and storm flows to the new point of discharge. It usually suffices to take to that point the dry-weather or ordinary flows, and to allow the storm flows with the sewage mixt with them to continue for the most part to discharge as formerly.

The Capacity of Intercepting Sewers is computed as if for the separate system, even tho combined sewers are used in a whole or a part of the area tributary to them. For example, the intercepting sewer is made sufficiently large to carry 100 gallons of actual sewage per capita daily, 100 gallons per capita daily in addition, representing fluctuations in rate of flow, and further 100 gallons per capita daily, representing ground water entering the system, and all other waters, making a total capacity of 300 gallons per capita daily, reckoned on the population to be ultimately provided for in the area under consideration. With an intercepting sewer so designed all of the sewage can be carried except when there are considerable quantities of storm water or melting snow.

Storm Overflows are structures built at the connections of the trunk sewers and the intercepting sewer, arranged so that the low water flows will be diverted to the intercepting sewer, and so that storm flows in excess of the capacity of the intercepting sewer will automatically go thru their old channels.

Storm overflows usually consist of long weirs with their crests a little way above the bottom of the trunk sewer arranged so that the water that does not pass over the weir goes to the intercepting sewer. With this arrangement the storm overflow will not ordinarily operate until the full contribution has been diverted to the intercepting sewer and until that sewer is running full.

Automatic Valves operated by floats have been sometimes installed so that when the intercepting sewer becomes filled the connection with the trunk sewer is shut and no more sewage goes to the interceptor until the level in it falls. Such devices allow the entire flows during storms to go as before.

Pumping Stations are often necessary in connection with intercepting sewers. This happens where the natural slope of the valley is not sufficient to give the requisite fall to the sewer. In such cases the economical slope of the intercepting sewer must be carefully considered. A steep slope means cheaper sewer construction and more expense for pumping, while a flatter slope means a larger sewer and less expense for pumping. If the intercepting sewer is very long it may be cheaper to install two or more pumping stations along its length, as this keeps the flow line near the surface of the ground and the sewer does not have to be built so deep, the cost of construction being thus reduced. Pumping at two stations is more expensive than pumping at one station, so that this procedure must be followed with caution.

Storm Sewers as distinguished from sewers carrying fecal matters are used separately in connection with sewers on the separate system. The principles covering their design are substantially the same as those covering the design of sewers on the combined system, except that with their use it is generally possible to utilize gutters to carry the storm flows for greater distances and therefore to omit the storm sewers in side streets to a considerable extent, using the gutters as part of the system. The total mileage of a system of storm sewers will be materially less than the mileage of a system of sanitary sewers. Storm sewers may also be often built at a higher level and so at less cost.

Where the system of storm sewers is installed it is often possible to utilize natural valleys in their natural condition, or with paving and other improvements to carry storm flows. This can often be done for less money than it costs to build entirely artificial channels. Valleys used for this purpose are best owned by the city for a width sufficient to give capacity for the greatest flood flows. Ordinary flood flows are very much less than the extreme flood flows, and the sides of the valleys, overflowed but seldom, may be parked and may be made attractive features of the plan. The fact that such areas are overflowed at long intervals in exceptional storms does not detract materially from their usefulness in other ways. It is difficult to apply this system to old cities already developed along other lines, but where additions are being developed and laid out it is usually possible to apply it.

30. Maintenance and Operation

Use of Combined and Separate Systems. Most of the older cities were sewered on the combined system. In the last decades there has been a great increase in the use of the separate system. The combined system is more economical in cities compactly built up and near points of discharge where no question is raised as to the discharge at the outlet of all that comes in the sewers from whatever source. The separate system is to be preferred in most cases where the sewage has to be treated before discharge, or where it has to be carried for any considerable distance to an acceptable point of discharge, or where it has to be pumped. The advantage of the separate system in these cases lies in the great reduction in the volume of sewage to be carried, treated, or pumped.

Sewerage systems are seldom laid out and built as units. A little is built by each successive administration, and the additions frequently represent the individual ideas of those in charge at the time that the additions are made. For this reason, sewerage systems, especially old systems that have been long building, seldom represent a comprehensive plan. Portions of combined and separate sewers are found in the same system, and the greatest divergence in carrying capacities is found in different streets.

The Problem Presented in Sewerage Design is seldom to design a new system, but rather to find out what already exists and how that can be best utilized in the development of the system to meet changed and changing needs and new conditions. RECORDS should be kept of all sewers built, showing exact profiles, connections, cross-sections, materials, and all essential facts. When not so kept, changes and additions must be based upon surveys, often made at great expense and then inadequate because not revealing conditions that are covered up, but which could easily have been shown on proper record plans when the sewers were built.

Ventilation of Sewers. It was formerly supposed that various diseases were caused by sewer gas, and the ventilation of sewers was studied from this standpoint and with reference to preventing the air which had been in the sewers from finding its way where it might be breathed. Increased information has not supported these views. Diseases are carried rarely, if at all, by sewer gas, and there is less reason for apprehension than was formerly supposed. Even the men working in sewers and cleaning them are not especially subject to disease.

The ventilation of sewers, therefore, is primarily a question of æsthetics, and not of sanitation. Objectionable smells from sewers are occasionally experienced, especially where sewers are very flat, or where for any reason considerable deposits collect and decompose on their bottoms and sides. Such odors are most likely to occur in sewers on the combined system in long periods of dry weather when natural flushing is absent, or in very cold climates where, during the winter, all the precipitation is in solid form and does not contribute to the flushing of the sewers.

Ventilation thru Manholes. The manhole covers are commonly perforated, and considerable ventilation takes place thru them. When the sewer system is otherwise nearly air-tight cold air will go down thru a certain number of manhole covers and up thru the others. If the sewers are dirty, bad-smelling, objectionable odors will be noticed by those passing over those manholes in which there is an upward current.

Special Ventilators have sometimes been built on the sides of streets, carried to considerable elevations. Such a ventilator will act as a chimney. There will always be an upward flow of warm air thru it, and thruout a considerable distance in the sewerage system all the flow of air thru other openings will be into the system, and consequently no odors will be observed in passing them. Such sewer ventilators have seldom been used in America.

Ventilation thru Soil Pipes. In most Continental and in many American cities the soil pipes of houses are mainly relied on for sewer ventilation. When this is done the traps on the entrances from the houses to the sewers, universally used in England and in many American cities, are omitted. There is then a flow of warm air from the sewer thru each house connection to the soil pipe and thru it to its end above the roof of the house.

In cold climates special protection of the top of the soil pipes must be applied to prevent them from filling up with frost. This is best done by surrounding them with galvanized iron or other metallic structures, with suitable openings, which prevent the top of the soil pipe from becoming chilled. This method of making house connections without traps and of ventilating the sewers thru them has been satisfactory wherever it has been used.

31. Disposal of City Refuse

City Refuse consists of various solid substances incapable of being carried by sewers. It includes ashes, garbage, rubbish, manure, etc. Most of it is collected by householders in cans and removed by the municipality in carts. This gives rise to three interrelated problems, household storage, transportation and disposal. The method selected for final disposal controls the other two,

There are two principal systems, the mixt system and the separate system. With the mixt system the ashes, garbage and rubbish are stored and transported together and disposed of by incineration. This is the method common in Europe. With the separate system the three classes of refuse are kept apart, the ashes being used for filling low land, the rubbish being dumped or burned, and the garbage being fed to animals, reduced or otherwise disposed of. This requires separate household receptacles and separate transportation.

Refuse Incineration consists of burning the mixt refuse of a city instead of disposing of them separately. There are two general types of destructors, (1) the mutual assistance type, having several grates and divided ash pits, the products of combustion commingling above, thus combining several furnaces into one; and (2) the separate-unit type. The minimum temperature of combustion is about 1250° F.; maximum, seldom above 2000° F. The capacity of existing plants is about 1200 to 1500 pounds per day of mixt refuse per square foot of grate surface. One to two pounds of water are evaporated per pound of mixt refuse. The cost of the process is about $1.50 per ton of mixt refuse.

Garbage Reduction consists of separating from the garbage such substances as glass, tin cans, etc., and submitting the garbage proper to a steam-cooking process, whereby certain by-products, such as grease, fertilizer, ammonia, etc., are recovered. Naphtha is sometimes used in the grease extraction. At Barren Island, N, Y., the garbage was cooked by steam for 8 or 10 hours, at 310° F., pressure 60 to 65 lbs. At Buffalo, N. Y., the percentage of grease amounts to 1 to 3% of the garbage and the marketable tankage is about 10%.

The Cobwell method of garbage reduction avoids some of the disagreeable odors. It involves steam cooking and tankage drying. The garbage is put into steam jacketed extraction tanks and treated with naphtha (or kerosene) and stirred mechanically. The garbage becomes dehydrated, naphtha and water going off together to a separator, and then the fats are dissolved in the solvent and recovered by distillation. The tankage, containing 8% moisture and very little grease, is removed, dried, ground and sold as fertilizer. The naphtha is recovered and used again with but little loss. The largest plant of this type is at Staten Island. It has a nominal capacity of 2000 tons per day and is used for the disposal of the garbage of New York City.

DISPOSAL OF SEWAGE

32. Composition of Sewage

The Constituents of Domestic Sewage are about the same in all places, but the quantities vary with the water supply, diet of the people, the use of soap, etc. The concentration varies according to the per capita consumption of water, ground-water leakage, and storm-water flow. The admission of street wash and trade wastes materially alters the character of sewage. The first washings of a street after a shower are sometimes as foul as domestic sewage, while the wastes from certain industries add materially to the mineral and organic constituents. The age of the sewage modifies its composition and its physical and biological character. The sewage of a separate system is usually more uniform and more concentrated than that of a combined system.

Analysis of Sewage. The methods are practically the same as those for analyzing water. The standard methods are given in "Standard Methods for the Examination of Water and Sewage," third edition, 1917, revised by committees of American Public Health Association, American Chemical Society, etc. The most important determinations are those of suspended matter, organic matter, fats and dissolved oxygen, but in many cases determinations of iron, alkalinity, acidity, incrustants, chlorine, free carbonic acid, etc., are required, besides microscopical and bacteriological tests. Observations of turbidity cannot be as well substituted for determinations of suspended matter as in the case of water analysis. The organic matter is best represented by determinations of total nitrogen and oxygen consumed. Analyses of single samples of sewage are of little value from the standpoint of sewage purification. In order to obtain a fair idea of the average composition of sewage, samples should be collected in series and integrated so as to obtain an average sample, taking into account the time and the volume of flow. On account of the liability to rapid putrefaction it is necessary to have analyses of sewage made very soon after the sample is collected.

Per Capita Constituents of Sewage. In the absence of analyses of properly collected samples the following estimates of the constituents of sewage may be used for the purpose of approximate calculation except where trade wastes play an important part. The effect of trade wastes on the character of the sewage is very great, and the figures given in the table for this class of sewage do not indicate the extreme conditions, but are taken as representing those which generally obtain.

Constituents of Sewage in Grams per Capita Daily

Sewage matter	Total solids	Organic matter	Mineral matter	Chlorine	Nitrogen	Nitrogen as albuminoid ammonia	Nitrogen as free ammonia
Fecal matter	70	50	20	7	8	....	....
Domestic sewage	110	60	50	10	10	1.4	6.4
Domestic sewage plus polluted ground water ...	170	70	100	20	11	1.7	7.0
Domestic sewage plus street wash	220	100	120	25	13	2.0	8.0
Domestic sewage plus manufacturing wastes	220 to 500	100 to 200	120 to 300	25 to 50	13 to 18	2.0 to 4.0	8.0 to 10.0

To change to parts per million multiply these figures by 264 and divide by the volume of sewage in gallons per capita per day. To change to tons per year per 1000 population, divide by 2.5.

For average sewage the amount of suspended matter is about 100 grams per capita daily; fats, 20 grams; bacteria, 300 billion per capita daily.

Sewage, consisting of the water-carried wastes of a city, is disposed of either by dilution, that is, by discharge into a body of water without purification, or is first submitted to some form of purification.

33. Disposal by Dilution

Disposal by dilution consists in allowing sewage to flow into the water of streams, lakes, or harbors. The dissolved oxygen in the water into which the sewage flows is depended upon to oxidize the organic matters in the sewage before they become objectionable. In order to be successful the sewage must be mixt within a short time with a sufficient body of water so that the oxygen in it will do its work. The supply of oxygen is increased by oxygen absorbed

from the atmosphere as the supply in the water is exhausted. The disposal of sewage by dilution is much the most common method. A secondary source of trouble from disposal by dilution in still water is the formation of deposits of sewage mud immediately about the sewer outlets. This difficulty is principally experienced in lakes and in mill ponds upon small streams and in the vicinity of docks where the sewer outfalls are not carried out to the pierheads. It is not likely to happen where there are considerable tidal currents, and in large streams flood flows usually remove such deposits before they accumulate to an objectionable extent.

Pollution of Streams. The disposal of sewage by dilution in streams tends to their pollution. The pollution of streams when it goes too far is objectionable: (1) In causing local nuisance; that is, by causing odors, scums, and deposits objectionable to sight, and making the watercourses and the lands near them less desirable as places of residence, business, or pleasure. (2) In the pollution of public water supplies taken from the watercourses at points below.

Purification of Sewage is generally undertaken solely to prevent local nuisance and in those cases where the local nuisance otherwise produced would be so detrimental to the public interest as to warrant the expense of sewage purification. The conditions arising from local nuisance are not in general injurious to health.

The purification of sewage to prevent the pollution of public water supply has been attempted only in exceptional cases by small towns and cities upon small catchment areas, as, for instance, some of the villages upon the catchment area of Boston's water supply. In these cases the party profiting by the treatment has paid most or all of the expense. To make the process effective it must be bacterially efficient and the treatment must apply to all storm-water flows. These two conditions make the application of sewage purification to cities on large rivers to preserve the purity of the streams for water-supply purposes practically out of the question in the present state of the art, and, in general, the purification of water supplies can be carried out more certainly and at less cost than corresponding results can be reached by purification of sewage.

Natural Agencies of Purification. The method of disposal by dilution makes use of the following natural agencies: (1) The oxidation of organic matter of all kinds by the oxygen in the water or by that taken from the atmosphere, either destroying the organic matters or changing them into stable inoffensive residues. (2) Sedimentation, removing suspended matters wherever the flow is sluggish, thereby purifying the flowing water and forming deposits of sewage mud, which deposits, in rapid streams, will be flushed out at the next flood. (3) Bacterial changes, especially the death of pathogenic bacteria, which in temperate climates are unable to multiply in flowing waters and which gradually disappear under the influence of sunlight, aeration, and the antagonism of other organisms.

Pollution of Harbors. In the case of the disposal of sewage by dilution in harbors there are no questions of public water supplies to be considered, but, on the other hand, there is some danger of the contamination of oysters and other shellfish and from the use of the water for bathing. The problem is often complicated by tidal phenomena which influence the circulation of the water; by the greater specific gravity of salt water, which has an effect upon the dispersion of sewage in water, and by the fact that salt water holds less dissolved oxygen than fresh water.

Dissolved Oxygen in Water. The amount of oxygen dissolved in fresh water saturated with air varies according to the temperature as given on p. 1268. The figures, which are in parts per million by weight, are for sea level, or, more strictly, for a barometric pressure of 760 mm.

Temp. C.	Oxygen	Temp. C.	Oxygen	Temp. C.	Oxygen
0	14.70	10	11.31	20	9.19
1	14.28	11	11.05	21	9.01
2	13.88	12	10.80	22	8.84
3	13.50	13	10.57	23	8.67
4	13.14	14	10.35	24	8.51
5	12.80	15	10.14	25	8.35
6	12.47	16	9.94	26	8.19
7	12.16	17	9.75	27	8.03
8	11.86	18	9.56	28	7.88
9	11.58	19	9.37	29	7.74

Deduct 1% for each 270 ft of elevation above sea level. For sea water deduct 20% and for mixtures of fresh and sea water in direct proportion to the amount of sea water.

Dilution of Sewage Required to Prevent Nuisance. The following formula represents the degree of dilution required to oxidize sewage and prevent nuisance: $D = x/s = fm/o$, in which x = the volume of water, s = the volume of sewage, o = the amount of dissolved oxygen in the water, m = the result of the "oxygen consumed" test, express in parts per million, and f = a factor depending upon the method used for determining the oxygen consumed, and wh'ch is approximately 4 for the five-minute test as made in this country, 6 for the two-minute test, 7 for the four-hour test as made in England, and 12 for the fifteen-minute test as made in England. For example: the amount of "oxygen consumed," as shown by the five-minute test for an average city sewage, is 58 parts per million when the volume of sewage is 100 gallons per capita daily. If the amount of oxygen in the water is 10.14 parts per million, which corresponds to a fully saturated water at 15° C., then $D = x/s = 4 \times 58/10.14 = 23$, that is, the dilution of the sewage required to prevent putrefaction is 23 times the volume of the sewage. This is further equal to 3.5 cu ft per second per 1000 of population.

River waters carry less oxygen in summer, and therefore more dilution is required. Stream flows are ordinarily less in summer than in winter, and in general pollution is greater in summer than at other seasons. The problem of local nuisance is mainly a summer problem which need only be discussed with reference to summer conditions.

Flow Required for Dilution. The Chicago Drainage Canal was designed by Rudolph Hering to provide a flow of at least 3.33 cu ft per sec of water for the dilution of the sewage of each thousand persons. X. H. Goodnough places the limits for Massachusetts conditions between 3.5 and 6 cu ft per sec. Rafter used 4 cu ft per sec for certain New York conditions. No single figure can be applicable in all sewages, but the above figures may be taken as reasonable for those conditions in which no opportunity is offered for absorption of oxygen from the atmosphere, as in sluggish, stagnant streams or bodies of standing water. Where these conditions are favorable for the absorption of atmospheric oxygen, the required dilutions are less. Such conditions are found in rapidly flowing streams with many ripples and waterfalls, and in bodies of standing water subject to strong wave action.

It would be possible to have a channel in which the velocity would prevent deposits, and in which falls would produce aeration, thru which sewage could be discharged continuously without dilution, and without the production of local nuisance, until, if the channel were long enough, the sewage became fully oxidized. This extreme condition is not reached in practise, but some mountain streams approach it, and receive sewage without offense in quantities that would be intolerable in a sluggish stream.

The application of dilution ratios is difficult because the flows of streams are constantly changing. In a given case the natural flow of the stream may be sufficient for dilution for ten months in the year and inadequate for two months in the year, or the flow may be sufficient for dilution at all times during an average year and may fail to give sufficient dilution in a dry year. In general the method is insufficient only when it fails to give reasonably satisfactory results for some considerable length of time.

The required oxidation for dilution is affected by the amount and character of the population on the banks of the stream below the outfall. If there is a large population to be

affected, and if the water is used for boating and bathing, higher standards are properly required than where there is only a scattered rural population and no special use made of the water. In some cases there is no population below for some distance, and it may be then questioned whether a nuisance exists. The amount of discomfort and damage resulting from pollution should be taken on its merits on actual evidence in each case where sewage purification is proposed, and the amount of damage to be prevented by such purification should be reasonably commensurate with the required expenditure in order to justify the works.

34. Screening and Sedimentation

The Processes involved in sewage purification may be classified as follows: (1) Preparatory Processes, including screens, roughing filters, detritus tanks, plain settling tanks, septic tanks, and chemical precipitation tanks. (2) Purification Processes, including sub-surface irrigation, broad irrigation, intermittent filtration, contact beds, and sprinkling filters. (3) Finishing Processes for clarification are sedimentation and coarse filtration, while those for bacterial improvement are land treatment, sand filtration, mechanical filtration, and disinfection.

Processes of sewage purification may be divided in another way into three classes, as follows: (1) Processes separating without destroying the objectionable matters, afterward disposing of them in a concentrated form by burning, burying, or otherwise. (2) Processes which have for their object the oxidation and destruction of the organic matters in sewage by oxygen taken either from the air in the pores of filtering materials or contained in water with which sewage is mixt. (3) Processes for killing objectionable organisms without otherwise purifying the sewage. The first class generally includes all the processes listed above as preparatory processes, and also, in the finishing processes, the final sedimentation, coarse filtration, and the disposal of sludge. The second class covers especially intermittent filtration, broad irrigation, sprinkling filters, and contact beds.

The purification of sewage by any process is often attended by a certain amount of nuisance. For this reason it is customary to locate works at distances of one-quarter to one-half mile and farther if convenient from residential districts.

Screening. Where sewage is to be pumped or purified it is usually screened thru a grating of iron bars or thru a coarse or fine wire cloth. The object of screening is to remove the larger substances that might injure pumps, clog filters, or appear as unsightly litter. Coarse screening plays but little part in the real purification of sewage, but fine screening is an important preliminary process. Where gratings are used the bars are usually flat bars, spaced ½ to 1 inch apart, cleaned either by hand or by automatic cleansing devices. Screening has attained its greatest development in Germany.

In Birmingham, England, the screens are constructed as endless belts carried over two cylinders and operated by an undershot water wheel turned by the sewage. The screenings fall into a trough, where a worm forces them into the cart by which they are removed. Fine screens usually choke badly, but in Reading, Pa., a revolving cylindrical screen is used and kept clean by jets of water playing upon it from the outside. The sewage passes thru the cylinder, which is inclined, and the screenings pass to one end and are carried upward by means of a bucket lift to a room where they are dried in a centrifugal drier.

The material screened from sewage are sometimes prest or dried and burned under a boiler, sometimes treated in a garbage crematory and sometimes buried in land. The volume of screenings varies with the nature of the sewage and fineness of the screens.

Fine screening is attracting increasing attention. Screens may be called fine if the clear opening is less than about half an inch. Often the mesh is much finer than this. Naturally they clog rapidly and for that reason they are movable instead of stationary

Quantity of Screened Sludge and of Water in Same

City or town	Screen	Cubic yards per million gallons of sewage	Percent of water
Boston, Mass.	Iron bars 1 inch apart	0.06	....
Plainfield, N. J.	½ inch clear spaces	0.20	85
Columbus, Ohio	2 screens of 0.5 and 0.375 inch mesh	0.17 (300 lb)	....
Reading, Pa.	Wire cloth, 40 mesh per inch	0.75 to 1.10	85
Hamburg	Band screen, 0.6 inch clear openings	0.34	87
Frankfort	Wing screen, 0.4 inch clear openings	0.7	....
Strassburg	Shovel vane, 0.1 inch clear openings	1.6	89
Dresden	Reinsch-Wurl, 0.08 inch clear openings	0.97	84

and special arrangements are made for cleaning. The collected material is usually scraped off by a continuous process from a part of the screen as it slowly emerges from the sewage. There are at least six types of fine screens: (a) The Band Screen, an endless flexible band of wire or links which passes over upper and lower rollers, and which is inclined in the sewage channel; (b) the Wing Screen, consisting of meshed vanes or paddles on a horizontal axis, and which in the lower positions, are across the path of the sewage; (c) the Shovel-Vane Screens which differ from the preceding in having curved vanes; (d) the Cylindrical Screen, which revolves in an inclined position on an axis nearly parallel with the sewage flow, the sewage flowing through the cylinder, and the screen being kept clean by jets of water playing upon it from the outside, the screenings passing to one end of the cylinder and evacuated by means of a bucket lift; (e) the Drum Screen, a truncated cone of wire mesh or perforated plate, which rotates on a horizontal axis; (f) the Inclined Disk Screen, commonly known as the Reinsch-Wurl Screen, which consists of a perforated disk surmounted by a truncated cone, which moves on an inclined axis.

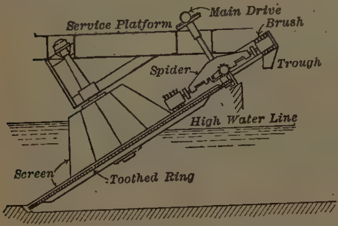

Fig. 18. General Arrangement of Reinsch-Wurl Screen

The openings in the plate are slots commonly about 2 mm wide and 30 mm long, staggered in rows, 6 mm apart, but these dimensions vary. The plate is swept by brushes as it emerges from the sewage. This process forces some of the friable solid matter through the screen, but leaves it in a finely divided state.

Sedimentation is accomplished by checking the velocity of the sewage in tanks so as to permit some of the suspended solids to settle to the bottom. The laws of sedimentation of suspended matter in water apply to sewage, but are modified because of the low specific gravity of the suspended organic matter and are further complicated by the bacterial actions that occur in the liquid and in the accumulated sludge. Four forms of sedimentation are distinguished, namely, grit chambers, plain settling basins, septic tanks, and chemical precipitation.

Grit Chambers, or detritus chambers, are small settling basins in which the sewage remains for only a brief interval, seldom more than an hour and usually not more than a few minutes, and where the velocity is commonly between 10 and 30 inches a minute. Cleaning is required at frequent intervals. Grit

chambers remove especially sand, gravel, and other heavy mineral matters which would otherwise be troublesome in subsequent operations.

Plain Settling Basins are large enough to retain the flow of sewage from 1 to 12 hours. Sludge is removed at frequent intervals in order to prevent too much bacterial action. The velocity of flow is commonly from 0.1 to 0.5 inch per minute. Bacterial action is of minor importance.

Dortmund Tanks (Fig 19) are deep settling tanks with conical bottoms, in which the sewage enters at the bottom and flows out at the top, and in which the sludge accumulates at the bottom and is forced out thru a pipe leading from the bottom and discharging below the elevation of the surface thru the pressure of the liquid in the tank. They may be used for any of the sedimentation processes, and are the cheapest tanks to operate because of the ease with which the sludge may be removed from them.

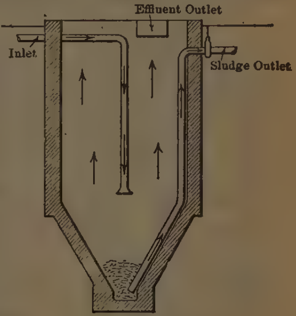

Fig. 19. Dortmund Tank

Removal of Suspended Matter by Sedimentation depends upon the period of retention, the velocity of the liquid in the tank, the presence of baffles, the amount and character of the suspended matter, the frequency of cleaning, temperature, and bacterial action, and varies from 10 to 25 % in grit chambers up to 50 to 85 % in septic tanks. The figures in the following table show the approximate percentages of removal for weak, medium, and strong sewage, corresponding to various periods of retention in well-designed tanks.

Percentage of Suspended Matter Removed by Sedimentation

Period, hours	Weak sewage	Medium sewage	Strong sewage	Remarks
1	10	15	25	Grit, or detritus, tanks
6	25	40	60	Plain sedimentation
12	30	50	75	Plain or septic sedimentation
24	40	65	80	Septic sedimentation
48	50	75	85	Septic sedimentation

Trade Wastes in sewage modify the effect of sedimentation. The presence of iron tends to act as a coagulant, hastening sedimentation, while soap tends to retard it on account of its colloidal character.

Removal of Suspended Matter by Sedimentation

Place	Process	Period of sedimentation in hours	Suspended matter in parts per million			Remarks
			Influent	Effluent	Percentage removed	
Columbus, Ohio	Grit chamber	0.3	209	163	22	Experiment Sta.
Columbus, Ohio	Grit chamber	1.5	209	138	34	Experiment Sta.
Columbus, Ohio	Plain settling	6.0	209	63	63	Experiment Sta.
London, Eng....	Plain settling	6.0	281	125	55	....
Columbus, Ohio	Plain settling	8.0	209	71	66	Experiment Sta.

35. Septic Tanks and Chemical Precipitation

Septic Tanks are settling tanks large enough to retain the flow of sewage for from 8 to 24 hours or longer, the sludge being allowed to remain for a long period in order to give opportunity for bacterial action to occur. The velocity of flow varies from 0.1 to 0.3 or more, inches per minute.

Hydrolytic Tanks are modified septic tanks in which the sludge is separated from the liquid and enters a compartment where septic action takes place, the liquid effluent being only partially septic.

Action of Septic Tanks. The object of septic tanks is to retain the sewage and give time for bacterial action, so that the oxygen in the sewage will be used up, permitting the growth of anaerobic bacteria that tend to act upon solid organic matter and liquefy or gasify it, and thus reduce the amount of sludge in the tank. The process is spoken of as "digestion of the organic matter." It is usually accompanied by the presence of a scum on the surface and by a continual rising and falling of sludge masses thru the liquid. The amount of solid organic matter digested varies from 10 to 40 %, being greatest in strong, domestic sewage and least in the weak sewage containing trade wastes. The following figures illustrate the amount of digestion of solid organic matter in certain typical sewage works in England: Birmingham, 10 %; Manchester, 25 %; Exeter, 25 %; Sheffield, 33 % The suspended matter in sewage consists approximately of one-third mineral matter not alterable in the septic tank, one-third organic matter not alterable and one-third organic matter digested and destroyed or changed in character. Long-continued septic action interferes with sedimentation in the septic tank. For example, in Huddersfield, England, the septic effluent at the beginning of a run contained 66 parts per million of suspended matter and 233 parts after eleven months operation.

Covers for Septic Tanks are of no material advantage so far as the action of the tank is concerned, but they serve to make them more sightly and less of a nuisance. Care must be taken to avoid explosions under covers due to inflammable gases liberated by the septic action. The amount of gas is from 1 to 8 times the volume of sewage.

Removal of Suspended Matter in Septic Tanks

Place	Period of sedimentation, hours	Suspended matter in parts per million			Remarks
		Influent	Effluent	Percentage removed

The Effluent from Septic Tanks is not more easily purified by subsequent processes than that of plain settling tanks. The odor from the effluent in sprinkling filters or other purifying devices may be somewhat greater. The SLUDGE is drier and for that reason less in amount, and more easily and cheaply handled, and has less smell than sludge from either plain sedimentation or from chemical precipitation. The improved condition of the sludge is the chief reason for the use of septic tanks.

Two-story Tanks, also called Imhoff or Emscher tanks, are tanks in which the septic action is confined chiefly to the sludge which settles into a lower sludge chamber from an upper sedimentation chamber through which the sewage flows. The two chambers are separated by inclined baffles so arranged that the sediment may pass downwards altho the gases resulting from the septic action may not ascend to the upper chamber. Separate vents are provided for these gases. By the use of tanks of this type the sludge becomes better digested, less offensive and more compact, while the sewage flowing thru the upper tank does not become charged with the products of decomposition from the sludge.

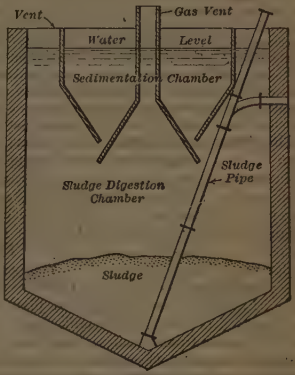

Fig. 20. Typical Cross-section of Imhoff Tank

Two-story tanks are usually deep. They may be rectangular or circular. The flow of sewage may be transverse or radial, i.e., from the center outward. Several tanks may be used in series. Provision is made for drawing off the ripened sludge thru a sludge pipe without interfering with the flow of sewage. The sludge contains from 87 to 93% of water. If well digested it is black, and smells like coal tar. It dries readily. The gas consists chiefly of methane, carbonic acid, nitrogen and hydrogen. The quality of gas is greatly influenced by temperatures. The period of detention of the sewage varies from 1 to 3 hours; the rate of flow from 20 to 100 feet per hour. The slope of the baffle is from 1.2 to 1.5 to 1. The slot is from 6 to 12 inches wide.

Chemical Precipitation is sedimentation hastened and increased by the use of chemicals. Lime, copperas (ferrous sulfate), and alum (aluminum sulfate) are most commonly used and are applied either singly or in combination. The active coagulants are aluminum hydroxide and ferrous hydroxide, formed by the reactions of these chemicals. Frequently the sewage itself contains all the iron necessary and lime only has to be added. The percentage of suspended matter removed by chemical precipitation usually varies from 50 to 75% and in some instances reaches 85%.

Acid sewages require lime. Sulphuric acid is used when the sewage is rich in fats, as, for example, in cities where wool wastes are prominent. Alumino-ferric and ferrozone are crude forms of sulfate of alumina commonly used in Europe. In England, where chemical precipitation is most common, the amount of alumino-ferric applied to domestic sewages varies from 500 to 1500 pounds per million gallons, according to the

strength of the sewage. Somewhat smaller amounts are sufficient if lime is used with the alumino-ferric.

The sewage of London receives about 500 pounds of lime and 120 pounds of copperas per million gallons; Glasgow, 600 pounds of lime and 1000 pounds of copperas; Worcester, Mass., about 1000 pounds of lime and no copperas; Providence. R. I., about 600 pounds of lime and little or no copperas. Sewage at both Worcester and Providence carries an excess of copperas put in by pickling works of wire mills.

In chemical precipitation tanks the flow is usually continuous, the capacity of the tanks being equal to 6 to 12 hours dry-weather flow of sewage. Intermittent sedimentation is sometimes used, the period of quiescence being about two hours.

The amount of dry sludge produced by this process commonly varies from 1 to 3 tons per million gallons of sewage. In Worcester, Mass., in 1905 it was 1.65 tons. In Providence, R. I., in 1903, it was 1.07 tons. In London in 1904 it was 2.30 tons. The percentage of water in the sludge commonly varies from 90 to 95%. In London and Glasgow the volume of wet sludge varies from 40 to 50 cu yds per mill galls of sewage.

Chemical precipitation is sometimes the only method of purification used, as in London, Glasgow, and Dublin. In cities where the sewage contains large amounts of trade wastes chemical precipitation is coming to be used as a preparatory process, the effluent from the chemical tanks being submitted to further purification.

The Amount of Sludge that collects in grit chambers in practise varies from 0.1 to 1.0 cubic yard of wet sludge per million gallons of sewage, in plain settling tanks from 1 to 4 cubic yards, and in septic tanks from 1 to 2 cubic yards. In chemical precipitation tanks the volumes of sludge are much larger, being often 20 to 25 cubic yards per million gallons of sewage. The weight of sludge per cubic yard is from 1750 to 1850 pounds, corresponding to specific gravities of 1.035 to 1.095. The percent of organic matter in dry sludge varies from 25 % to 50 %. The percent of water varies with the period of sedimentation and the time that the sludge is allowed to remain in the tank. Freshly deposited sludge in plain settling tanks commonly contains 90 % to 95 % of water, septic tank sludge, after several months storage, 80 % to 85 %, sludge from chemical precipitation works, 90 % to 92 %.

Sludge Disposal. The methods of sludge disposal may be classified as (1) Preliminary treatment: pressing, lagooning, air-drying, mixing with house refuse, centrifugal drying, and recovery of fats. (2) Final disposal: use as manure, depositing at sea, shallow burial in the ground, spreading on land, and burning.

Sludge Pressing is sometimes done in filter presses and the dry cake used for filling low ground or for fertilizer. The presses are operated by hydraulic power. To facilitate pressing lime is added. Sludge pressing is best adapted to the chemical precipitation process. Septic sludge is more difficult to press. The following data from Worcester, Mass., and Providence, R. I., are illustrative of sludge pressing in connection with the process of chemical precipitation.

	Worcester (1905)	Providence (1904)
Wet sludge prest, cu yd per mil gal of sewage	22.1	19.5
Prest cake, cu yd per mil gal of sewage	5.9	....
Prest cake, tons per mil gal of sewage	5.3	5.08
Percent of water in prest cake	67.6	73.5
Dry solids in prest cake, lb per mil gal of sewage	3420	2700
Lime used for precipitation, lb per mil gal of sewage	999	726
Lime used for pressing, lb per mil gal of sewage	265	137
Cost of pressing, hauling and dumping sludge, per mil gal of sewage	$6.33 *	$3.43 †

* Spread on land. † Dumped at sea.

The manurial value of sewage sludge is just about equal, pound by pound, to that of animal manure.

36. Intermittent Sand Filtration

In this method sewage is applied intermittently to prepared beds of sand at such a rate that it quickly soaks away, leaving the bed bare for a number of hours or days between doses in order to facilitate aeration and give opportunity for oxidation of organic matter. The sand or gravel constituting the filtering material holds a considerable amount of water in its pores by capillarity when thoroly drained. The amount of sewage furnished at one application is less than the amount so held by capillarity. When the dose is applied it increases the amount of water in the filtering material temporarily, but the water previously held commences to flow out and the flow continues until as much old water has been displaced as new water has been added. The sewage is held by capillarity in the filtering material in contact with air. This air must change often, and the application of the doses tends to change it. Many organisms establish themselves on the grains of the filtering material, and these organisms facilitate the oxidation of the organic matters by the air and the change of nitrogenous organic matters to nitrates, called nitrification. This process results in destruction of the greater part of the organic matters. A regular circulation of air in the pores of the filter is essential to success, and is on the whole the most important matter to be secured.

An inadequate supply of air in the pores of the filter bed results in an imperfectly purified effluent. One of the first signs is the presence of ferrous iron which oxidizes and separates on exposure to the air. This condition is at once detected by an experienced operator, and beds showing it should always be rested or treated.

Some organic matters are especially stable and not readily oxidized. These accumulate in the filtering material, especially near the surface. This accumulation increases the amount of water held by capillarity, and makes circulation of air thru the surface layer more difficult. For this reason the amount of sewage that can be applied after a few years' use is less than with new material. If the amount of sewage that is applied thru a term of years does not exceed the amount which can be handled continuously, then these more stable organic matters oxidize slowly, and after a while an equilibrium is reached beyond which there is but little if any further accumulation.

Two Rates of Filtration may be used in connection with a given filtering material: (1) A higher rate which can be used successfully during a year or two, until the surface layer has become partially clogged. (2) A lower rate which may be used thru a long term of years without the continued accumulation of objectionable quantities of organic matter. Generally the second or lower rate will control. Sometimes it is better business to scrape off the dirty sand and replace it with new sand for the sake of using the higher rate. Intermittent filtration is extensively used in New England, where favorable material is frequently found in place, requiring only grading and underdraining.

The Rate of Application of sewage to the beds is usually from 50 000 to 150 000 gallons per acre daily, the population served per acre being from 300 to 1200. The sewage is usually applied with no preliminary treatment except the use of screens and grit chambers, but experiments have shown that with sedimentation higher rates of application may be used and the sewage of 1500 to 2000 persons per acre successfully handled. The filter area is divided into beds by means of earth embankments in which are placed the distributing pipes. Underdrains are used where required. In fine material they are sometimes laid 20 to 30 feet apart, in coarse material as much as 100 feet apart. Sand depth is from 3 to 6 or 8 feet. The effective size of the material used for intermittent sand filters varies from 0.15 to 0.75 mm, but the most favorable size is from 0.30 to 0.50. The nitrogen applied should

not exceed 1 to 2 grams per day for each square yard of filter area. Coarse sands can receive higher nitrogen loads than finer sands.

The sewage is sometimes applied at one point in the bed and allowed to flow naturally over the surface. Sometimes it is distributed by means of wooden troughs or by channels and ditches controlled by hand gates worked by an attendant. The doses are applied at intervals of one-half day to three or four days, the beds meanwhile lying idle. Fine materials do best with large doses at long intervals; coarse materials require small doses at short intervals. Crops are commonly grown. Corn does particularly well, and does not interfere with purification. After repeated application the beds become clogged, requiring raking, harrowing, plowing, and finally a removal of the surface scum. Just before winter the beds are plowed into ridges so that the ice may form above them and permit the distribution of sewage during cold weather in the channels beneath the ice.

The Efficiency of intermittent sand filters is generally higher than that of any other process. Well-operated plants are capable of removing from 95 % to 98 % of the suspended matter, 90 % to 95 % of organic matter, and 95 % to 98 % of bacteria. In practise, however, the efficiency is often less than these figures, as shown by the following table, taken from analyses made by the Massachusetts State Board of Health.

Results of Sewage Purification by Intermittent Filtration in Massachusetts Cities

City or town	Period in years	Area in acres	Number of connected persons per acre	Sewage per acre daily in thousand gallons	Oxygen consumed, parts per million			Suspended matter, parts per million. Raw sewage
					Raw sewage	Filter effluent	Percent removed	
Andover	4	3.8	999	34	87	7	90	333
Brockton	7	21.5	1160	41	43	2	90	139
Clinton	4	23.5	426	33	121	12	91	255

Westborough	4	4.0	770	71	39	7	82	266

Intermittent Sand Filtration of Sewage in Massachusetts

	Minimum	Maximum	Approximate average
Percent of population connected to sewers	14	80	50
Population per sewer connection	5	13	8
Population per mile of sewers	160	934	445
Population per acre of sand filter, basis of total population	580	2 570	1 090
Population per acre of sand filter, basis of sewered population	222	1 390	540
Rate in gallons of sewage per acre daily	20 800	120 800	63 400
Cost of land per acre	$23	$279	$100
Cost of filters per acre (approximate),			
conditions very favorable	$ 500	$1 000	
conditions favorable	1 000	2 500	

	Minimum	Maximum	Approximate average
Cost of filters per acre (approximate)			
conditions unfavorable	\$2 500	\$4 000	
conditions very unfavorable	4 000	7 000	
all conditions (actual)			\$2 715
per 1000 persons connected	1 110	10 300	3 785
Cost of disposal works per 1000 persons connected, gravity plants	3 452	12 150	5 790
Cost of disposal works per 1000 persons connected, pumping plants	4 070	40 700	17 000

The above data relate to 16 sewage-disposal plants in Massachusetts and are taken from the Annual Report of the State Board of Health for 1903.

37. Disposal by Irrigation

Broad Irrigation consists in the application of sewage to land so that it may serve as food for crops, the liquid being spread over the surface by means of ditches and other channels as in the ordinary irrigation of land. The sewage of Berlin, Germany, and of Paris, France, is purified by broad irrigation. The land used in both cases is sandy and is thoroly underdrained and the process differs from intermittent filtration only in degree, the rate of application being lower and more attention being paid to the crops. The purification obtained from a bacterial standpoint is most complete, but the effluents sometimes carry dissolved iron due to an inadequate supply of oxygen in some part of the filtering material, and growths of various organisms take place in the effluent channels. In 1903 the following rates were used:

	Paris	Berlin
Area actually under irrigation in acres	13 100	17 500
Average daily quantity of sewage applied per acre, gallons	12 300	3 530
Number of persons served by each acre	207	112
Gallons of sewage per capita daily	59	32

The sewage farms are attractive, and several villages stand upon them. There is some odor at times, but the health of those living in the neighborhood and working on the farms is not injuriously affected. Crops raised on the Berlin farms more than pay the expenses of operation, not including the cost of pumping the sewage, but are not enough to pay interest on the investment. In arid or semi-arid climates broad irrigation may become profitable.

Irrigation has often been used with clayey or other impervious soils, especially in England. The amount of water that can be absorbed and filtered is much less and the area required correspondingly greater. Clayey soil will not absorb sewage in wet weather. In many works sewage is allowed to flow thru basins or simply over the nearly level surface of fields and flow away without having entered the soil at all at wet times or even at all times. Suspended matters may be removed, and where the sewage flows in a thin layer thru a field of growing grass considerable purification may result. The suspended matters are retained on the surface of the soil and are ultimately absorbed or plowed in.

Broad irrigation is especially adapted to treating sewage where purification is only required in dry, hot weather. At such times almost any land is benefited by a moderate application of sewage, and this is frequently the time when sewage purification is required to prevent local nuisance. With many streams it may be the only time that sewage treatment is needed. Considered in this way broad irrigation may be more attractive than when the purification of sewage thruout the year, wet and dry, hot and cold, is required.

Sub-surface Irrigation. The sewage is discharged thru 3 or 4 inch tile pipes laid in the ground 10 to 18 inches deep, in rows 2.5 or 3 ft apart. In

sandy soils this method is extremely useful for small installations, as all nuisances are avoided, but it cannot be used with compact soils on account of clogging. Under favorable conditions the sewage of 150 to 250 people can be applied to one acre provided that it is first submitted to sedimentation in a septic tank or cesspool. The rate of application is commonly 1 to 2 gal per linear ft, or from 20 000 to 30 000 gal per acre daily.

An automatic siphon is used so that the sewage may be applied rapidly for a short interval, after which there must be a considerable period of rest before another dose. The lines of pipe must further be divided into two or three sections to be used in rotation. A careful application of these principles is essential to success, as a slow, continuous flow of sewage cannot be successfully treated.

38. Contact Beds

Contact Filters consist of water-tight compartments filled with porous material used for the purification of sewage in the following manner: the bed is slowly filled with sewage and allowed to remain full for a certain period, after which it is slowly emptied and allowed to remain empty for a longer period of rest. The applied sewage is usually first subjected to a preparatory treatment, either plain or septic sedimentation. The number of times a day that the bed is filled and emptied depends upon the volume and character of the sewage, the nature of the material in the tank, and other factors. In England it is common to employ three cycles a day, allowing one hour for filling, two hours for contact, one hour for emptying, and four hours for rest. The principal factor involved in this method of purification is sedimentation, but chemical and biological processes are also at work. During the period of contact the suspended matter of the sewage tends to settle on and adhere to the exposed surfaces of the material filling the bed. Some of this washes out when the bed is emptied, but much of it remains behind. While the bed is standing full anaerobic conditions exist and septic action occurs. There is also an absorption of organic matter by the accumulated film. When the bed is being emptied air is drawn into it and in consequence of this there is a partial oxidation of the organic matter adhering to the material in the bed. While the bed is resting aerobic conditions prevail. The result is a partial removal of suspended matter and a slight amount of oxidation of the organic matter, the degree of purification depending upon the character of the sewage and the opportunities permitted for sedimentation and oxidation.

Single Contact Beds are sometimes used, but more often there are two sets of beds, the second receiving the effluent from the first. These are termed double contact beds. Occasionally triple contact is used. As between single contact and double contact, the total area being the same, there is comparatively little to choose, but it is generally believed that it is more economical and efficient to employ double contact.

Materials for Contact Beds are broken stone, clinker, coke, slag, and broken brick. Broken stone has the advantage of permanence, but coke, clinker, and slag possess slight advantages from the standpoint of sedimentation, on account of their rough surfaces. The material used for primary beds is usually coarse, the particles often exceeding two or three inches in diameter. For the secondary beds the material is finer, a common size being from ½ to 1 inch. For the tertiary beds, and sometimes for the secondary beds, material finer than ¼ inch is used. The depth of the material in the contact beds varies from 2½ ft to 6 ft, and usually there is 6 inches of very coarse material at the bottom to serve as drainage. With the depth between these limits

the efficiency of the bed depends more upon the volume of material than upon its depth. The choice of size of material and depth depends, to a large extent, upon the allowed rate of application and the amount of suspended matter in the applied sewage and the admission of air. Beds of fine material are made shallower than those of coarse material in order to provide for air circulation. For sewages containing large amounts of suspended matter coarse material is used and the rate of application reduced. For well-settled or dilute sewages, in which the amount of suspended matter is small, finer material and higher rates may be used.

Area. In order to obtain a sewage effluent that will not putrefy on standing, the amount of nitrogen applied should not exceed 3.5 grams per sq yd for each vertical foot in depth. For ordinary domestic sewage, therefore, contact beds should have about 1 acre foot for each 1000 population connected with the sewers; that is, the population should not exceed 5000 per acre for a bed 5 feet deep, while the rates should be between 300 000 gallons and 800 000 gallons per acre daily.

Permanency. The air space in a newly constructed contact bed amounts to from 40 % to 50 %. With continued use the deposition of suspended matter and other causes reduce this pore space to from 20 to 30 percent and sometimes to even less. The factors that tend to reduce the average capacity of contact bed are: (1) Disintegration of the material; (2) Consolidation of the material; (3) Deposition of suspended matter; (4) Growth of organism; (5) Insufficient rest; (6) Insufficient drainage, etc. Fats, colloidal matter, and fibrous suspended matter tend to clog contact beds.

After periods variously estimated at from one to six or eight years primary contact beds must have their material removed and washt. Secondary beds may run from four to ten or twelve years without washing, but ultimately they too become clogged. In estimating on the cost of this process of purification the item of washing and removing the material is an important one. In 1906 data obtained in England showed that the cost of this varied from 25 to 75 cents per cubic yard.

Rates for Double Contact Beds

From 5th Report of Royal Commission on Sewage Disposal.

Suspended matter, parts per million	Gallons per acre daily for each foot of depth			Frequency of washing, in years	
	Material larger than 3 inches	Material between ½ and 1 inch	Material smaller than ¼ inch	Primary beds	Secondary beds
300 to 500	525 000	....	....	1½ to 2	4 to 6
200 to 300	525 000 to 700 000	....	....	1½ to 2	4 to 6
100 to 150	....	875 000	....	3 to 5	7 to 8

Automatic Control. An important detail of contact beds is usually the arrangement for automatically diverting the flow of sewage from one bed to another and of emptying a bed after it has remained full for its required period and filling it again at the proper time. In large works these operations are controlled by hand, but in smaller works they are controlled automatically by siphons, of which there are many patterns. In cold climates these have to be protected from freezing, and are usually located in small buildings.

Efficiency. Contact beds properly operated, and receiving sewage after plain or septic sedimentation, should remove from 85 to 90 percent of suspended matter, from 65 to 70 percent of organic matter, and from 80 to 85 percent of bacteria.

39. Sprinkling Filters

Sprinkling filters consist of beds, with or without side walls, filled with porous material and thoroly underdrained with tiles or channels in the concrete floor, the whole so arranged as to provide thoro aeration of both drains and filtering material. The sewage is applied at the surface, by means of fixt or movable sprinklers, in such a manner that it becomes well aerated

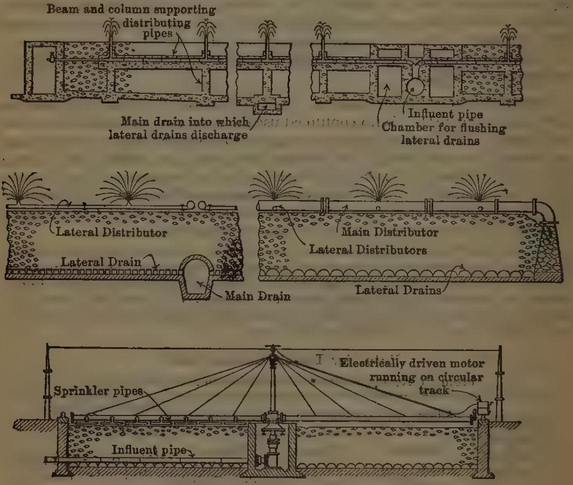

Fig. 21. Three Types of Sprinkling Filters

before it enters the bed. It percolates downward thru the material and flows out of the underdrains. The fundamental idea of sprinkling filters is the greatest possible exposure of the sewage to the air with the oxidation of organic matters and nitrification, and the construction of the filter in such a way that no deposit of suspended matter in it is possible. If there is a deposit of suspended matter in the filter, the filter will become clogged, the air supply shut off, and the process interrupted. The design should therefore permit flushing and cleaning of the lower parts. In the long run the effluent must contain as much suspended matter as the applied sewage. This suspended matter is removed by a final sedimentation or filtration. Three types of sprinkling filters are shown in Fig. 21.

The Material used in sprinkling filters is crusht stone, coke, clinker, slag, etc. In size it varies from particles ¼ inch diameter to particles larger than 3 in. Material from 1 to 2 in is perhaps the most common. Coarse material is used for deep beds where

the applied sewage contains large quantities of suspended matter. Finer material is used in shallower beds for the treatment of sewages that contain comparatively little suspended matter. Beds of coarse material are operated continuously. When fine material is used an intermittent application is preferred in order to provide the necessary aeration. The depth varies from 5 to 12 ft, but depths of from 6 to 8 ft are most common.

Rates for Percolating Filters in Gallons per Acre Daily for Each Foot in Depth

From 5th Report of Royal Commission on Sewage Disposal.

Suspended matter, parts per million	Coarse material larger than 3 in	Medium material between ½ and 1 in	Fine material smaller than ¼ in
300	875 000	437 500	....
100 to 200	1 750 000	....	....
100 to 150	....	875 000	....
40 to 70	1 750 000 to 2 625 000	1 312 500 to 1 750 000	1 312 500 to 1 750 000
10 to 40	2 625 000 to 3 500 000	2 625 000 to 3 500 000	2 625 000 to 3 500 000

The settled sewage is applied to sprinkling filters by means of sprinklers, rarely by trough distribution. Sprinklers may be classified as follows: (1) Traveling, either rotary operated by discharging sewage or by power, or rectilinear, operated by power. (2) Fixt, either upward discharge or downward discharge, the flow for each being constant or intermittent.

Fixt Sprinklers are best adapted to beds of coarse material where the amount of suspended matter in the sewage is large and where the application is constant. Traveling sprinklers are most useful where an intermittent application of sewage is desirable; that is, where the material in the filters is fine and the amount of suspended matter in the sewage small. Rotary sprinklers, used with circular beds, consist of two horizontal arms of pipe perforated on one side, attached to a central vertical shaft. The sewage discharging horizontally in opposite directions in the two arms causes the apparatus to rotate. With this apparatus the sewage is applied uniformly over the bed in intermittent doses, the frequency of which is equal to the speed of rotation of the arms. In beds of large diameter, the rotating arms are sometimes supported by wheels running on a circular track around the edge of the bed and operated by electrical power. In the rectilinear travelers the perforated discharge pipe moves back and forth over the bed, being supported at either end by wheels running on tracks, and being operated by electric power.

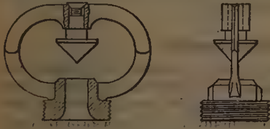

Fig. 22. Columbus Nozzle

When fixt sprinkler nozzles are used the sewage is distributed thru pipes laid either above the filter bed, as in Birmingham, England, or near the bottom of the bed, as in Columbus, Ohio. In the former the sprinkler nozzles are screwed into the distribution pipes; in the latter they are placed at the top of vertical risers that extend up thru the bed from the distributing pipes. Various types of sprinkler nozzles are in use; the types shown in Figs. 22 and 23 are the Columbus nozzle and the Taylor nozzle. They are both intended to distribute the sewage in the form of a circular jet, altho certain forms of the Taylor nozzle are designed to produce a square or hexagonal distribution.

To have the sewage applied uniformly over the surface of the bed it is necessary to vary the head on the nozzle, which is done automatically by means of a siphon which gives an intermittent flow from the nozzle, or by a controlling valve on the discharge pipe in which case the flow may be continuous. The sprinklers are spaced regularly over the beds, either in regular rows or staggered. The distance apart of the sprinklers varies from 10 to 15 feet. The head utilized is from 3 to 6 feet.

In nozzles with downward discharge the sewage falls from an orifice in the bottom of the distributing pipe and drops on a sort of pan that causes it to fly off on all sides as spray. All kinds of sprinkler nozzles give more or less trouble from clogging.

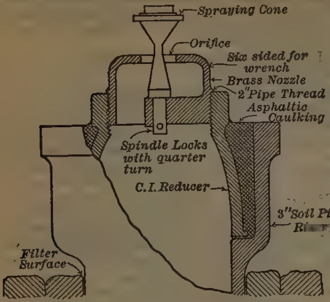

Fig. 23. Taylor Nozzle and Riser

Underdrains. Sprinkling filters require to be thoroly underdrained in order to provide ready ingress and egress of air. The underdrainage system sometime consists of half tile pipes laid in rows side by side and sometimes of circular channels covered with flat tiles in a concrete bottom. Provision should be made for flushing out or otherwise cleaning the underdrains. In large installations spaces are left between beds in order to permit cleaning of the underdrains which are likely to become clogged thru fungi.

Area. The amount of sewage applied to sprinkling filters should be such that the nitrogen should not exceed six grams per square yard per day for each vertical foot in depth. For sewage, therefore, sprinkling filters should have about 0.5 acre foot for each thousand population connected with the sewer; that is, for sprinkling filters 5 feet deep the population should not exceed 10 000 per acre, with the rate of filtration from 0.5 to 1.3 million gallons per acre daily.

Efficiency of Sprinkling Filters. Well-operated sprinkling filters, receiving sewage after plain or septic sedimentation, should remove from 85 to 90 percent of the suspended matter, 65 to 70 percent of organic matter, and 90 to 95 percent of bacteria, and yield an effluent that is non-putrescible. If the filters are overdosed or the sewage not properly applied, the efficiency may be much less than the figures given. Sprinkling filters operate best where the climate is warm, altho experience has shown that they may be operated under winter conditions with some loss of efficiency.

40. Activated Sludge Method

This is a method of treating sewage in tanks by blowing in compress air at the bottom thru porous plates or perforated distributors, the object being to supply oxygen and, by air agitation, to cause the sludge to be brought into intimate contact with the sewage. Fundamentally it is a biological process. The " ripened " sludge, sweeping thru the water, accumulates bacteria, organic matter and colloidal substances to such an extent that subsequent sedimentation results in a rapid precipitation of the suspended matter leaving a clear supernatant liquid. The process may be conducted on the fill and draw principle or in continuous flow tanks. In the former case duplicate tanks are necessary; in the latter case the sewage leaving the air tanks carries out some sludge and must be past thru settling tanks, the sludge, or part of it, being returned to the air tanks. The process is still (1919) in the experimental stage.

The air pressure used is about 0.5 lb per square inch in excess of the pressure of the water over the air outlets. The tank depth varies from 8 to 15 feet. The quantity of air varies from 1.0 to 2.5 cubic feet per gallon of sewage. The resulting sludge contains about 98 to 99 percent of water, which makes

difficult the problem of disposal. To offset this high water content the sludge is rich in fertilizing constituents. The treatment is capable of removing 98 to 99 percent of bacteria from the sewage, the effluent being nearly clear and relatively stable. The cost of the process is not well known, as the engineering details remain to be worked out. It will probably be proven to be an expensive method of treatment, but useful under favorable conditions. Being a biological method it is subject to derangement, as such processes are influenced by extreme changes in temperature, by sudden changes in the composition of the sewage, by too much or too little agitation, by the accumulation of unaërated sludge in the tanks. At the beginning of the process a certain time is required to ripen the sludge.

41. Results of Purification

Finishing Processes. The effluent from sprinkling filters is not clear but contains large quantities of suspended matter. This suspended matter is removed by sedimentation or by filtration thru coarse material such as broken stone, coke, slag, etc. The sludge obtained in this way is more stable and less objectionable that that from plain settling tanks or septic tanks. Altho the effluents from contact beds and sprinkling filters contain fewer bacteria than the applied sewage, they are not bacteriologically pure enough to improve materially the character of a stream from the standpoint of water supply.

The Cost of sewage-purification works, exclusive of land and engineering expenses, was at Columbus, Ohio, in 1907–1909: Septic tanks with a capacity of 8 020 000 gallons cost $66 730, or $8320 per million gallons. Sprinkling filters cost $240 400 for 10 acres, or $24 000 per acre. Settling basins with a capacity of 4 000 000 gallons cost $37 920, or $9480 per million gallons.

176	8	5	Coke	532 000	408 200	76.00
251	5	2.5	Coke	614 200	616 200	34.50

Disinfection of Sewage. The best known disinfectant for sewage or sewage effluents is calcium hypochlorite, commonly called chloride of lime or bleaching powder. Hypochlorite of sodium prepared by electrolysis has substantially the same action. The best commercial grades of bleaching powders contain from 30 % to 40 % of available chlorine, cost (1910) $20 to $25 per ton. The chemical is applied in the form of a 1 % to 5 % solution. The quantity required depends upon the nature of the sewage or sewage effluent to be disinfected and upon the efficiency required. By using this chemical in the following quantities from 95% to 99% of the bacteria may be destroyed.

Quantity of Bleaching Powder (Calcium Hypochlorite) Required for Disinfection

Kind of sewage	Available chlorine in parts per million	Approximate quantity of bleaching powder, lbs per mill gals	Approximate time of contact required, hours
Septic sewage	10 to 15	250 to 375	0.5
Crude sewage	5 to 10	125 to 250	0.5 to 0.8
Poor effluents from sprinkling filters or contact beds	3 to 5	75 to 125	0.8 to 1.6
Good effluents from sprinkling filters or contact beds	1 to 3	25 to 75	1.6 to 5.0

42. Sewage Disposal for Small Installations

A cardinal principle in designing sewage disposal plants for small installations is to keep the liquids which contain soapy and fatty matters (sink wastes) apart from the water-closet wastes. The latter can often be satisfactorily disposed of in cess-pools, if not too near a well. Cess-pools are unsafe in limestone countries. Soapy wastes are best disposed of upon the surface of the ground by soakage, by filtration thru sand or by application to an improvised trickling filter made of broken stone, lathes piled cob-house fashion, or even brush.

DAMS

1. Masonry Dams

Foundations of high masonry dams should be only on rock, which should be stript and all loose or soft rock removed. The rock below if otherwise sound is made practically impervious by filling all crevices, and if seamy, by excavating a cut-off trench near the upstream toe to be filled with good masonry. It should be thoroly washt and if smooth it is usually roughened by chipping or blasting a fresh surface. Drains may be laid on the bed rock down stream from the cut-off wall and led out to the downstream toe to care for slight seepage that might otherwise produce some uplift.

Rubble Masonry. From the earliest times to the beginning of the present century rubble has been most frequently used for masonry dams. It is probably much better than the more expensive cut stone because of the better bond obtained. In the New Croton dam, one of the best examples of the rubble masonry type, the method of building was as follows. The derrick stones, limestone quarried near site, 15 to 50 cu ft in volume, were picked up by the derrick and while suspended, fins, sharp corners, and edges were sledged off, and the stones thoroly washt with a hose and then swung to place and lowered into a thick bed of mortar. Each stone was then picked up and examined for perfect bedding and at the same time spawls were packed into the mortar bed where it was thick enough. It was placed a second time and men with pinch bars worked it to a firm bed, being careful to move it only horizontally and not to rock it; sometimes the stone was removed and placed several times before the bedding was satisfactory. The vertical joints were then filled with hand rubble, consisting of spawls, well wetted and laid with soft mortar. On account of the irregular shape of the derrick stones the vertical joints averaged about 12 in in width. The cut stone facing was kept about one course above the rubble work, and shearing planes were prevented by allowing the hearting rubble to bond between the courses. The resulting proportions were: derrick stones 50%, spawls 26% and mortar 24%. In the Wachusett the proportions of the granite rubble were: derrick stones 54%, spawls 17%, and mortar 29%.

Cyclopean Masonry is rubble in which concrete is used in the place of mortar. Joints are correspondingly thicker. As portland cement became of better quality and cheaper, and skilled labor became dearer, cyclopean masonry began to replace rubble for masonry dams. In the case of several dams built between 1900 and 1910, the general method of constructing cyclopean masonry was as follows: One bucket or more of soft concrete was dumped, making a bed, say 1½ ft deep, on which large stones from 10 to 50 cu ft in volume were set by derrick as closely as their irregularities would permit. These settled into the bed, and were not usually picked up by the derrick again, as is the practise in bedding large rubble in mortar. Into the spaces between the derrick stones, averaging from 1 to 2 ft in width, soft concrete was dumped and as many spawls as possible, from ¼ to 1 cu ft in volume were forced into it. Care was always taken to prevent the formation of shearing planes by keeping a large part of the derrick stones projecting above the general level to form a bond with future work. In Ashokan dams 25% and in Kensico dam 27% of the total mass was composed of derrick stones.

Concrete Masonry. A variety of methods have been used in the construction of concrete dams. There are many advantages in the practise of building the dam in a series of detached piers, filling the intermediate spaces later. This is especially true with low dams, where each pier may be built without stopping. In the McCalls Ferry dam, built by this method,

the concrete was mixt wet, and contained stone graded from ¾ in to about 5 in, and large derrick stones were put in as plums. The mixing plant was large, and very large quantities of masonry could be placed without stopping work, thus avoiding the dangers of a weak section between two days' work. The largest day's work was 2057 cu yds in 11 hours and the largest month's work was 37 000 cu yds. Where the body of concrete is large the practise of placing large stones, called plums, in the concrete as it is being deposited has many advantages. It is usually specified that the plums shall not be over 15 to 25% of the whole volume, depending on the thickness of the walls and that they shall not touch one another. The Connellsville dam and others were built up in layers, depending on neat cement wash and plums to bond old layers with new. The San Mateo and the Pedlar River dams were built up of blocks containing 200 to 300 cu yds of concrete molded in place on the dam and so constructed as to dovetail with one another. This was also intended to reduce strains from the shrinkage of setting concrete.

Temperature Cracks. It is observed that all straight dams and most curved dams in localities having considerable range of temperature have developed cracks which open in winter and close in summer. The question of temperature cracks has received much study, but the total knowledge derived is still meager. It seems to be fairly well established that temperature cracks in large masses of masonry are widest at the surface, becoming gradually narrower with penetration; that in the latitude of New York they disappear from 10 to 20 ft depth depending on exposure, character of masonry, and whether the masonry was laid in warm or cold weather, so that if the dam is less than 20 or 30 ft thick the cracks extend thru. At the New Croton dam liquid dye was run into cracks and later the surrounding masonry was removed. All cracks were found to have the same general profile at their bottoms, as indicated in Fig. 1. In general the cracks formed a vertical plane located without regard to joints, passing, in some cases, thru headers within two or three inches of their edges. Thermophones were placed in the masonry of Boonton and Kensico dams as they were built and observations made for a period of several years in each case. In the former many instruments became unreliable so that complete laws could not be deduced; in the latter the readings for nearly all positions were maintained for a period of four years. It was observed that the temperature at any point began to rise as soon as the concrete was placed and rose various amounts depending on the temperatures of the air and foundations, the mass of the concrete, the rate of placing the masonry, the distance to the nearest exposed face, the exposure of that face, and possibly upon the brand and content of cement used and the wetness of the mix. The time required to reach the maximum temperature depended on the same factors. The time required for dissipation of the heat generated by the reactions of the cement and water depended primarily upon the distance from an exposed face, the exposute of that face and the temperature difference inside and outside the dam.

Fig. 1

The measurements at Boonton dam indicated the conclusion that a range of 130° F. in the atmosphere reduces to a range of about 70° F. 2 to 4 ft below the surface of the masonry with a gradual but slower decrease of range with greater depths, also a reduction in range of 10° F. per 1¾ ft depth.

The last measurements in Kensico dam made in 1917 when the heat of setting practically had been dissipated, indicate that with a range in mean atmospheric

temperature of 73° F. the range in temperature R in the masonry for depths in the masonry from 0 to 40 ft may be approximately exprest by the formula $R = 48 - 12.3 \log_e D$ where D = distance from nearer face; which face had a sunny exposure. Measurements were taken at elevations where thickness of masonry ranged from 45 to 90 ft and where D was always equal to or less than ½ such thickness.

Expansion Joints. Contraction joints were provided in several dams recently constructed, notably in Ashokan and Kensico dams. Fig. 2 shows the joint in Kensico dam. $ABCDE$ is the trace of vertical planes of weak bond, made so by building first one side of precast concrete blocks, coating it with soft pitch, and later pouring the adjacent block against it. At B a sheet of copper $^1/_{16}$ in thick was placed across the joint with its two edges embedded in the concrete on either side in such a way that it will be bent but not ruptured by the movements of the concrete. At Ashokan the joint is the same except that there is no copper strip. CD is an inspection well.

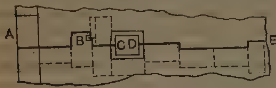

Fig. 2. Expansion Joint

Openings in Ashokan and Kensico due to temperature changes have for the most part been confined to the joints provided. Leakage in the latter has been prevented, and in the former it has been slight, not more than 300 gallons per minute at the maximum.

Waterproofing and Drainage Galleries. Water-tightness in dams is desirable because water in penetrating increases the stress and may reduce the strength of the masonry. To construct a nearly vertical wall over a hundred feet high perfectly water-tight is a matter of great difficulty. The method most commonly depended upon is to make the water face of cut stone and point its joints very carefully with rich portland cement mortar, so that if the stone is impervious the leakage may be reduced and the downstream face will be practically dry. The following notes taken from published comments give the extent of leakage in some of the dams treated in this manner. The Lake Cheesman dam under a head of 212 ft shows no sign of leakage and is entirely free from the appearance of seepage. The Sodom dam shows a few damp spots on humid days only. The Furens dam in France, under a head of 154 ft, showed only a few damp spots. The Bear Valley dam, which for the greater part of its height is less than 8 ft thick, showed only sweating under a head of about 50 ft. There is a growing practise of providing a drainage system in the masonry a short distance from the upstream face. In the Ashokan and Kensico dams there are drainage galleries 5 ft by 7.5 ft, large enough for inspection, one near the top and the other near the base of the dam, connected by inclined drainage holes 16 in in diameter. These drainage holes are formed in blocks of porous concrete 3 ft by 3 ft in plan set about 15 ft from the upstream face and 12 ft apart along the axis of the dam. The water face of the Mouche dam was given 3 coats of hot pitch and then whitewashed. The upstream face of the Urft dam was waterproofed with a plaster coat of cement 1 in thick, on which a coat of asphalt was applied; against this to hold it in place a 3-ft wall of masonry was built, backed by an earth embankment, and drainage pipes were placed in the masonry downstream from the asphalt coating. The upstream face of the Sand River dam, South Africa, was treated as follows: soap and alum washes were applied to the faces with a flat brush, the soap solution being at 212° F. and the alum at 60° to 70° F. The washes contained 1 lb soap to 1.6 gal water and 1 lb alum to 9.6 gal water. Three coats of each were used.

Essential Details of notable precedents are given in the following condensed statements, where the numbers in parentheses refer to corresponding numbers within small circles on the cross-sections in the figures. Of all structures dams are probably most governed by precedents in their design and method of construction.

Straight Masonry Dams without Overflow. (Fig. 3)

(1) Gros-Bois, France. 1830–38. 1805 ft long, 21.3 ft wide at top. Founded on soft rock. When filled slid 2 in. Reinforced by 11 buttresses 37 ft thick at bottom and 13 ft thick at top. 96 ft high; 52.5 ft wide.

(2) Lozoya, Spain. About 1850. 238 ft long; 105 ft high; 128 ft wide. Wall of cut stone backed by rubble masonry, partly covered on back face by sloping bank of gravel. Top width 21.98 ft.

(3) Habra, Algiers. 1856–71. Rubble masonry. 1082 ft long. Top width 14.1 ft. Rock poor and porous. Mortar, natural hydraulic lime and fine clayey sand. When filled leaked badly, later leakage practically ceased. Failed 1881 during flood which overtopt dam; 300 ft carried out down to base. About 400 lives lost. Repaired 1883–87. Profile was much changed and strengthened. 124.2 ft high; 89.2 ft wide.

(4) Cagliari, Sardinia. 1866. Granite, rubble, hydraulic mortar. 345 ft long. Top width 16.4 ft. Height 70.5 ft. Width 52.4 ft.

(5) Boyd's Corner. New York City Water Supply. 1866–72. Cut-stone face, concrete heart (large plums in lower half). Concrete weighed 133.25 lbs per cu ft. Length 670 ft. Top width 8.6 ft. Earth embankment upstream side 20 ft wide on top, 4 : 1 slope. 27 000 cu yds masonry. Height 78 ft. Width 57 ft.

(6) Poona, India. 1868. Uncoursed rubble founded on rock. Length 5136 ft, of which 1453 ft is waste-weir, 11 ft below top of dam. Alinement is several tangents. Reinforced by heavy buttresses at intersections. At first masonry showed signs of weakness. Reinforced by earth bank on lower face. Top width of bank 60 ft, height 30 ft. 360 000 cu yds masonry. Cost $630 000. Height of masonry dam 100 ft. Width 60.7 ft.

(7) Tlelat, Algiers. 1869. 325 ft long. Top width 13.12 ft. Height 68.9 ft. Width 40.3 ft.

(8) Djidionia, Algiers. 1873–75. Resultant said to be outside middle third. Top width 13.12 ft. Height 83.7 ft. Width 52.4 ft.

(9) Bouzey, France. 1878–81. 1700 ft long. Red-sandstone foundation pervious. When filled dam slid 1 ft. Reinforcement at toe added 1888. Failed 1895, upper 33 ft overturning for length of 558 ft. 150 lives lost. Height 84.5 ft. Width 57.3 ft.

(10) Gran-Cheurfas, Algiers. 1882–84. Rubble. 508.4 ft long. Top width 13.12 ft. Partially failed when filled 1885; immediately repaired. Height 131.2 ft. Width 134.5 ft.

(11) Lagolungo, Italy. Genoa Water Supply. 1883. Raised 10 ft 1903. Top width 8.2 ft. Height 145.9 ft. Width 140 ft.

(12) Vingeanne, France. 1885. Top width 11.48 ft. Height 113.8 ft. Width 80.1 ft.

(13) Hamiz, Algiers. 1885. Rubble. 532 ft long. Top width 16.4 ft. Height 124.6 ft. Width 91.2 ft.

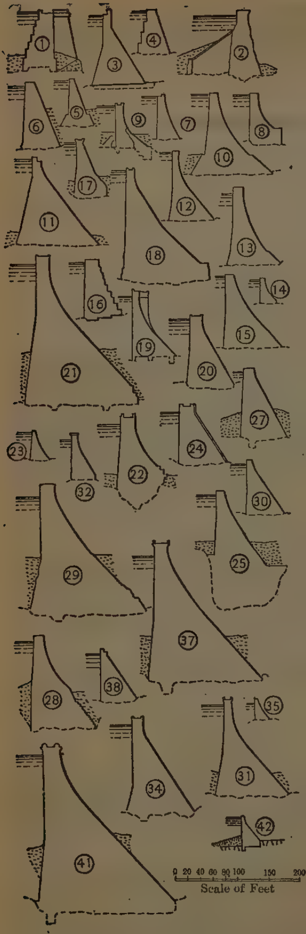
(14) Bridgeport, Conn. 1886. Gneiss rubble. Rosendale 1 : 2 mortar. 640 ft long. Top width 8.0 ft. Base length 50 ft. Height 45 ft. Width 29.5 ft.

(15) Tansa. Bombay Water Supply. 1886 91. Total length 8800 ft. 1650 ft of dam is waste-weir, 3 ft below top of dam. Uncoursed rubble masonry. Stones, hard trap or greenstone. Cement, hydraulic lime burnt from kunkur nodules. Masonry 408 520 cu yds. Reported to be water-tight. Cost $988 000 by contract. Designed strong enough to permit height being increased 17 ft. Height 118 ft. Width 99.8 ft.

(16) Tytam, China. 1887. Granite ashlar and concrete. Intended for 20 ft higher. Present crest width 21 ft. Height 95 ft. Width 63.4 ft.

(17) Sodom. New York Water Supply. 1888–93. Coursed rubble on solid rock. Faces cut stone; beds perpendicular to faces. Mortar, 1 portland cement to 2 sand, 500 ft long. Top width 12 ft. 35 887 cu yds. Cost $366 499. Max. progress 3000 cu yds per mo. No leakage except slight sweating at joints. Height 94.7 ft. Width 53 ft.

(18) Periyar, India. 1888–97. Faces uncoursed syenite rubble; heart concrete; hydraulic lime. Situated in jungle. Unskilled labor. 1231 ft long. Top width 12 ft. 185 000 cu yds masonry. Upstream face plastered with hydraulic lime and sand 1 : 1. Height 183 ft. Width 135.5 ft.



(19) Mouche, France. 1885–90. Rubble, 134.2 lbs per cu ft. 1346 ft long. Top width 11.5 ft. Given three coats hot pitch on upstream face, then whitewashed. Height 101.5 ft. Width 66.5 ft.

(20) Titicus. New York Water Supply. 1890–95. Rubble rough coursed, cut stone faces; beds perpendicular to faces. Mortar, 1 portland or natural cement to 2 sand. 534 ft long. Top width 20.7 ft. Max. progress 5700 cu yds monthly. Cost $933 065. Height 109 ft. Width 75.2 ft.

(21) New Croton. New York Water Supply. 1892–1907. Rubble faced with ashlar. Part cyclopean. Length 1200 ft. Top width 18 ft. Rock in greater part of dam 185 lbs per cu ft. 855 000 cu yds masonry. Max. progress 5700 cu yds monthly. Height 238 ft. Width 185 ft.

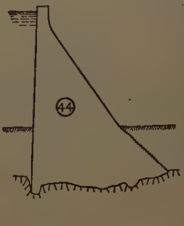
(22) Burrator, England. 1893–96. Granite blocks bedded in rich concrete. Cut stone face. Joints pointed and calked with neat cement mortar. Length 361 ft. Top width about 18 ft. Cost $495 700. Height 77 ft. Width 63 ft.

(23) Indian River, New York. 1898. Top width, 7 ft. Length 207 ft. Height 47 ft. Width 33 ft.

(24) Assuan, Egypt. 1898–1902. Granite rubble laid in 1 : 4 portland cement mortar. Length 6400 ft, 1800 ft solid, remainder has 180 sluices each 6.56 ft wide. Top width 17.8 ft. Masonry 704 000 cu yds. Cost $11 907 000. Height 95 ft. Width 80.3 ft.

(25) Coolgardie, Australia. 1900–02. Rubble concrete. Length 755 ft. Top width 10 ft. Height 119.9 ft. Width 88 ft.

(26) Blackbrook, England, 1900–05. Length 525 feet. Top width 14 ft. Height 108 ft. Width 65 ft.



(27) Boonton, New Jersey. 1900–1906. Cyclopean syenite masonry. Top width 17 ft. Length 2150 ft. Masonry 166 lbs per cu ft. 255 000 yds. Max. progress 21 000 cu yds per month. Height 103 ft. Width 77 ft.

Fig. 3. Straight Masonry Dams without Overflow

(28) Spier Falls, New York. 1900–05. Rubble. Length 552 ft. Top width 17 ft. 180 000 cu yds masonry. Height 150 ft. Width 107 ft.

(29) Wachusett, Mass. 1900–06. Granite, rubble, cut stone faces. Top width 22.5 ft. Length 971 ft. ¾ of heart is laid in natural cement. Volume 266 663 cu yds. Cost $2 270 117. Height 205 ft. Width 187 ft.

(30) La Jalpa, Mexico. 1902. Body of dam rough limestone rubble laid in mortar of native hydraulic lime and sand. Clay embankment, slope 2 : 1 on upstream face. Length 1800 ft. Top width 9.1 ft. Contents 92 000 cu yds. Cost $500 000 gold. Height 87.2 ft. Width 65.6 ft.

(31) Cataract, Australia. 1902–08. Cyclopean masonry. Sandstone blocks in cement mortar packed with concrete; blocks about 65% of mass. Faces, concrete downstream, concrete blocks upstream. Length 811 ft. Top width 16.5 ft. Rectangular conduits filled with broken stone and earthen pipes for drains. 146 242 cu yds. Height 154 ft. Width 120 ft.

(32) Pedlar River, Virginia. 1904. Concrete with large stones embedded. Length 415 ft. Width at crest 10 ft. Concrete laid as large blocks about 10 × 10 × 15 ft and dovetailed. Portland cement on face, natural in heart. Contract price $103 708. Height 73.5 ft. Width 39.2 ft.

(33) Swansea, Wales. 1905. Cyclopean masonry, brick facing. In heart concrete 1 : 2 : 5. Lower base and upper 6 ft of water face 1 cement : 2 sand : 3.4 parts of fine crusht rock. Length 1250 ft. Max. height 144 ft. Thickness at base 107 ft. Max. depth water 100 ft.

(34) Cross River, New York. 1905–07. Cyclopean masonry, concrete block facing. Length 772 ft. Top width 23 ft. 158 000 cu yds. Max. progress 18 400 cu yds per month. Contract price $1 246 212. Height 155 ft. Width 125.3 ft.

(35) Connellsville, Pa. 1906. Concrete, bowlders used as plums. Ashlar facing. Length 650 ft. Top width 6 ft. Bowlders about 25% of masonry. Height 39 ft. Width 26 ft.

(36) Sand River, South Africa. 1906. Concrete 1 : 1.3 : 5.5 with large quartzite rocks, iron rods and rails embedded. Length 398 ft. Height 55 ft. Base width 38 ft. Foundation hard shale. Contents 9000 cu yds. Cost about $140 000. Masonry 150 lb per cu ft.

(37) Ashokan. Olive Bridge dam, New York. 1908-1913. Cyclopean masonry. Length 1000 ft. Top width 26.3 ft. Facing concrete blocks. Height 220 ft. Width 190.2 ft. Contraction joints, wells and galleries for inspection and drainage, and vertical drains provided. (See Fig. 51, page 717.)

(38) Blackwater, Scotland. Cyclopean concrete. Top width 10 ft. Height 84 ft. Width 58 ft.

(39) Esperanza, Mexico. Rubble masonry. Length 580 ft. Top width 19.7 ft. Base width 75.7 ft. Max. height 137.5 ft. 55 000 cu yds. Mortar of lime somewhat hydraulic. Leakage estimated 0.4 cu ft per sec.

(40) Barker, Col. 1909. Masonry 1 : 3 : 5 concrete with plums. Expansion joints in upper 145 ft, 48 ft apart. Length 625 ft. Top width 16 ft. Height 175 ft. Max. base width 124 ft.

(41) Kensico, New York. Cyclopean masonry; concrete blocks on upstream face, cut stone on downstream face. Length 1830 ft. Top width about 27.75 ft. Base width 227.7 max. Expansion joints, vertical drains and inspection galleries. Height 250 ft.

(42) Austin, Pa. 1909. Max. height 50.5 ft. Width at base 30 ft. Top width 2.5 ft. Length 554 ft. Foundation, sandstone in layers 8 in to 3 ft thick with beds of shale and disintegrated sandstone between the layers. When filled in January, 1910, a section 90 ft long slid 18 in at bottom and 31 in at top Dam then repaired but not strengthened. In September, 1911, it failed suddenly with loss of eighty lives and $3 000 000 of property.

(43) Medina, Texas. 1911–1912. 1 : 3½ : 6½ concrete with 9.9% plums. Length 1580 ft. Top width 25 ft. Max. height 164 ft. Base width 128 ft. Total volume 300 000 cu yds.

(44) Elephant Butte, N. M. 1910–1916. Cyclopean concrete. Length 1200 ft. Top width 18 ft. Max. height 304.5 ft. Base width 212.58 ft. Volume 611 400 cu yds. Drainage gallery, vertical drains and expansion joints.

(45) Brisbane, Australia. Completed, 1916. Heart 1 : 2.5 : 6.5 concrete with 25% plums. Upper 30 ft and faces to toe and heel 1 : 2 : 4 concrete. Length 580 ft

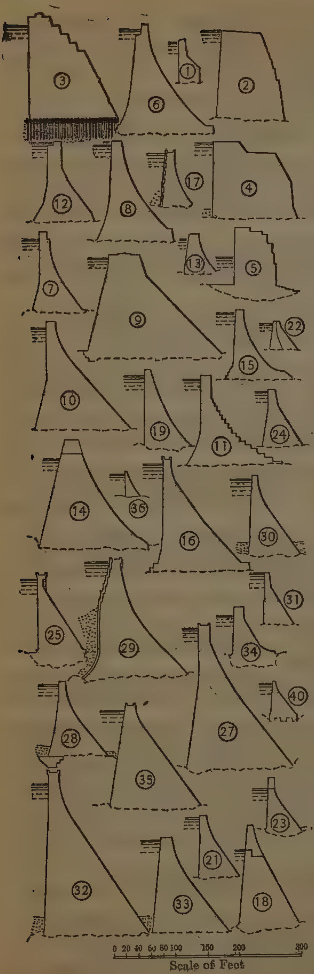


Fig. 4. Curved Masonry Dams with Gravity Sections without Overflow

Top width 10 ft. Max. height 125 ft. Volume 58 400 cu yds.

Curved Masonry Dams with Gravity Sections without Overflow. (Fig. 4)

(1) Almanza, Spain. Built before 1586 Radius 86 ft. Rubble cut stone face. Oldest existing masonry dam. Top 9.84 ft thick. Height 67.8 ft. Width 33.7 ft.

(2) Alicante, Spain. 1579–84. Rubble, cut stone facing. Radius at top 351 ft. Height 134.5 ft. Width 110.6 ft.

(3) Puentes, Spain. 1785–91. Polygonal in plan, arched upstream; 925 ft long. Rubble, cut stone facing. Mostly founded on rock; on piles over deep pocket. Held 82 ft depth for 10 years. 1802 water rose to 154 ft depth and pile foundations washt out, leaving dam bridging deep pocket. 608 lives lost. Height 164.2. Width 145.2 ft.

(4) Val de Infierno, Spain. 1785–91. Polygonal arch. Reservoir silted to top of dam. Built on rock. Height 110.3 ft. Width 136.4 ft.

(5) Nijar, Spain. 1843–50. Rubble, cut stone facing. Height, 90.5 ft. Width 67.6 ft.

(6) Furens, France. 1862–66. Rubble of mica schist with cut stone front face. Length about 330 ft. Top width 9.91 ft. Radius 828.4 ft. Built in narrow gorge. No leakage. Few damp spots. 52 300 cu yds. Cost $318 000. Height 170.6 ft. Width 161 ft.

(7) Ternay, France. 1865–8. Granite rubble. Top width 13.12 ft. Radius 1312 ft. Height 124.6 ft. Width 81.7 ft.

(8) Ban, France. 1867–70. Rubble, Length 512 ft. Top width 16.4 ft. Radius 1325 ft. Built on rock. Cost $190 000. Height 156.8 ft. Width at base 126.9 ft.

(9) Gillepe, Belgium 1870–75 Sandstone rubble. Top width 49.2 ft. Radius 1640 ft. Length top 771 ft. 325 000 cu yds. Height 156.5 ft. Width 215.89 ft.

(10) Villar, Spain. 1870–78. Rubble. Top width 14.75 ft. Length 349 ft. Radius 440 ft. Cost about $390 000. Height 170.3 ft. Width 154.6 ft.

(11) Hijar, Spain. 1880. Top width 16.4 ft. Length 236 ft. Radius 210 ft. Height 141.1 ft. Width 146.9 ft.

(12) Gorzente, Italy. Genoa Water Supply. 1880–83. Serpentine rubble with casale lime mortar. 492 ft long. Top width 22.96 ft. Height 126.3 ft. Width 99.4 ft.

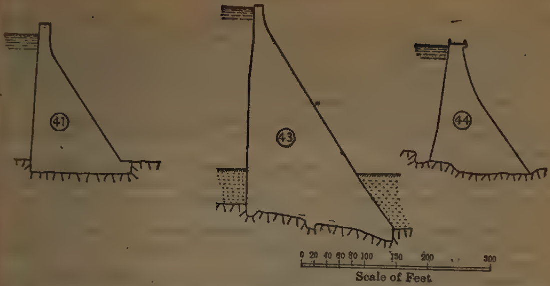

Fig. 4 (continued). Curved Masonry Dams with Gravity Sections without Overflow

(13) Thirlmere, England. 1886–93. Top width 18.5 ft. Plan is reverse curve to follow bed rock. Radius 100 ft. Height 63 ft. Width 51.7 ft.

(14) San Mateo, California. 1887–88. Concrete molded into dovetailed blocks on dam. Planned for max. height 170 ft. Stopt at 146 ft. Top width 25 ft and top length 680 ft at 170 ft height. Radius 637 ft. Volume 139 000 cu yds. A few damp spots on face only sign of leakage. No cracks visible. Concrete 1 : 2 : 6.5. Width at base 176 ft.

(15) Beetaloo, Australia. 1888–90. Concrete. Top width 14 ft. Length 580 ft. Radius 1414 ft. 60 000 cu yds masonry. Founded on rock. Cost $573 300. Height 110 ft. Width 110 ft.

(16) Chartrain or Tache, France. 1888–92. Rubble or porphyritic rock and hydraulic mortar. Wt per cu ft 150 lbs. Top width 13.12 ft. Radius 1312 ft. Upstream face coated to 33 ft below coping with artificial cement of slaked lime, 1¼ in thick, made of equal parts of cement and sand. Some leakage. Height 174.7 ft. Width 15[illegible].9 ft.

(17) Remscheid, Germany. 1889–92. Rubble Linneite slate in trass mortar. Water face plastered with cement and asphalt, covered by brick wall. Top width 13.1 ft. Radius 410 ft. 22 886 cu yds. Height 82 ft. Width 4[illegible].2 ft.

(18) Hemet, California. 1890–95. Granite rubble and concrete. Designed with max. height 160 ft; only carried to 122.5 ft. Top width 10 ft. Length 260 ft including 50 ft spillway in center. Radius 225.4 ft. 31 105 cu yds at present height. In time of flood spillway too small. Base width 100 ft.

(19) Bhatgur, India. About 1891. Uncoursed rubble. Upper portion concrete and rubble blocks. Faces coursed rubble. Top width 12 ft. Length 3257 ft. Irregular curve to follow outcrop of bed rock. Height 127 ft. Width 73.7 ft.

(20) Butte City, Montana. 1892. Concrete, granite facing. Top width 10 ft. Max. height 120 ft. Bottom width 83 ft. Length of top 350 ft. Radius 350 ft.

(21) Lauchensee, Germany. 1892–95. Cyclopean masonry. Trass mortar, 1 lime, 1 trass, 2½ sand made by crushing sandstone. Earth bank to protect from sun. Top width 13 ft. Length top 840 ft. Radius 2950 ft. Cu yds 37 400 of which 65% stone and 35% mortar. On sandstone. Total cost $243 750. Height 98 ft. Width 65.3 ft.

(22) Lennep, Germany. Old dam, 1893, length 416 ft. Radius 460 ft. Dam was increased in height from 37.7 ft to 48.4 ft and buttresses built to take added thrust. Width at base 50.8 ft.

(23) Wigwam, Conn. 1893–96. Designed for 90 ft height, built only 75 ft high. Width 12 ft at designed height and length 600 ft. 14 887 cu yds in completed portion. Radius 600 ft. Width at base 62 ft. Completed to designed height in 1903.

(24) Einsiedel, Germany. 1894. Rubble. Top width 13.12 ft. Length 590 ft. Radius 1310 ft. 31 600 cu yds. Height 93.6 ft. Width 65.5 ft.

(25) Echapre, France. 1894–98. Top width 17 ft. Length 541 ft. Radius 1148.2 ft. Hydraulic mortar coat on upstream face, on which coat of hydraulic cement was later placed. Max. depth of water 121.4 ft. Width at base 88.6 ft.

(26) Ondenon, France. 1900–04. Top width 15.4 ft. Length 420 ft. Radius 984 ft. Max. height 123 ft. Base width 94 ft.

(27) Lake Cheesman, Colorado. 1900–04. Top width 18 ft. Length 710 ft on crest,

30 ft at base. Granite rubble, coursed rough-pointed facing. Radius 400 ft. 103 000 cu yds. Total cost about $1 000 000. Height 227 ft Width 176 ft.

(28) Komotau, Austria. 1901–04 Cyclopean masonry. Gneiss in portland cement concrete. Top width 13 ft. Length 508.5 ft at top, 170 6 ft at bottom. Radius 820 ft. 53 600 cu yds. Asphaltum and tar coat held in place by concrete dovetailed into upstream face. Height 118.9 ft. Width 98.4 ft.

(29) Urft, Germany. 1901 04. Slate and trap masonry, earth embankment to 77 ft. below crest, slope 2 : 1, rock paving. Length 741 ft. Top width 18 ft. Radius 656 ft. Height 190 ft. Width 165.5 ft.

(30) Mercedes, Mexico, 1901–05. Rubble, cut stone facing. Top width 11.48 ft. Length at crest 535 ft, also 98-ft spillway; 13 ft at base. Straight for half the length, rest 196.8 ft radius 28 000 Cu yds. Cost $200 000 Mexican currency. Height 135.6 ft. Width 84.5 ft.

(31) Granite Springs Wyoming 1903–04. Uncoursed rubble. Wt per cu ft 165 lbs. Top width 10 ft. Length 410 ft on top, 10 ft at base. Radius 300 ft. 14 422 cu yds. Cost $109 194. Height 96 ft. Width 56 ft.

(32) Roosevelt, Arizona. 1905 1911. Cyclopean masonry, range rubble facing. Sandstone. Top width 16 ft. Length 680 ft. Radius 400 ft. About 340 000 cu yds. Height 260 ft. Width 158 ft.

(33) Marklissa, Germany. 1905. Gneiss rubble. Upstream face has 2 in mortar layer coated with siderosthen. Has interior drainage system. Length 427 ft. Radius 410 ft. 83 700 cu yds. Height 147.7 ft. Width 124.8 ft.

(34) Marquina, Manila, P. I. 1906. Rubble, hard crystalline limestone marble. Length 400 ft. Radius 500 ft. Height 75 ft. Width 68 7 ft.

(35) Cher, France. Top width 15.4 ft. Radius 656 ft Height 154 ft. Width 141 ft.

(36) Burraga, Australia. Cyclopean concrete in heart T rails bedded near top. Top width 2 ft. Length 285.6 ft. Radius 539.8 ft. Cost $44 500. Height 41 ft. Width 25.3 ft.

(37) San Jose, Mexico. Rubble. Top width 15 ft. Max. height 151 ft. Base width 128 ft. Length 592 ft including 2 spillways 95 ft and 86 ft. Radius 6560 ft.

(38) Murrumbidgee River, Australia. Concrete, large stones embedded. Max. height 232 ft. Length 910 ft. Radius 940.5 ft. Max. base width 160.33 ft. Crest width 18 ft.

(39) Mochne. Germany. Length 1312 ft. Max. height 98.4 ft 353 160 cu yds.

(40) Griffin, Pa. Concrete laid in 12-in courses usually from end to end during one working day. Length 284 ft. Radius 400 ft. Top width 4 ft. Spillway near center 80 ft long. Concrete 8000 cu yds. At first leaks appeared near ends. Height 62 ft. Width at base 44 ft.

(41) Barren Jack, New So. Wales. 1909–13. Cyclopean concrete. Length 784 ft. Top width 18 ft. Base width 163 ft. Height 240 ft. Radius 1200 ft.

(42) La Boquila, Chihuahua, Mexico. Cyclopean masonry with 10 ton blocks of limestone Length 840 ft. Top width 19 ft. Base width 200 ft. Radius 866 ft.

(43) Arrowrock, Boise, Idaho. 1912–13. 1 : 2.5 : 5 concrete with large rock and cobblestone. Length 1050 ft. Top width 15.5 ft. Height 351 ft. Base width 238 ft. Radius 662 ft. Inspection gallery. Contraction joints every 150 ft.

(44) Mauer, Silesia, Germany. Completed in 1912. Largest dam in Europe. Stone masonry. Length 918 ft. Top width 23.6 ft. Height 203 ft. Base width 165 ft. 332 000 cu yds. Radius 820 ft. Drainage and inspection tunnels.

Curved Masonry Dams Depending on Arch Action without Overflow. (Fig. 5)

(1) Meer-Allum, India. About 1800. Large arch made up of 21 small arches with buttresses between. Spans between buttresses 70 to 147 ft in clear. Spillway provided, but at times water flows few inches deep over entire dam. Length about 2640 ft.

(2) Zola Dam, France. 1843. Rubble masonry. Length 205 ft. Top width 19 ft. Radius at top 158 ft.

(3) Bear Valley dam, Cal. 1884. Radius 335 ft. Rough granite ashlar facing and rubble hearting. 300 ft long. Thickness 2.5 ft to 3 ft at top and 8 5 ft 48 ft below crest. Inaccessible location. Haulage of cement to site cost $10 per bbl. 3400 cu yds. In 1911, in order to store more water, a new reinforced concrete dam 30 ft higher than the old was built just below this dam, submerging it.

(4) Sweetwater, Cal. 1887–88. Rubble. Weight per cu ft. 164 lbs. Length about

380 ft. Radius 222 ft. 19 269 cu yds. Top width 12 ft. Mortar used mostly 1 portland to 3 sand, but near upstream face mortar was 1 : 2. Cost about $234 000. 1895 dam was overtopt by 22 in of water for 40 hours without damage. In 1911 the dam was increased 20 ft in height and a new section, reinforced with old rails, was built on the downstream side, 76 ft wide at the base and reducing to nothing at the elevation of the top of the old dam. Care was taken to bond the old and the new concrete.

(5) Belubula, Australia. 1898. Concrete and brick. Lower part up to 23 ft height is concrete, above this brick arches and buttresses built 36.7 ft higher. Series of buttresses

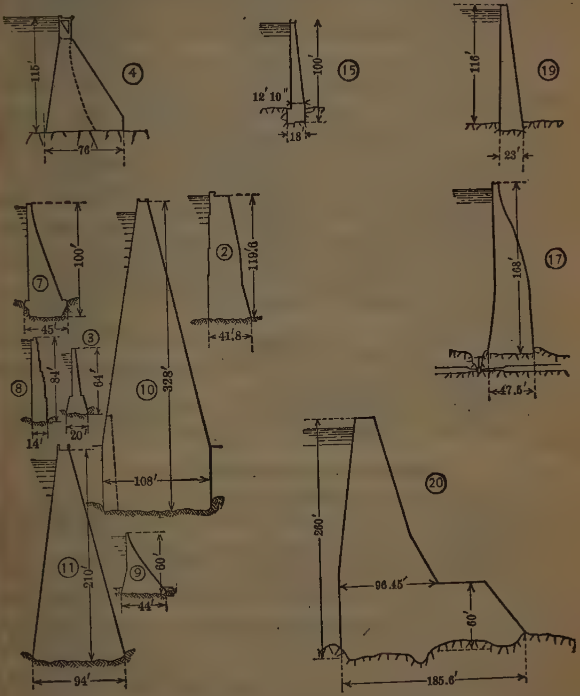

Fig. 5. Arched Masonry Dams

28 ft. c to c, elliptical arches between, axes inclined 30° to vertical. Arches 4 ft. thick at bottom, 1 ft 7 in at top. Buttresses 40 ft. long, 12 ft wide at wall and 5 ft at outer end. Each buttress forms a segment of circle 36 ft 2 in radius and diminishes in thickness from 8½ ft at center to 4 ft at outer circumference.

(6) Johannesburg, So. Africa. 1898. Rubble masonry, hard blue quartzite, concrete foundations reinforced with rails. Top width 7 ft. Length 585 ft. 30 000 cu yds. Arch and tangent; part on tangent, gravity section. Radius of arch section 275 ft at crest, decreasing to 206 ft 75 ft below to meet lines of gravity section.

(7) Barossa, South Australia 1899-1903. Concrete with plums, reinforced at top with steel rails. Length 472 ft. Radius 200 ft. Cu yds 17 975, of which 12.3% large stones. Top width 4.6 ft. Range of temperature during construction was from 30° to 168° F. Total cost $827 000.

(8) Upper Otay, Cal. 1900. Masonry reinforced with steel plates and cables. Top width 4 ft. Length 350 ft at crest, 20 ft at base. Radius 359 ft. In a rock gorge.

(9) Geelong, Australia. Sandstone concrete. Top width 2.5 ft. Radius 300 ft.

(10) Shoshone, Wyoming. 1903 10. Concrete. Top width 10 ft. Length 200 ft. Radius 150 ft. 75 000 cu yds. In narrow solid granite gorge. Contract price $515 730.

(11) Pathfinder, Wyoming. 1905-1909. Cyclopean masonry. Radius 150 ft. 54 000 cu yds. Length on top approximately 425 ft, at base 80 ft. In narrow granite gorge. Contract price $482 000.

(12) Sand River, Port Elizabeth Waterworks, So. Africa. 76 ft high. Radius 300 ft. Length 360 ft. Cyclopean masonry faced with concrete blocks. Soap and alum washes on faces for waterproofing. Dam reinforced with steel rails.

(13) Dam at Hume, Cal. Concrete reinforced by railroad iron and cable. Concrete approximately 1 : 2 : 4. crusher run of granite being mixt with sand. Series of buttresses parallel to stream with arches between; 12 arches each of 50-ft span. Water face and parts of downstream face plastered. Water face two coats cement mortar 1 to 1½ and wash coat of neat cement on bases of middle arches. 2207 cu yds.

(14) Salmon River dam, Idaho. Cyclopean masonry. 220 ft high. 463 ft long. Top width 15 ft. Base width 119 ft. Radius upstream face 225 ft.

(15) Huacal, Mex. 1911-1912. Crest length 140 ft. Radius 76 ft. Max. height 100 ft. Base width 12 ft 10 in. 80 ft ± below top. (See (15) in Fig. 5.)

(16) Goodwin, Cal. 1911 1912. Concrete 2 spans of 135 ft radius abutting on central pier. Length 466 ft. Width at top 8 ft and bottom 16 ft. Max. height 78 ft.

(17) Salmon Creek, Juneau, Alaska. 1913 1914. Concrete. Constant angle arch type. 52 000 cu yds Height 168 ft. Width at top 6 ft. Base 47.5 ft. Radius at top 331 ft at bottom 147.5 ft.

(18) Eagles Nest, N. M. 1916-1918. Concrete. Length 300 ft. Top width 8 ft. Bottom width 46 ft. Max. height 140 ft. Radius 155 ft.

(19) Corfina, Italy. 1915. Concrete. Top width 5 ft. Bottom width 23 ft. Max. height 116 ft Radius 75 ft. Built in 65 days

(20) Spaulding, Cal. Built to height of 225 ft in 1913 and raised to 260 ft in 1916. Estimated yardage 169 000. Width at 260 ft level 14 ft. Planned ultimately to be 305 ft high. 304 000 cu yds. Vertical drains and inspection gallery. Lower 60 ft of gravity section.

Straight Masonry Overflow Dams. (Fig. 6)

(1) Vir Weir, India. Uncoursed rubble. 2340 ft long 43 5 ft high. Top width 9 ft.

(2) Henares Weir, Spain. Concrete with ashlar facing. 390 ft long. Maximum height 23 ft. Base width 45.8 ft.

(3) Vyrnwy England. 1882–89. Cyclopean masonry. Length 1164 ft.

(4) Lynx Creek, Arizona. Intended for ultimate height of 50 ft. Height was about 31 ft. In 1891 flood overtopt and destroyed dam.

(5) Folsom, Cal. 1886–91. Rough granite ashlar blocks. 48 590 cu yds. Top width 24 ft.

(6) Betwa, India. 1888. Length 3296 ft made in three tangents between islands. Top width 15 ft. Rubble masonry laid in native hydraulic line. Ashlar coping 18 in thick in portland cement mortar. Cost $160 000. Has had 16 4 ft head on crest.

(7) Austin, Texas. 1891-92. Hard line stone rubble, granite facing and coping Length about 1100 ft. 88 000 cu yds. Cost $608 000. Failed under head of 11.07 ft on crest. Previously stood 9 8 ft head. About 300 ft slid forward No overturning.

(8) New Holyoke, Mass. 1897. Rubble with drest stone cap and facings and concrete toe. Length 1020 ft. Upper part of downstream face is parabolic, lower part is cycloidal

(9) McCall's Ferry, Pa. 1904. Concrete with plums. 2350 ft long

(10) Great Northern Power Co., Minn. 1907. Concrete. 365 ft long, 38 ft high 42 ft wide at base. curved crest.

(11) Connecticut River dam. Concrete with plums (1 : 2.5 : 5 except in deep foundations where 1 : 3 : 6 was used). Length 600 ft.

(12) Escanaba. Concrete with earth banks at end. Length 810 ft. Concrete i

heart 1 : 3 : 6 on sides and bottom 1 : 2 : 4. Facing 1 ft thick upstream and 1 5 ft downstream. Founded on stratified limestone 8-in drain pipes at 10 ft intervals from cut-off to toe of dam.

(13) Hales Bar, Tenn. 1905–1913. Cyclopean concrete. Foundation limestone badly fissured. Fissures closed in part by grouting and in addition, 26 reinforced concrete caissons 30 × 32 to 54 × 72 were sunk by pneumatic process thru fissured rock to solid foundation. Height 65 ft. Length 1200 ft. Width 72 ft. Curved crest.

(14) Holter, Wolfcreek, Mont. 1910. Concrete with plums. Length 1362, 504 ft.

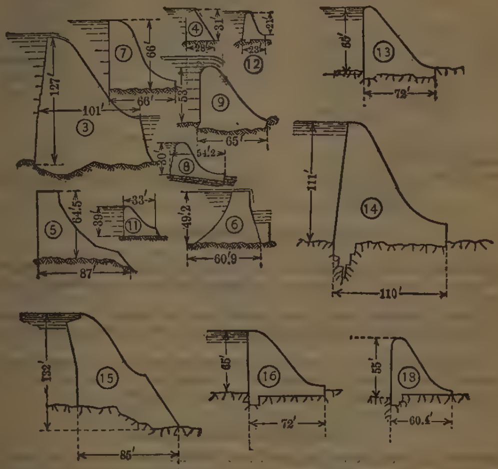

Fig. 6. Straight Overflow Dams

overflow section. Height 111 ft. Width 110 ft plus 70 ft of apron. Cut-off trench 44 ft, deep.

(15) Hauserlake, Montana. Completed, 1911. Replacing steel dam which failed by undermining. Length 490 ft, 85 000 cu yds. Max. height 132 ft. Width 85 ft. Ogee type. Part of foundations placed by pneumatic caissons.

(16) Coosa River, Lock 12, Alabama. 1912–1914. Cyclopean masonry. Length of spillway 930 ft. Height 65 ft. Width 72 ft. Parabolic crest.

(17) Keokuk, Ia. 1-3-5 concrete. Length 4278 ft. Height 32 ft. Width 42 ft. Ogee type.

(18) Youngstown, Ohio. 1916– . Concrete. Length 638 ft. Height 55 ft. Width 60 ft 5 in. Earth embankment at ends.

Curved Masonry Overflow Dams. (Fig. 7)

(1) Elche Spain. 16th century. Rubble, cut stone facing. Length 230 ft. Radius 205.38 ft. 1836 breach made during flood.

(2) Verdun, France. 1866-70. Rubble, cut stone facing downstream. Concrete foundation. Riprap in front of wall. Length 131.23 ft. Radius 108 83 ft. Width of top 14.17 ft. Designed for depth 16.4 ft water on crest.

(3) La Grange or Turlock, Cal. 1891 94. Rubble. Length 320 ft on crest and 80 ft at base. 39 500 cu yds. Radius 300 ft. Has had about 15 ft depth of water on crest,

(4) Cornell University dam, New York, 1897 Concrete of 4 parts argillaceous shale. 2 parts of sand, 1 part of cement Length 153 ft. Rad. 166 5 ft. Max. height 30 ft.

(5) Walnut Canyon, Airzona. Rubble faced with ashlar. Length about 268 ft. Radius 400 ft. 6 986 cu yds.

(6) Seligman, Arizona. 1897-98. Concrete foundation. Rough rubble above with drest ashlar facings Top width 1.75 ft. Total length on crest 643 ft. The center section, 340 ft long, is built as an overflow dam. Length at base 145 ft. Radius 800 ft.

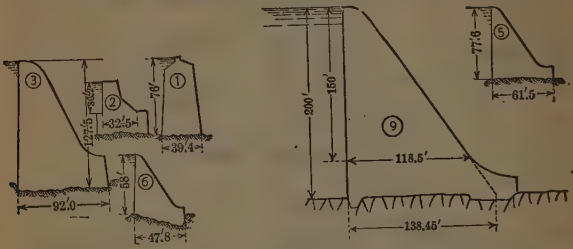

Fig. 7. Arched Overflow Dams

(7) Espanola, Ontario. Concrete with plums. Built for 10 ft overflow. Radius in plan 187 ft.

(8) Tallulah, Georgia. 1914. Crest length 444 ft. Radius 900 ft Automatic flashboards of the Stauwerke type installed between piers on the 280 ft spillway. Height 135 ft.

(9) Yadkin Narrows, N. C. 1917. Cyclopean concrete 525 000 cu yds with 25% plums. Length 1400 ft. Radius 1678 ft. Height 200 ft. Designed for 10 ft overflow. Taintor gates on crest. Drainage and inspection galleries.

2. Reinforced Concrete Dams

Reinforced concrete dams are usually of cellular construction, in some cases containing power houses. If properly designed they are admirably adapted to many situations. The general practice is to build a series of piers or buttresses 12 to 18 ft apart and cover with a flat deck of concrete reinforced between the different bays as a beam. In the multiple arch type, the buttresses are spaced 30 to 40 ft apart and support a deck of concrete arches springing between the buttresses.

Unit stresses in such dams should be much lower than would be safe for ordinary building construction for an incipient failure in the latter case usually means only an unsightly crack, while for a dam it might mean a catastrophe. The following data refer to Fig. 8.

(1) Schuylerville New York 1904. Rollway 250 ft long. Designed for 5 ft head on crest. Founded on Hudson River shale 5 × 3 cut-off wall. Passageway thru dam from shore to shore Average height 25 ft with base width 52 ft.

(2) Ellsworth, Maine. 1907-08. Buttresses 15 ft centers, 1 ft thick at top, 2 ft at bottom and braced by 12 in × 18 in reinforced concrete beams Deck 1 ft 2 in thick at top, 3 ft 1 in at base. Total length 500 ft. Concrete, 8000 cu yds. Flashboards provided. Designed for flood 6.5 ft on crest. Vents to prevent vacuum on apron.

(3) Pittsfield, Mass. 1907-08. 42 ft high. 465 ft. long. 3950 cu yds concrete Founded on gravel underlain at depth of 12 ft by dense yellow clay. Cut-offs extend 3 ft into clay. Work carried on continuously when temperature was 12° below zero, by

heating materials and using "salamanders." Concrete laid in winter and in moderate weather said to be uniform in quality.

(4) La Prele, Wyoming. 1908. Buttresses 18 ft centers, 1 ft thick at top, 4 ft 2 in at bottom, braced by 18 in × 24 in reinforced concrete beams. Deck 1 ft thick at top, 4 ft 6 in at base. About 15 000 cu yds concrete. Cut-offs 15 ft to 18 ft deep Concrete in buttresses 1 : 3 : 6, deck 1 : 2 : 4.

(5) Dam at Dansville, New York. 368 ft long including earth embankment. Gravel concrete used. Footing course on water bearing gravel and bowlders. Bed of seamy blue stone under gravel. Cut-off around footing course. At height of 10 ft base width 14 ft. Failed by undermining when water stood about 14 in against flashboards. Deck slab snapt where reinforcing bars came together. Bars were not bent after failure.

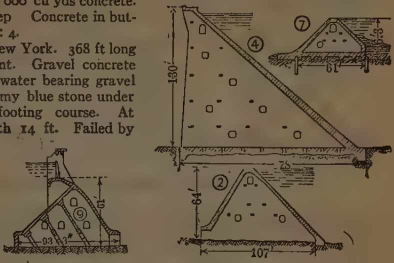

Fig. 8. Reinforced Concrete Dams

(6) D. L. & W. R. R., Scranton, Pa. 262 ft long. 16.5 ft high, base width 11.5 ft. Uniform slab thickness 10 in. Buttresses 7½ ft apart in center, increasing to 10½ ft at end. Soil under dam partly sand and partly yellow clay. ½-in cup bars 12 in c to c. 1½ in from face, to prevent temperature cracks. Clay bank 8 ft high at center to prevent percolation under dam.

(7) Uncas Power Co., Conn. Spillway 80 ft long. Foundation very compact gravel. Buttresses 10 ft centers, 1 ft 6 in thick at bottom, 1 ft at top, stiffened by 12 in × 15 in beams. Upstream deck 1 ft 6 in to 1 ft 8 in thick, downstream 1 ft 8 in.

(8) Bear Valley, Cal. 1910–11. Multiple arch of Eastwood type. Ten arches between buttresses. 33 ft 6 in centers. Radius of extrados 16 ft axis of arches vertical for 14 ft height at top below which are on batter of 4 on 3. Buttresses 1 ft 6 in thick at top increasing by .36 in per ft to bottom. Arch rings 12 in thick at top increasing by .17 in per ft in radial thickness. Downstream edge of buttress 2 : 1 slope. Buttresses stiffened by reinforced concrete struts. Max. height dam 92 ft length 363 ft. 4684 cu yds concrete.

(9) Austin, Texas. 1911-1915. 560 ft long. Replaces portion of straight masonry overflow section which failed in 1900. Buttress 20 ft centers. Height 61 ft to crest, which is provided with automatic gates 14 ft high.

(10) Stony River, West Va. 1912–1913. Buttresses 15 ft centers. 12-in thick at top and 18 in at bottom. Braced with reinforced concrete struts and a curtain wall. Six months after erection, foundation for length of 7 spans was washed out and buttresses and deck dropped into the hole. Reconstructed 1914–15 by deepening cut off wall, increasing the safety against sliding and adding 3 ft flashboards. Max height 51.17 ft.

3. Steel Dams

Steel dams are not very numerous. In many cases they may be built much more cheaply than other types, but to keep them safe requires frequent and careful inspection, and the question of their maintenance and length of life should always be taken into account when considering their relative economy. The following data refer to Fig. 9.

(1) Ash Fork, Arizona. 1898. Steel portion 184 ft long and 46 ft max height. 24 triangular bents, vertical downstream side and 1 : 1 upstream, 8 ft apart c to c braced laterally in pairs. Batter posts 20 in I beams, 65 lb per ft and reinforced on under side with plate ½ in thick and 18 in wide. Series of ⅜ in curved plates on upstream face concave upstream with radius 7½ ft. No leakage. Total weight of steel 478 704 lbs. Framed and erected at $55.78 per 2000 lbs.

(2) Redridge, Michigan. 1900–1. Steel portion 464 ft long. Max height of dam 74 ft. Concrete base thruout. "A" frame bents 8 ft apart, ⅜ in face plates concave upstream radius 7 ft 6 in, riveted to I beams 15 to 24 in deep. Batter upstream face 2 : 3. To cut off percolation under dam, line of drill holes 2 in diam and 10 ft long, 7 in apart

drilled and filled with grout under heavy air pressure. Rock floor covered with concrete and then by bank of puddle clay.

(3) Hauser Lake, Montana. 1907. 630 ft long. Maximum height 81 ft. Inclination upstream face 3 : 2. Portion of dam founded on solid rock. About 300 ft founded on steel sheet piles in gravel. Bents 10 ft apart connected in groups of four. Actual head

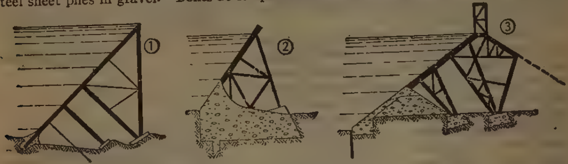

Fig. 9. Three Types of Steel Dams

to top of flashboards 69 ft. Working head about 66 ft. About 1700 tons of steel. Blanket of volcanic ash above dam to prevent seepage. Downstream face had flat plates on slope 7 : 11, connecting with plank apron carried on stone-filled cribs. Dam undermined where founded on gravel. Concrete placed over top of steel piling, said to have been placed in depth of 10 ft or more water so quality may have been very poor. Part of dam on rock remained standing. Replaced by concrete dam in 1911.

4. Timber Dams

The Rafter and Strut-Framed Dam (Fig. 10) is a structure which may be proportioned with reference to its stresses, but requires careful design, sawn timber and skilled workmen and is proportionally more expensive.

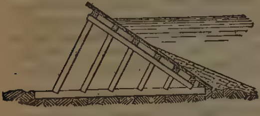

Fig. 10. Framed Timber Dam

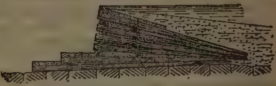

Fig. 12. Beaver Type Dam

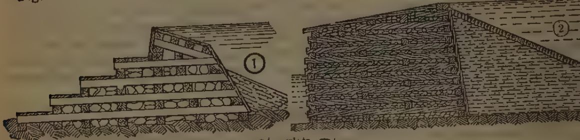

Fig. 11. Crib Dams

Crib Dams, (Fig. 11), have been extensively used where timber was cheap and masonry dear. They must be designed largely by judgment and following precedent. They are not subject to a very rigid analysis of stresses. The whole crib filled with loose rock may be considered as a unit adapted to resisting ordinary stresses of compression, tension and shear. The compressive stresses are resisted largely by the bearing of the timbers, one on the other; the tensile stresses resisted by the bolting and sometimes dovetailing of the timbers and the shear largely by the friction in the rock fill. Considered from this angle the crib dam can be designed with some reference to stresses. Another way of looking at it is to give about the width required for a rock fil

dam and consider the crib acting somewhat as a binder and mainly as an attachment for a water-tight timber sheeting to cut off leakage on the upstream side and to take wear and impact of the overflow on the top and downstream sides. The width of the crib-work is seldom less than one and one-third times the height and may be two or three times where long aprons are provided for overflow as in (1) Fig. 11. The highest dam of this type which has not failed was the Butte dam, about 70 ft high. No. (2) Fig. 11 is a cross section of a crib dam in the Schuylkill River subject to floods 11 ft high over crest. If crib dams are subject to heavy floods provision should be made for admitting air to the downstream side underneath the sheet of overflowing water.

The Beaver Type of timber dam is adapted to comparatively small heights. It is built as indicated in Fig. 12. The longitudinals are all laid with butts downstream. The crevices are filled with gravel, and the whole is covered with brush tightly packed and a bank of the most impervious earth obtainable. A plank flooring is carried from the crest well under the earth fill. Most failures of timber dams have been due to leakage underneath or to undermining by the overfall

5. Earth Dams

Foundations. One of the reasons for building a dam of earth is usually that a rock foundation cannot be had, tho several of these dams have been built on the best of bed rock. The foundation, whether earth or rock, should be thoroly examined to learn if it is impervious. If not impervious, cut-offs should be constructed, if possible down to an impervious stratum. Imperviousness is a relative condition. No earthy material is absolutely impervious, and if the width of the dam is so extended that the loss of head of water flowing thru the shortest course to an exit is so great that the velocity is so slight that water will not move the earth or reduce its cohesion at the exit, then the cut-offs under the dam may be unnecessary. In any case the site is usually stript and shallow trenches are dug across it. If the foundation is rock the creeping of water along its surface is guarded against usually by building a masonry wall entirely across the valley. This may be extended upward to the top of the dam as a core-wall, as in the Titicus dam, or, if the embankment is impervious, it is sometimes only 3 or 4 ft high, as in the Borden Brook dam, Mass. Where the foundation is open sand or gravel, deep cut-off trenches have usually been excavated and filled with concrete or puddle clay. Sheet piling is sometimes used. The character of the ground and other local conditions must determine the kind of cut-off wall best to use. Springs which may be found within the area of the foundation may sometimes be dug out to their source outside the area of the dam, or intercepted outside that area and diverted.

Core-Walls. The dam itself usually consists of three parts: an interior impervious part with an embankment on each side to support it. The impervious part is a masonry, puddle or steel core-wall or a heart of selected impervious material. Occasionally the builders are fortunate enough to have at hand a natural mixture of gravel and clay of which the whole dam may be built, thus combining the three parts in one, but usually the impervious material available is either too expensive or is unstable at a practical slope. What is the best type of core-wall is a mooted question. Rubble, concrete, puddle clay, sheet steel and wood have been used. It is argued that masonry, whether rubble or concrete, must have a solid rock foundation, and that even then it is in danger of being cracked by settlement of the embankment or by temperature changes. On the other hand, it is argued that slight

cracks will not be made larger by water but will be silted tight, and that if embankments are well built and the masonry core wall is 4 to 6 ft thick at top with sides battered at about 1 to 10, it will not crack from settlement of the embankments, and also when outlets pass thru or under the dam, that they are much safer when masonry core-walls are used.

In regard to clay puddle it is argued that its integrity depends entirely upon great care and much intelligence and skill in mixing and placing, and that if once punctured its entire integrity is destroyed. On the other hand, it is argued that settlement does not rupture it, and that it makes a better union with the rest of the embankment.

At the Boston Water Works the endeavor was made to overcome all objectionable features and preserve the merits of both by building a masonry core-wall and placing a selected clayey material next the upstream side of the masonry.

Riveted steel plate cores coated with asphalt have been used. Timber sheeting should not be used, as it is likely to decay. Whether the core-wall should be placed in the middle or near the upstream side of the embankment will depend upon the material used and local conditions. If the core-wall is to be of masonry it should be vertical, and this usually requires it to be under the crest of the dam. If the core-wall is of clay it is usually placed vertically under the crest, but sometimes on the upstream face, in which case it should be protected by additional filling. The slope must be very flat or else there must be considerable filling outside it to prevent slipping; also provision must be made against burrowing animals, if the clay is near the surface. Small stones or furnace slag mixt with the puddle are frequently used for that purpose.

The Placing of Embankment when not done by the hydraulic process is usually done by carts or cars. It is usually specified that the earth shall be spread in from 4 to 8 in layers, rolled with a heavy steam roller, and that, before placing the next layer, the last one shall be sprinkled and harrowed to insure bonding. Variations in details of construction on different dams have been the use of a drove of horses and sometimes goats to trample the earth, also heavy four-horse teams for hauling, runways being avoided. Rollers having grooves or projections on their faces are used on many dams.

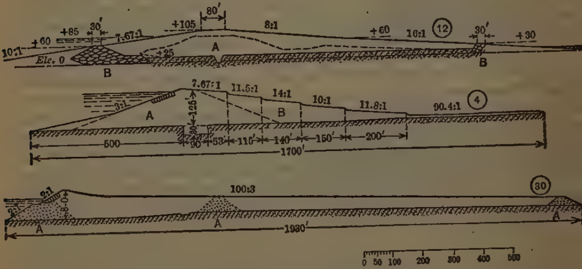

Fig. 13. Earth Dams

The embankment is usually kept four or five feet higher on the outer edg than in the middle.

Slopes must be determined by the engineer for each individual case. Prece dents may be studied in the following table. If it were simply a questio of the stability of the face the slope for the same material should be flatte on the upstream side than on the downstream side, for the angle of repos

Data of Earth Dams

P = Puddle. C = Concrete. R = Rubble. O = No core-wall.

especially of very fine material, is less in water than when not saturated bu slightly damp, which is usually its condition on the downstream side. If th dam is without a core-wall or other impervious hearting and subject to seepag either under or thru the embankmen it may be necessary to make th downstream slope very flat. Th upstream face is pitched or other wise protected against wash waves. The downstream slope sodded to protect it from wash rains. Berms with paved drai are used frequently in addition sodding.

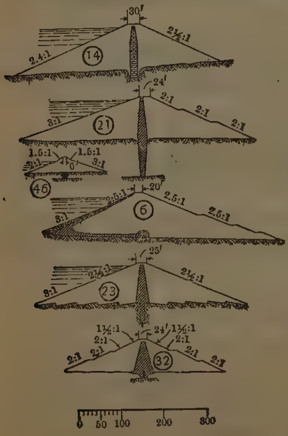

Fig. 14. Earth Dams

Top Width and Height abo Water. The formula $W = 1/5$ + 5, in which h = height of da in feet, has been suggested as gi ing safe widths in feet, for tops earth dams. The top should be high and wide that no burrowi animals can reach the heart of t dam at water level. It shou also be high enough above the hig est water level to be beyond the rea of all waves. Stephenson's form for height of waves is commo used,

$$X = 1.5\sqrt{F} + (2.5 - \sqrt[4]{F})$$

in which X is the height in feet, F the fetch in miles or sweep of the wind in the longest straight line which may be drawn from the dam on the water surface of the reservoir.

(1) Goose Creek, Idaho. 1910-13. Upstream face covered with 3 ft of loose rock, and loose rock dumped at toes. Core-wall 3 ft thick to 10 ft above natural surface and 2 ft thick from this point to top. Length 1050 ft.

(3) Patillas, Porto Rico. 1914 Length 1020 ft. Contains 970 000 cu yds. First 50 ft in height made by dumping from two trestles near either toe. Successive lifts then made by shifting track. Outer slopes of gravel and boulders. Middle of dam about 25 per cent clay washed into position and allowed to settle in pool maintained by the side banks. Total settlement 0.56 ft in three years.

(4) San Leandro, Cal. 1874-76. Portion "A" in cut built in 1874 of earth in layers 1 ft thick. No rollers used, but material dumped and sprinkled and band of horses used to compact. In 1898 portion "B" was placed by the hydraulic process. Shaken by San Francisco earthquake 1906. No damage. Puddle trench 30 ft below ground.

(5) Lahontan, Nev. 1913. Length 1359 ft. Vol. 710 000 cu yds. Upstream portion of gravel and silt, mechanically mixed and rolled in 4-in layers and faced with riprap and gravel. Downstream portion of pit run gravel. Foundations a red sand stone. Puddled cut-off wall. Grouted rock foundation.

(6) Tabeaud, Cal. 1900-02. Built in 6-in layers first 60 ft. Not over 8-in layers above. Top kept basin-shaped. Clay puddle on bottom and part of upstream face. 1 berm upstream, 3 downstream. Foundation hardpan and rock.

(7) New Croton, N. Y. Dam partly constructed then replaced by masonry structure. 2 berms downstream.

(8) Costilla, Col. 1917. Length 600 ft. Upstream slope riprapped. Cut-off wall 30 ft into clay and gravel foundation and 5 ft above natural ground surface. Built by dumping earth in ridges about 5 ft high and partly filling trench between with water. Then filling the trenches by dumping from wagons, then building new ridge over former trench and repeating process.

(9) Druid Lake, Md. 1864-70. Upstream face covered with puddle. Stone wall in bottom of core-wall. Embankment each side of puddle core-wall well rolled. Part of the material in dam placed in basins filled with water. Surface soil stripped, and where foundation is sand, core carried to impervious stratum.

(10) Belle Fourche, So. Dakota. 6-in layers. Some sheet piling near upstream toe. $819 164 contract price.

(12) Gatun, Panama. Portion A in cut is hydraulic fill, B is rock fill and the remainder is dry fill. There is a layer of 3 ft of rock paving 170 ft wide on the upstream slope to resist wave action.

(13) Standley Lake, Col. 1908-12. Length 6630 ft Material lumpy, blue clay which slacked very readily and became a slimy ooze on being saturated. Upstream face protected by loosely dumped riprap. In 1912 a small slide of the downstream face occurred and in 1914 there was a much larger slide of the same face. In 1916, following a rapid draining of the reservoir for irrigation purposes, about 88 000 cu yd slid from the inner face.

(17) Somerset, Vt. 1911-13. Length 2100 ft. Contains 1 000 000 cu yds. Material was coarse gravel and sand with some clay. Excavated by steam shovel, hauled to site and dumped from trestles on the upstream and downstream slopes. From there the material was sluiced down about a 2 1 slope toward the middle of the dam, the object being to leave coarse material on the faces and gradually grading to a fine impervious heart. Length 2100 ft.

(18) Temescal, Cal. 1866-68. Originally built in layers with carts and scrapers, with top width 18 ft at maximum height of 105 ft and slopes 3 : 1 upstream and 5 : 2 downstream. In 1869 downstream slope flattened by sluicing. In 1886 height increased to 115 ft by sluicing. As finished downstream slope 5 : 1

(19) Carite, Porto Rico. 1914. Length 520 ft. Upstream face paved. Down-stream slope, lower half paved. 200 000 cu yds. Fill dumped from trestle and spread by scrapers and wheelbarrows. Very little sprinkling done. Settled 0.96 ft. in three years.

(21) Yarrow, Eng. Max depth excavation 97 ft. Puddle core-wall on concrete foundation in rock. 2 berms on downstream slope.

(22) Morris, Conn. 1910. Upstream slope 3 : 1 for a height of 30 ft from toe, 2.5 : 1 above, faced with 1 ft 6 in of paving stones. 4 berms 8 ft wide on downstream slope, and

slope sodded. Core wall carried to rock 12 ft wide at base and 2 ft 5 in at top. Leng
1100 ft.

(23) Pilarcitos, Cal. 1864–66. Puddle core-wall 24 ft thick, keyed to rock with co
crete wall 3 ft by 6 ft. Length of dam 640 ft. 1¾ miles from fault line of San Francis
earthquake of 1906.

(24) Dale Dyke, Eng. Failed; opinions as to cause varied. Said to be because ou
let pipes laid naked or because dam above core-wall was a sort of rock fill, bringing
static pressure against core-wall.

(25) San Andreas, Cal. 1868–70. Dam raised in 1875. Puddle core-wall keyed
rock with concrete wall 3 ft by 5 ft. Length 800 ft. Fault line of San Francisco ear
quake of 1906 passes across east end. Crack 2 to 3 inches wide along axis of dam.

(26) South Haiwee, Cal. 1912. Length 1523 ft. 559 750 cu yds. Upstream sl
paved with 3-in concrete. Cut-off trench carried down to rock, in some cases to a de
of 120 ft.

(27) Forest Park, Md. Clay puddle on upstream face and carried to bed rock i
trench near upstream toe.

(28) Dry River, Watervliet, N. Y. 1913–14. 1 berm 8 ft wide, 40 ft below top
both faces. Material rolled in 6-in layers. Upstream face partly paved.

(29) Sherburne Lakes, Mont. 1918. Length 900 ft. 250 000 cu yds. Upstre
slope has 18-in paving of field stone on a 12-in layer of gravel, and concrete parapet
3 ft high at top. Downstream slope covered with 12 in of gravel. Unique feature
permeable core-wall of screened gravel 5 ft thick at crest, increasing with 3.5 in
batter, with system of pipe drains running from base of core to downstream toe.
cut-off trenches on upstream side, 1 on downstream. Material hauled in dump wag
spread in 6-in layers rolled with 20-ton roller.

(30) Wachusett, N. Dike, Mass. 1900–05. This dam is about 10 000 ft long. 5 500
cu yds. There are three embankments of sand and gravel shown at "A" in the
The remainder was built largely of fine loamy soil stripped from the reservoir site. M
rial spread in 1-ft layers and rolled by steam road roller and harrowed before adding
layer. Foundation pervious sand and gravel. For a portion of the length a trench
dug 60 ft deep in this gravel, and triple lap tongued and grooved sheet piling built u
2-in plank was jetted down from 20 to 60 ft. On Apr. 11, 1907, a portion of the upstr
face 675 ft long, of a thickness of 35 ft normal to the slope, slid down the bank, cau
little damage but indicating that 1 vertical to 2 horizontal was too steep for such
material under water.

(31) Cold Springs, Ore. No core-wall. Cut-off trench.

(33) Talla, Scotland. 1897–04. The clayey or adhesive material in middle
placed in 9-in layers. Outside this is stony or open material in 18-in layers.

(34) Throttle, N. M. 1914. Length 1060. Concrete core wall 600 ft long with
corrugated iron extending from cut-off wall to crest. Upstream slope paved. C
portion of dam well puddled. Downstream slope faced with selected rock, hand
(35) Seros, Spain. 1913–14. Dam No. 3 is the highest of 7 earth dams in hy
electric development near Barcelona. Length 1312 ft. Vol. 497 250 cu yd. Upst
face riprapped. Puddled cut-off trench. 1 berm downstream slope.

(36) Las Vegas, N. M. 1917. Upstream slope riprapped 9 in thick. 1 berm on d
stream face. Length 1400 ft. Material hauled by dump cars and sluiced into
with water jet.

(37) Mammouth, Utah 1908 14. Proposed height 125 ft. Concrete core-wall
buttresses. Earth placed by wagons and scrapers and rolled. In June, 1917, dar
at a height of 70 ft with water stored to nearly the same height. Washout occ
at flume carrying water across the top. One-half billion cu ft water released cuttin
to foundation causing great damage to structures below.

(38) Johnstown, Pa. Lower face entirely stone, 4 ft thick at top, 20 ft at bo
and backed by slate rock 3 ft thick at top and 30 ft at bottom. Heart of selected
Upstream face of dry rubble 15 in thick. Failed: Flood overtopped dam.

(39) Keechelus Lake, Wash 1914. Length 6500 ft. 522 000 cu yds. Ups
slope faced with riprap. Concrete cut-off wall.

(40) Phelps Brook, Conn. 1917. Length 1200 ft. Upstream slope 3 : 1 below
surface, 2 : 1 above, faced with 12-in or riprap. 1 berm on downstream slope.
crete core-wall to rock.

(41) Youngstown, Ohio. 1913–16. Length 2202 ft. Concrete cut-off. Up
slope faced with 9 in to 18 in of concrete.

(43) Glenwild, N. Y. 1902. Core-wall is broken bowlders grouted with 1 : 3 cement mortar. Dam curved upstream with radius of 708.6 ft. Contract cost $47 360.

(44) Hatchtown, Utah. 1908. Failed in May, 1914, probably due to leakage along the outer surface of the outlet culvert and leakage thru foundations of black clay sand and gravel. Length, 780. 126 000 cu yds.

(45) Bog Brook, N. Y. Masonry core-wall 10 ft thick at base and 6 ft at top. Upstream face has 12-in paving on 6-in broken stone. Berm on downstream side.

(47) Hebron, N. M. 1914. Length 3700 ft. Puddled cut-off trench. In May, 1914, a section 200 ft long washed out.

(48) Horse Creek, Col. 1911-12. Length 5150. Vol. 714 000 cu yds. Downstream slope 1.5 : 1 for distance of 16 ft from crest, and 2.5 : 1 for balance. Upstream slope 1.5 : 1 face paved with 5 in of concrete. Earth placed by dump wagons and spread with scrapers. No sprinkling and no packing of material done. In January, 1914, 200 ft of the dam above the concrete culvert outlet washed out. Immediately after reservoir emptied, 3600 ft concrete paving slid down slope.

Failures of Earth Dams. In a record of 30 failures of earth dams, which may be assumed to be representative, 11 were due to overflowing, 10 to leaks in outlet pipes; 3 to undermining, and 1 was attributed to burrowing animals. The causes of the other five were somewhat doubtful, but several causes were assigned, such as poor foundations, slopes too steep, lax construction methods and carelessness in preparing the site.

6. Hydraulic Fill Dams

Sluicing is a method of building earth dams by which, especially in mountainous regions, the material often may be excavated, conveyed to the site and placed much more cheaply than by any other means. The ideal material

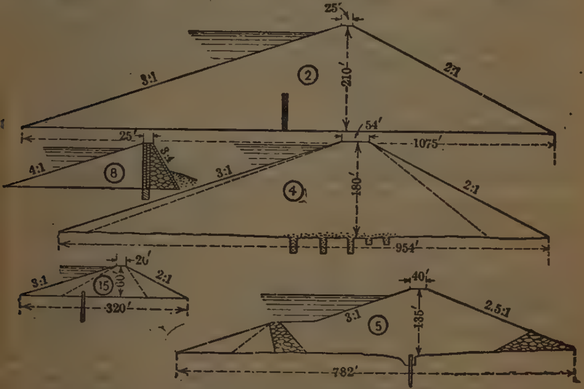

Fig. 15. Hydraulic Fill Dams

is a mixture of sand, clay and gravel with plenty of small rock. The development of the art has evolved a number of excellent properties of such dams, so many, in fact, that a number have been built by hauling dirt with cars to the site and sluicing it into place. The practise is for the sluices to discharge near the outside edges of the embankment. The coarse material drops there, and the fine flows with the water toward the middle of the dam, depositing

as it goes, the coarser first, the medium next, most of the clay going to the pond of still water in the center, where it is precipitated, forming a wide clayey core-wall. The coarse material remaining on the outer edge is most useful in maintaining the slopes due to its greater angle of repose. In practise, however, the danger is that the material will not be properly graded, either too fine, making the faces unstable, or too coarse, making the core permeable. Even if the material is properly graded the sluices may not deliver a uniform mixture, resulting in permeable layers across the dam. This danger is believed to be avoided by keeping men continuously spading and kneading the bottom of the pond in the middle of the dam. As the work progresses, a few men keep the edges built up just enough to keep the discharge from the sluices always flowing toward the center. The pond is sometimes allowed to drain by filtering thru the coarser outside material, and sometimes by a vertical waste pipe built up in short lengths of from 6 to 15 inches, changing its direction at the foot to a horizontal leading to the downstream face.

Data of Hydraulic Fill Dams

Numbers in parenthesis refer to following notes and to Fig. 15.

No. and location	Date	L'gth, feet	Max height, feet	Top width, feet	Slope up-stream	Slope down-stream	Total volume, cu yds	Water used, cu ft per sec

(18) Tyler, Texas	1894	575	32	......	3 1	2.1	24 000	1 4

(1) Calaveras, Cal. Material is clay sand and gravel with dry rock fill at toes. Material sluiced from borrow pits down open channel 5 to 7% grade into concrete sumps an raised to dam with 12-in centrifugal pumps Designed to contain 3 000 000 cu yd After 2 800 000 cu yds placed, upstream face for length of 700 ft slid. Aggregate to 50% clay.

(2) Terrace, Col. Material sluiced from a clayey bank to form heart of dam, and fro a separate bank clean rock and gravel were sluiced to the two slopes in flume on 7 grade using 26 sec ft of water Concrete core-wall about 65 ft high in bottom of canyo

(3) Little Bear Valley Cal. Disintegrated granite and clay deposited from spoil trai on toes of dam and finer materials were washt to the center. Concrete core-wall.

(4) Necaxa, Mexico. Broken limestone and yellow clay. Concrete core-wall, abo

6 5 ft above stript surface. Sluicing flumes 20 in diameter, 4 ft wide, rect section with V-shaped bottom, grade 5% and 8%. During construction a slide of the upstream face occurred which was attributed to the use of unsuitable material. Dam since completed and now in use.

(5) Magic Reservoir, Idaho. Cut-off walls in sides of canyon. Cut-off trench and sheet piling under dam Constructed by combination of methods. Excavated by steam shovels; spoil trains delivered material close to site, thence it was sluiced to place.

(6) San Leandro, Cal. 160 000 cu yds sluiced. Sluicing flume grade 4% to 6% See earth dams.

(7) Crane Valley, Cal. Sluicing flume 12 in by 10 in. Flumes on 6% grade. Ground sluicing was used, that is, material was dumped into flume after loosening.

(8) Waialua, Hawaii. Rock fill portion: base width 80 ft, crest 11 5 ft, downstream batter ¼ to 1, upstream face vertical, volume 26 000 cu yds. Wooden diaphragm embedded at bottom in concrete wall. Earth fill 141 000 cu yds. Soil dumped into flowing stream of 8 sec ft in ditch 1300 ft long with bottom grade 4%. The soil was a decomposed lava of a cohesive and unctuous character, very free from grit. Earth fill 11 cents per cu yd Leaked during first year. 1905 material obtained by enlarging spillway sluiced against lower toe.

(9) Santa Maria, Colo. Two cut-off trenches to hardpan sheeted and puddled. Dirt and boulders conveyed by rectangular sluices 3 × 3 ft.

(10) Quemahoning, Johnston, Pa. Slopes 4 : 1 for lower half and increasing 3 : 1 for the upper half Concrete cut-off wall extends 10 to 27 ft into the shale rock also puddled cut-off. Rectangular flumes 24 in wide and 18 in deep, grade 6%. Material a mixture of clay and shale rock.

(11) Lake Frances, Cal. Old earth dam failed, about 20% being washt away. Repaired and enlarged by hydraulic process. 182 937 cu yds of new dam sluiced in 1.76 sec ft of water used at first; later 4.5 to 7 sec ft. Sluicing flume 22 in diameter, minimum grade 2 2% Most of material sluiced was clay. Brush used to maintain slopes.

(12) Snake Ravine, Cal. Built of fine silt and clay, slid as a body 1000 ft down ravine at rate 6 to 10 ft per sec Failure attributed to lack of coarse material on slopes and fact that fine material did not drain when building.

(13) Santo Amaro Brazil. Clay and disintegrated granite. Slip of blanket over core-wall of section east of hydraulic fill occurred during construction Excess of clay in blanket did not allow good drainage outward. Sluicing flume 2000 ft long, grade 3%.

(14) Croton Mich. Fine yellow sand. Sluicing flume 30 in in diameter semi-circular, grade 8% to 9%, length 800 ft Cost 6 8 cents per cu yd, including plant, materials, labor, power, etc.

(15) Conconully, Wash. Loose rock, gravel, sand and silt. Sluicing flume, sloping side 2 ¾ ft apart at top No 10 steel curved bottom bent to 12-in radius, clear depth being 2¼ ft. Lateral flumes trapezoidal 12 in wide at bottom. Sheet piling across valley 70 ft upstream from center line driven 33 ft and projecting 3 ft above valley bottom. Flume grade 4%

(16) Silver Lake, Cal. Heavy sandy loam containing considerable clay which was carefully separated and placed in center. Drains to prevent slipping during construction Concrete core-wall under dam and 3 to 6 ft above original surface. Sluicing flume 8 in diameter, 2 5 sec ft water used in later stages. Flume length 4000 ft.

(17) Yorba, Cal. About 80% by hydraulic ground sluicing process. Adobe clay soil, sand and gravel. No core-wall; puddle trench thru top soil. Material supplied to parts too high for gravity flume by pumping thru an 8-in pipe a maximum distance of 800 ft. Cost 8 cents per cu yd for ground sluicing Flume grade 4 to 7%.

(18) Tyler, Texas Sluicing flume 13 in in diameter. Material 65% sand and 35% clay. Cost 4¾ cents per yard, including everything

7. Rock-fill Dams

Dams of Loose Rock were designed to meet the requirements of miners in western America, where the great cost of hauling cement made its use prohibitive Since most of these structures are located in deep rock canyons, it was a simple matter to quarry the material at a higher elevation than the dam and transport it by gravity to the site or even to throw the material directly to place by blasting Dams of this type are made watertight by a variety of methods In some cases the upstream face is covered with planking spiked to studding buried in the rock-fill, or with steel plates fastened to I

beams set in the face, or with rubble masonry walls or reinforced concrete facing. Steel core-walls are also used. A later development is the combination earth and rock-fill dam in which the earth is either dumped or sluiced into place on the upstream face.

Most of the failures of rock-fill dams have been due to insufficient spillway, causing overtopping. Some have been caused by poor design in making the slopes steeper than the natural angle of repose of the loose fill and trusting to dry rubble facing walls to hold the mass in position.

The following numbers correspond to those on the cross-sections of Fig. 16:

(1) Escondido, Cal. 1895. Faced with redwood plank. Timber face backed with concrete. Contains 6000 cu yds dry rubble and 31 157 cu yds rock fill. Leakage when full 450 000 gal per day. Cost $110 000. Stones laid by hand on inner face to form dry wall 15 ft thick at bottom and 5 ft at top. Bed-rock trench at upper toe filled with rubble masonry, in which plank facing is embedded. 76 ft high. 380 ft long on top and 100 ft on bottom. 140 ft wide at base and 10 ft on top. Slopes are 1:2 on water face; 1:1 on back for half the height and 5:4 from mid height to base.

(2) Castlewood, Col. 1890. Lower slope covered in steps of 2 ft with large blocks of stone in cement mortar. General slope 1:1. Upper face wall rough rubble masonry 4 ft thick, on batter 1:10. Walls joined at top with coping. Crest width 8 ft. Dam founded on clay. Front face wall carried 6 ft to 22 ft into clay. Lower slope wall also founded on clay at depth 10 ft below surface. Length 600 ft. Height above reservoir floor 70 ft, above foundation of face wall 92 ft. Rock pavement 25 ft wide, 200 ft long, 3 ft to 6 ft deep heavily grouted at top with cement mortar to prevent scouring. Dam leaked. Earth embankment added to upstream face, 8 ft wide at crest with 3:1 slope faced with 12 in riprap.

(3) Lake Avalon, New Mexico. Length 1050 ft. Earth slope covered with revetment of loose stone 2 ft to 3 ft thick for wave protection. Failed 1893, water passing over top, washing out 300 ft length to bed rock. Immediately repaired and built 5 ft higher. Second failure 1904. Stated that water did not pass over top but forced way thru the dam. Failure attributed to burrowing animals, or faulty construction where dam connected with bank. Reconstructed with top width 43 ft. Substantial addition made to earth fill and core-wall built of concrete heavily reinforced. Part of core-wall on concrete base and part on sheet piling driven to rock.

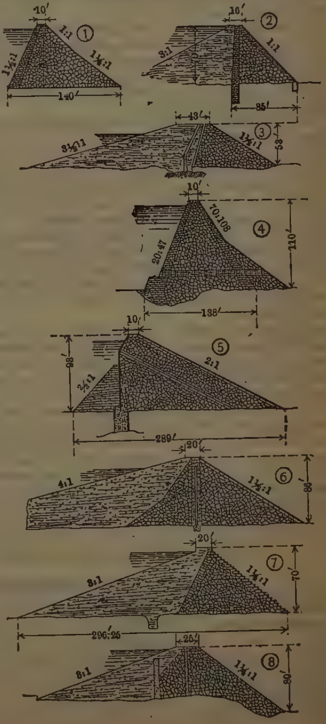

Fig. 16. Rock-fill Dams

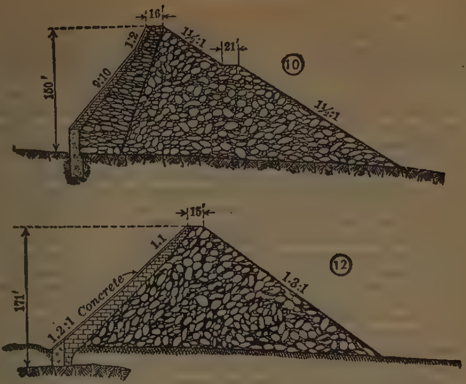

Fig. 16 (continued). Rock Fill Dams

(4) Walnut Grove, Arizona. 1887–88. Destroyed by flood 1890 with loss of 129 lives. Length 400 ft. Slopes much steeper than natural angle of repose of loose rock. Faces laid up as dry walls. With 70 ft of water above bed rock, dam leaked 3.75 cu ft per sec.

(5) East Canyon Creek, Utah. 1899. Originally built 68 ft high. Length 100 ft. Concrete wall 15 ft thick, carried down thru gravel to bed rock and steel plates for core anchored in center. Rock thrown on wall by blasting sides of canyon. Open cut made in pile of rocks thrown down and steel core-wall built from anchor plates. Asphalt concrete 4 in each side of plate. Settlement of wall caused asphalt to draw away from steel an extreme distance of 5 ft at top. Dam cost $60 200 and required 23 000 cu yds rock, 810 cu yds cement concrete, 183 cu yds asphalt concrete, 69 800 lbs of steel and 50 500 ft B.M. of lumber. Enlarged 1900–01 by addition to downstream side. Max. height 93 ft. Additional work required 16 000 cu yds rock, 410 cu yds of masonry and 370 cu yds concrete, 62 000 lbs steel and 20 000 ft B.M. lumber. Length 173 ft. Crest width 10 ft. Steel core-wall continued to top, protected by concrete.

(6) Milner, Idaho. 1903–05. Three dams form one main structure. Rock fill with core of wood. Earth embankment sluiced into voids of rock above core. Main Channel Dam: Length 340 ft. Max. height 86 ft. Crest width rock fill 10 ft. Downstream slope rock fill 3:2; upstream 3:4. Crest width earth fill 10 ft; slope 4:1. Rock fill 39 650 cu yds. Earth fill 58 000 cu yds. Middle Dam: 335 ft long. 81 ft max. height. 42 800 cu yds rock, 62 850 cu yds earth. South Dam: 560 ft long. Max. height 66 ft. 34 700 cu yds rock; 48 000 cu yds earth. Total length of 3 dams, spillway and reg. gates, considered as one structure, 2100 ft.

(7) Zuni, New Mexico. Combination rock and hydraulic fill. Rock fill built as dry wall. Rock fill 720 ft long. Total volume dry wall 40 160 cu yds. Indian labor. Cost rock work $2.50 per cu yd. For sluicing, steam pumping plant with capacity 2.5 sec ft at 90 to 95 lbs per sq in pressure. Total volume earth in dam 60 120 cu yds, about 40 000 yds sluiced in. Total cost for sluicing 12 cents yd. All earth, either very fine sand or clay, no attempt being made to separate them. Undermined 1909 by passage of water under cap of lava rock which flanked dam and extended beneath spillway. Spillway, south abutment and extreme south end of dam undermined. Considerable portion of spillway dropt 7 ft and settlement of 9 ft at junction of spillway and abutment. Small amount of fill at south end washt out and there was 5 ft settlement about 30 ft long in earth fill at north end. Main part of dam appears uninjured.

(8) Minidoka, Idaho. Rock fill, earth facing and concrete core-wall. Length 625 ft. Max. height 80 ft above bed rock and about 60 ft above original bed of stream. Crest

width 25 ft. Base averages about 300 ft. Total volume 191 000 cu yds. Concrete core on solid rock. Top of wall 44 ft below crest in central portions and about 11 ft near end. Earth and rock-fill banks built up and core-wall built in trough between them. Fill then carried up on both sides over core-wall to required height. Cost $425 923.

(9) Lower Otay, Cal. 1897. Originally planned for masonry dam and masonry carried up 8 ft above river bottom. Core of steel plates anchored to masonry and carried up to crest, protected with asphaltum and burlap and 1 ft thickness of concrete either side. Failed January 27, 1916, by flood overtopping the dam. About 30 lives lost.

(10) Morena, Cal., 1896–1909. Length 520 ft. 306 000 cu yds. Built in canyon about 130 ft wide at stream bed with narrow fissure 4 to 16 ft wide, extending 112 ft below. In 1896 a rubble concrete wall 36 ft thick at bottom and 12 ft thick at top was built to seal fissure, and carried up 30 ft above stream bed, when work was suspended in 1898. Construction resumed 1908. Upstream face for width of 7 ft built of 6 to 10 ton granite blocks, set in cement mortar. Behind this for width of 50 ft at bottom, reducing to 16 ft at top, rock was placed by hand and derricks. Remainder of rock-fill dumped by 2 cableways. Reinforced concrete slab 1 ft thick on upstream face.

(11) Swift, Montana. 1914. Upstream face covered with a layer of hand-placed rock, 4 to 6 ft thick, with face plastered with cement mortar. On top of this was placed a concrete slab heavily reinforced, 6 in thick at top of dam and 2 ft at toe. Dam built on curve of 1276 ft radius. Foundation of sand, gravel and boulders.

(12) Strawberry, Cal. 1914–1916. Upstream slope faced with 9 in to 18 in of concrete carried down to concrete cut-off wall and backed by hand-laid rock. Main portion of rock dropped from cableways. River bed a cemented gravel. Dam arched in upstream direction. Radius 1880 ft. Contents 400 000 cu yds. Length 612 ft.

8. Overflow Dams on Earth Foundation

Three Conditions influence the design of overflow dams on earth foundations. First, the character of the earth, ranging from loose fine sand to firm, well cemented hardpan; second, the height of the fall; and third, the volume of water to be past. Designs for dams to meet various combinations of degrees of severity of these conditions may best be studied from precedents. The engineers of India have developed a type for their rivers in alluvial beds subject to great floods. The type has been adopted by the U. S. Reclamation Service for similar conditions, the Laguna being a case in point. One form of the India dam is essentially a rock fill with very flat slopes downstream protected by heavy pitching or concrete-slab construction and containing one or more masonry core or cut-off walls. This type has never been used except for very moderate heights of from 6 to 15 or 20 ft. They have, however, been built on sand foundations and have past great floods. The greatest trouble is usually experienced at the toe where the structure is likely to be undermined. The Avignonet dam is a precedent for a high dam on an earth foundation, but there the earth foundation is compact gravel, fine sand, and bowlders. Following numbers in parentheses refer to Fig. 17.

(1) Narora Weir, India. Brick. Base 8 ft thick. Founded on blocks or wells 10 ft square and 18 in thick sunk 7 ft below river bed. Downstream from weir floor is 40 ft wide, 5 ft thick, consisting of 3 ft 3 in concrete, 9 in brick and 12 in ashlar. Beyond floor talus is 100 ft wide. Crest covered with ashlar. First crest covering destroyed and replaced with masonry set with wider joints. Head on crest 8 ft. End of talus 14 ft below crest.

(2) Dauleshwiram, India. 1840. 16.8 ft head on crest. Length 12 000 ft. Crest 11 ft above normal bed level. Width 230 ft. Crest covered with ashlar masonry.

(3) Srivakantham, India. Length 1380 ft. Discharge over weir 123 000 sec ft. Weir wall and curtain walls on clay which lies under 3 ft bed of sand.

(4) Pelandorai, India. Length 860 ft. Head on crest 13.3 ft. Crest 9 ft above the river bed above weir.

(5) Burma Crib Weir, India. Boards were placed on top at first pending grouting of weir body with silt, and final settlement, with idea of replacing by rubble.

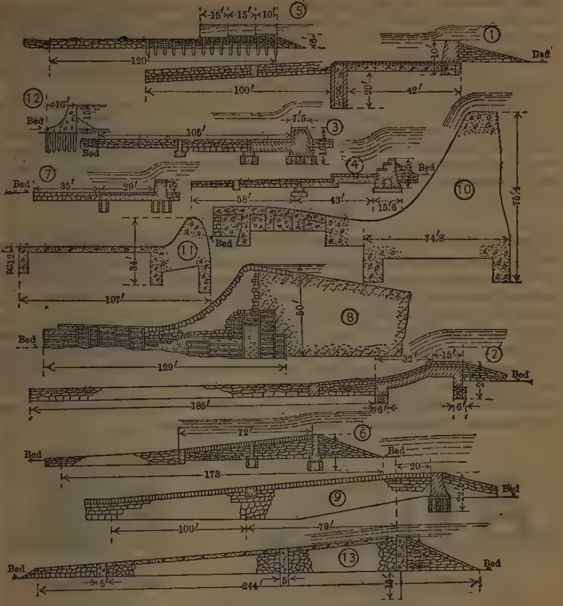

Fig. 17. Overflow Dams on Earth Foundations

(6) Mahanuddee Weir. 6400 ft long. Folding shutter 3 ft high on crest. Calculated to discharge about 900 000 sec ft. Crest 13 ft above average summer water level of river. Face of weir protected by rubble-stone packing with base varying from 20 to 40 ft. Breach 1886 at site of center sluices; about half sluices and portion of weir carried out and deep hole scoured on line of weir and below it. Cause never explained.

(7) Upper Colerum, India. 1836. Length 2929 ft. Head on crest 8.6 ft. Crest 7.4 ft above river bed. River bed, fine sand. Founded on double row of wells sunk 6 ft into river bed on upstream side and single row on downstream side. Masonry floor 27 ft broad, 3 ft thick, 2 ft being brick masonry. Season after completion about 240 ft of weir swept away. Caused by leakage undermining foundation. Weir repaired.

(8) Old Croton. 1837–42. 180 ft long. Mud and bowlders cleaned from river bottom and crib cofferdams built enclosing space where masonry was to be laid. These cribs were left in the foundation. Space between cofferdams excavated to hardpan and filled with concrete and masonry. Earth bank 5 : 1 slope paved near top and with bottom width 275 ft against upstream face. Dam has past 8 ft depth on crest.

(9) Kistna Weir, India. 1854–55. Length 3000 ft weir proper; nearly 4000 ft including under sluices and piers. Crest 20 to 25 ft above original river bed. Flood velocity over weir said to be 16 ft per sec and depth on crest 20 ft. Deep holes that had been scoured in river bed by floods were filled with sand and wells sunk for foundation of weir.

(10) Avignonet, France. 1902. Concrete. Length 197 ft. Curved radius 656 ft. Height 75.5 ft. Built in narrow canyon on bowlders, sand and gravel. 2 cut-offs, 13 ft deep and 8 ft thick. Passes over 35 000 sec ft during flood.

(11) Granite Reef, Arizona. 1906–08 Partly founded on gravel and bowlders 1000 ft long. Three curtain walls. Openings in the wall under lower toe 6 in sq 5 ft apart and about 6 ft above bottom of wall to allow drainage of seepage. About 3-in joints in apron to allow escape of water.

(12) Spooner, Wisconsin. Concrete structure 72 ft long. Foundation sandy soil covered with thin layer of gravel. Pile foundation.

(13) Laguna, Arizona. Begun 1905. Crest 19 ft above natural river bed. Three concrete walls 4800 ft long and 57 and 93 ft apart. Upper wall on row of sheet piling 12 to 20 ft long. Between walls is rock fill. Apron of derrick stone extends 40 ft beyond lower wall. Rock fill between walls covered by 18-in concrete. Approximate quantities: rock fill 350 000 cu yds; concrete paving 37 000 cu yds; concrete core-walls 28 000 cu yds, sheet piling 90 000 lin ft. Discharge from 4000 to 100 000 sec ft.

9. Movable Dams

Needle, Wicket and Curtain Dams form a group of movable dams having many common and numerous interchangeable features. Common to all are upright pieces, the lower ends of which bear against a sill on the river bottom, the upper ends of which bear against some form of bridge. The bridge may be a stationary structure or a collapsible structure. In case needles are used (Fig. 18) they form the closure. In case wickets are used (Fig. 19) the closure is formed by sliding stop gates down grooves in the upright pieces. With curtain dams (Fig. 20) an overhead bridge is generally used, and a screen rolling on the upright pieces is let down from above. When a draw or fixt bridge is used, the upright pieces are hinged at the upper end and are swung up out of the water with suitable machinery.

Fig. 18. Needle Dam

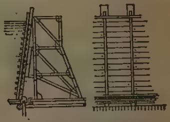

Fig. 19. Wicket Dam

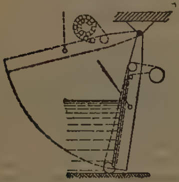

Fig. 20. Curtain Dam

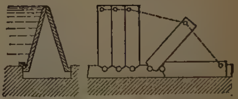

Fig. 21. Thomas A Frame Dam

The Thomas A Frame Dam (Fig. 21) consists of a series of *A* frames set side by side and pivoted at the bottom to a sill. The plates which fasten the two legs of each section together at the top form a footpath. One o these dams 120 ft long and 1 ft high was built as part o Dam No. 6 in the Ohio River

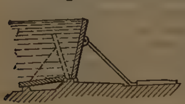

Fig. 22. Thénard Shutter Dam

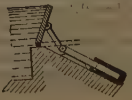

Fig. 23. Girard Shutter

The Thénard Shutter Dar (Fig. 22) consists of leave hinged to a sill which extend

across the channel. The leaves are raised and supported by struts hinged to the leaf and at the lower end fitting into a socket from which they may be tript and the leaf lowered. Above is a counter shutter which is raised by the current as a temporary dam until the main dam can be raised by hand. A dam of this type, built in France and finished in 1843, has shutters 5.6 ft high and 3.9 ft wide. Others have been built in India to close flushing sluices, and some of them support heads of nearly 10 ft. The counter shutter is held in position by chains, which on account of the severe shocks occurring when the gate swings up, often break and are objectionable.

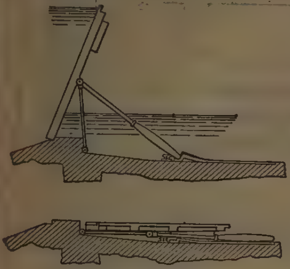

Fig. 24. Chanoine Wicket

The Girard Shutter (Fig. 23), invented as a substitute for the Thénard, does away with the counter shutter, and the main dam is raised directly by hydraulic pressure. Seven of these were erected at Auxerre, the shutters of which were 11½ ft wide and 6½ ft high.

The Chanoine Wicket (Fig. 24) was invented in 1852. The shutter is pivoted a little below its center point to a collapsible horse held in place by a long prop. It is adapted to large rivers where the flood rises are very sudden.

The Rolling Dam (Fig. 25) consists of a large steel cylinder placed across the current between piers or abutments and arranged to be rolled up entirely clear of the current on an inclined rack track. They are operated by cables wrapt around one or both ends of the cylinder and passing to a winch. They have been built for openings up to 115 by 6½ ft and 60 by 14 ft and are said to operate very quickly and pass ice readily.

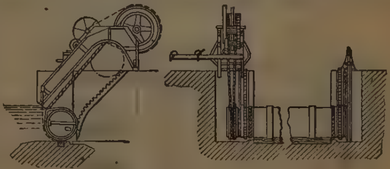

Fig. 25. Rolling Dam

Stoney Sluice Gates (Fig. 26) consist of a gate bearing at its ends against a train of rollers. The gate is usually hung to chains at either end, which pass over sheaves to a counter-weight. The roller train is also hung by a cable and counter-weighted. They are usually operated by gearing on the supporting sheaves turned by hand cranks or traveling electric motors. These gates have given excellent satisfaction and are widely used. Power for operating has usually been underestimated. Fig. 26 is an example of Stoney sluice gate at the lake regulating works, Sault Ste Marie, Canada. Fig. 27*a* shows the detail of the end bearing Fig. 27*b* shows the end bearing of the Stoney gates on the Manchester Canal, Eng.

On the New York Barge Canal several movable dams of the bridge type have been used (Fig. 65*a*). These dams have abutments, piers and superstructures

like ordinary bridges: from the downstream sides hang steel frames resting against shoes in concrete sills that stretch across the stream between the abut-

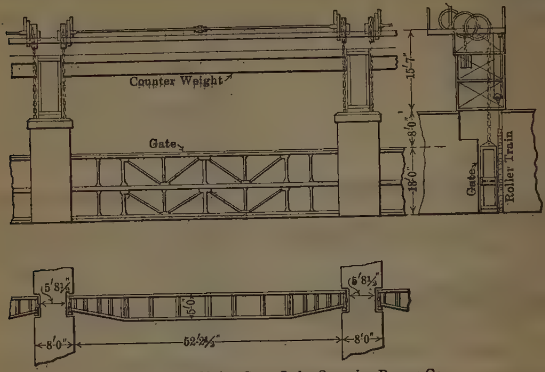

Fig. 26. Stoney Sluice Gate, Lake Superior Power Co.

ment and pier. Against the upright frames are placed "Boule" gates formin the dam proper. Electric winches raise the gates and uprights by chain The spans vary from 150 ft to 240 ft.

The Bear Trap Dam (Fig. 28), of which there have been many mod fications, consists of two rectangular leaves extending over the full width the opening, an when in their low position the u stream leaf overla the downstream lea The gate is rais by admitting wat from the upper po to a chamber und the leaves. A da built at Davis Isla on the Ohio Riv in 1889 was of th type. The ga were of wood a 52 ft long. In 19 this was replaced

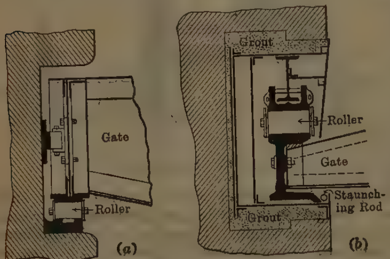

Fig. 27. Ends of Stoney Gates

a new bear trap with wooden leaves heavily bound with steel. The n leaves were much stronger than the old ones and were proportioned so th they would just float without the need of air forced to the underside. At t bear trap on the Marne in France a counter shutter was provided, as in t Thénard shutter dam, as an assistance to raising the main dam.

The Bear Trap on the Chicago Drainage Canal (Fig. 29) is of somewh different design. The two leaves do not overlap, but are hinged togeth

at the apex. The downstream edge of the dam is hinged to the foundation, while the upstream edge carries a roller and moves up and down on the masonry face. The gate is counterweighted and its movements up and down are controlled by hydraulic cylinders. The dam is 160 ft long, the downstream leaf 35 ft wide and the upstream leaf 21 feet wide.

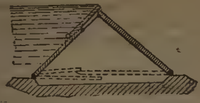

Fig. 28. Bear Trap Dam

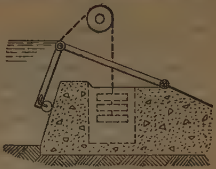

Fig. 29

The Parker Gate (Fig. 30) modifies the original bear trap by hinging the two leaves at the apex and introducing a hinge at a little above the mid-point of the upstream leaf; this does away with the sliding friction between the leaves. An auxiliary leaf, called the idler, is introduced above the upstream leaf to protect the moving parts from drift and ice. A dam for the Muscle Shoals Canal in Tennessee was built in 1892, 49 ft wide and 8.5 ft high.

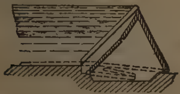

Fig. 30. Parker Gate

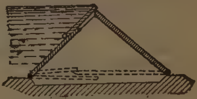

Fig. 31. Lang Gate

The Lang Gate (Fig. 31) is a modification of the Parker gate, in which the section of the upstream leaf above the hinge is removed and rods or chains take its place. The auxiliary leaf, or idler, is hinged to the downstream leaf, and its lower edge either slides or rolls on the upstream leaf. Several Lang gates, reaching in size to 80 ft long and 14 ft high, have been built in America.

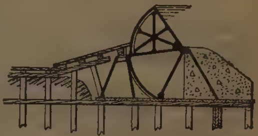

Fig. 32. Chittenden-Drum Dam

The Chittenden-Drum Dam (Fig. 32) consists of a gate in the form of a sector of a circle, with a central angle of 67½°, hinged at its center, and a water-tight chamber into which it fits snugly when down. Water admitted to this chamber from the upper pool raises the dam. A dam of this type was constructed on the Osage River, Missouri, in 1901, with a difference in head of 16 ft between the upper and lower pools.

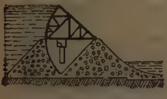

Fig. 33. Drum Dam, Chicago Drainage Canal

The Drum Dam of the Chicago Drainage Canal, Fig. 33, consists of a 45° sector of a cylinder 52 ft in diameter, having its face covered with steel plates carried by radial frames pivoted at the center on the downstream side and a water-tight chamber into which it fits when down. Dam raised or lowered by varying the head of water in the chamber, for which special valves are provided. This dam differs from earlier forms of sector dams in being pivoted on the downstream side. The vertical range of move-

ment is 18 ft. A drum dam similar to that noted in Fig. 33 has been built across the Genesee River at Rochester with a vertical range of 9.4 ft and each section 53 ft 11 in wide.

The Taintor Gate is similar to the drum dam (Fig. 32) except that the axis is higher and on the downstream side, and to open it, it is usually lifted clear of the water by cables and winches. It is often used on power dams. The U. S. Government built at Sterling, Ill., gates 21 ft wide and 13½ ft high. On the New York Barge Canal there are several Taintor gates, the largest having a lift of 14.3 ft and a width of 48 ft.

AQUEDUCTS

10. Reservoir Outlets

Outlets for all reservoirs are preferably put in the natural formation outside the dam whether earth or masonry. In masonry dams they weaken the section somewhat, changing the distribution of stresses, and if the opening is large the change of section may concentrate shrinkage and temperature cracks. In earth dams the inevitable settlement of the embankment is liable

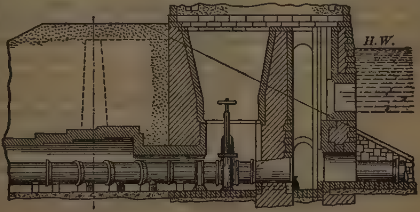

Fig. 34. Gatehouse, Jerome Park Reservoir

to break outlet pipes. They are sometimes carried thru tunnels in the adjacent hillsides, but usually this is impracticable and the common practise is to carry them thru the dam. If the dam is masonry, it is strengthened to compensate. If the dam is earth and high, the outlet may be placed in the natural earth below, where, if properly built, they are reasonably safe from dangers due to settlement. In low earth dams they are usually carried directly thru the

embankment. The fact that many failures of earth dams have been due to leaky outlet pipes demonstrates that the outlet pipes should not be in contact with the earth but placed in a masonry conduit, as in Fig. 34, where they may be inspected frequently and where any leakage will be quickly shown. Where the head of water in the outlet is small it is usually placed directly in the earth. This is the case when the embankment is low or when the gatehouse

Fig. 35. Outlet Borden Brook Reservoir

is above the core-wall and the outlet below is without pressure. Fig. 35 shows one of the latest designs of this type.

Gatehouses. For domestic water supply it is usually desirable to be able to draw water from either the top, bottom or mid-depth of a reservoir. It is desirable to have at each outlet opening a gate or valve which may be quickly operated and in addition a second emergency gate to be used in case the other is out of order, and a fish and trash screen. Fig. 36 shows the gatehouse of the Boonton dam, which is typical of many water-supply reservoirs. Where the dam is of earth the gatehouse is put either in the dam, as in the case of the Jerome Park Reservoir (Fig. 34), or as an intake tower built inside the reservoir, as at the San Mateo dam (Fig. 37). In the San Mateo dam the outlet is thru a natural hill. The former method complicates the construction of the dam, and the latter is more subject to ice pressure. Fig. 35 shows the gate house of the Borden Brook Reservoir, which is placed above the core-wall and protected from ice by thickening the upper part of the dam at that point. The fish and trash screens are usually copper netting having about 6 meshes to

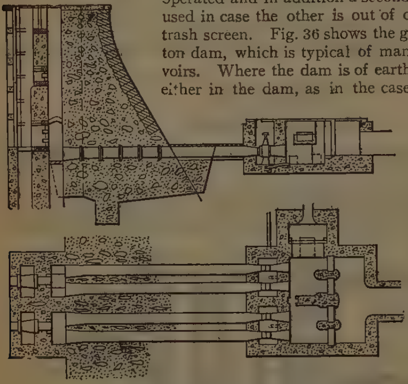

Fig. 36. Gatehouse, Boonton Dam

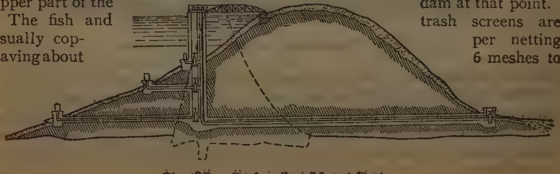

Fig. 37. Outlet, San Mateo Dam

the inch, with wire about $\frac{1}{16}$ in in diameter made up in frames which are slid into grooves and may be easily removed.

Fishways. The laws of many states require a fish-ladder or fishway to be built at dams. Fig. 38 shows the fish ladder recommended by the U. S. Commission of Fish and Fisheries. The cut shows two pools of the ladder which may be multiplied to surmount any desired height. Each pool is 1½ ft higher than the one below, 4 ft wide, 6½ ft long on one side, and 4½ ft on the other. The opening in the bulkheads between pools should be about one foot square at the lower pool, increasing in size toward the upper level to insure a waterfall over the bulkhead; the amount of increase will depend upon the leakage.

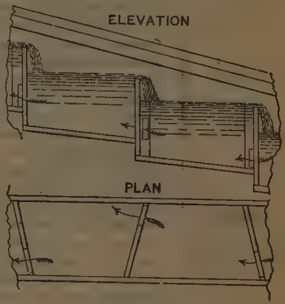

Fig. 38. Fishway

11. Flow Line Masonry Aqueducts

Closed Masonry Aqueducts have been used to convey water from distant sources to great cities for more than 2000 years. The first Roman aqueduct was built in the year 312 B.C. Altho inverted siphons were known to the ancients, the materials available for their construction, principally lead and earthenware, were not such as to admit of great success. Consequently, the first great aqueducts were built of masonry, either stone or concrete, on side hills, following nearly the contour of the ground, in tunnels, where it became necessary to pierce sudden rises, and on masonry arches over depressions, where it was impossible to follow the ruling gradient on the ground surface. Most of the flow line aqueducts constructed since 1900 have been of concrete of horseshoe shape built in open cut and back-filled. Where the detour would be too great to carry the flow line around valleys, inverted siphons of steel pipe or pressure tunnels are introduced. In some cases for short distances the flow line with the horseshoe cross section has been carried across depressions on filled ground Masonry aqueducts constructed on embankments require great care in securing an unyielding foundation, since even a slight settlement may cause cracks and leaks A crack below the water-line may erode the embankment materials and possibly give rise to destruction of a portion of the masonry with serious consequences A small quantity of steel reinforcement in the invert of concrete sections on embankment will increase the ability of the structure to resist the ill-effects of slight settlement where the construction of the embankment type cannot reasonably be avoided. Elevated crossings of valleys and streams are seldom resorted to. The Assabet Bridge 359 ft long on the Wachusett Aqueduct completed in 1898, is the most notable case of a recent bridge crossing. The horse-shoe shape is best adapted to resisting the pressure from the back-fill and to ease of construction, cleaning and maintenance and at the same time has fairly good hydraulic properties.

Contraction Joints. The practise in flow-line conduit construction is to place the concrete continuously in sections with a contraction joint, designed to prevent leakage between sections. The Catskill Aqueduct developed transverse cracks in some cases in those sections where the contraction joints were 75 ft

apart, but none in sections which were 60 ft or less in length. Two types of contraction joints were tried indicated by *A* and *B* in Fig. 39. Type *C* has been tried elsewhere with indifferent success, because of the construction difficulties of properly placing in the masonry of the curved sidewalls the thin bent strips of non-corrosive metal In the Catskill Aqueduct, type *A* was found unsatisfactory because of the practical difficulty of making the tongues and grooves sufficiently exact for sliding, the tongues breaking off in some cases. Type *B*, a steel plate coated with asphaltum, gave in general good results, although the concrete was cracked by the plate in pulling in a relatively small number of joints, due to improper placing of the plate or to other defects of construction. However, all of the joints, of whatever type of construction and condition, were stopped when open the maximum amount at the lower masonry temperatures in the cold season Several kinds of caulking materials were used with more or less satisfactory results, but the most successful treatment was the complete filling of the joint with Portland cement grout. Tests made subsequent to the grouting indicated that the outward leakage from the whole length of aqueduct, when carrying the maximum quantity, would not exceed one-quarter of one per cent of the capacity. For lesser quantities and aqueduct depths the leakage will, of course, be less, and moreover it has been the experience with this aqueduct, as well as with similar structures elsewhere, that the masonry tightens in service with consequent reduction in leakage.

* Sections given are typical.

Flow-line Masonry Aqueducts.

Numbers in parentheses in the table on page 1322 refer to Fig. 40 and to the accompanying notes.

(1) Lining is brick thruout.

(2) Lining is brick and rubble. Cost per lin ft, \$23.90.

(3) Lining is concrete with brick-lined invert. 2 miles in tunnels, 6.9 miles in cut and cover or embankment, and last three miles in open channel. Cost per lin ft \$22.90.

(4) Lining is concrete with brick-lined invert. 9.14 miles are in cut and cover or embankment, 1.02 miles are in open channel, 2.30 miles are in tunnel and 0.98 mile is in cast-iron pipe siphons. Cost per lin ft \$32.60.

(5) Arch and invert are brick, walls and backing rubble. Invert on concrete cradle.

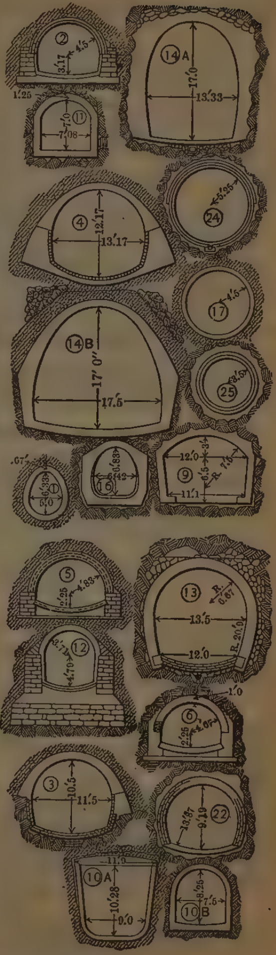
(6) Arch and invert are brick, walls and backing are rubble. Invert placed on concrete cradle. Average depth of cutting 16 ft. Maximum depth of cutting 23.9 ft.

(7) Lining is blue brick. About 11½ miles are in tunnel 25 miles in cut and cover and the remainder in cast-iron pipe siphons.

(8) Part of aqueduct was lined with masonry. About 10 miles are in open channel, 12 miles in tunnel and 4 miles in siphons.

(9) Lining is concrete. 1.42 miles are in cut and cover or on embankment, 18.97 miles in tunnel and 3.10 miles in siphons.

(10) 164 tunnels with combined length of 42.7



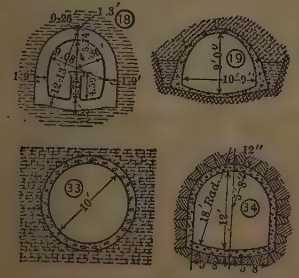


Fig. 40. Flow Line Aqueducts.

miles, not including 9 2 miles of power tunnel. Open unlined canals 21.1 miles Open lined canals 39 56 miles, concrete covered conduit 97.72 miles Siphons, steel and concrete 12.06 miles.

(11) The lining in tunnel and in cut and cover is concrete. 36 75 miles are in cut and cover, 14.12 miles in tunnel and 45.01 miles are in 40-in cast-iron siphons. Cost of whole work per lin ft $42 00

(12) 37 1 miles are in cut and cover or on embankment, the lining being brick backed with rubble, 0 8 mile is in 4-36 in cast-iron pipes, and 0.3 mile is in pipes carried on High Bridge over the Harlem River. Average cost was about $59.00 per lin ft.

(13) Lining is brick backed with rubble. 29 75 miles are in tunnel of which 7.17 miles are siphons, 1.12 miles are in cut and cover and the last 2.38 miles are in cast-iron pipe. Cost about $112.00 per lin ft.

(14) Lining is concrete even in siphons. 54 miles of flow line sections, 14*A* and 14*B* in cut, and cover at grade of 21 ft per thousand. 0 5 mile is in embankment, 13 9 miles are in grade tunnel, 35 miles in pressure tunnel and 6 3 miles in siphons.

(15) Concrete. 1.42 miles are in tunnel and 0.8 mile is in cut and cover.

(16) Concrete is used quite generally. 44 miles are in tunnels, the longest being 17 630 ft; there are also several iron pipe siphons, the longest of which is 6 miles, and a masonry arch bridge carrying a concrete aqueduct.

(17) Lining is brick and rubble masonry. 9.51 miles are in cut and cover or on embankment and 1 49 miles are in tunnel.

(18) Concrete. 99 tunnels of an aggregate length of 60 miles, the longest being 12 miles. 85 bridges.

(19) Concrete conduit in cut and cover or on embankment. Part on pile foundation. River crossing made by reinforced concrete siphons. Supply line from reservoir to city, a 5 ft 6 in diameter reinforced concrete pipe 10 miles in length.

12. Siphon and Pressure Tunnels

Data regarding siphons and pressure tunnels are given below, the numbers in parentheses referring to the notes and to Fig 40 The first pressure tunnel

* Section shown for Rondout typical for all pressure tunnels on the Catskill system.

of note was the Harlem River crossing on the New Croton Aqueduct, and this was lined with brick.

(20) Water Supply, N. Y. City. Rock tunnel lined with brick, backed by rubble masonry. The face of the brick lining was washed with three coats of neat cement mortar.

(21) Milwaukee Water Works, Wisconsin. Hard clay and water-bearing sand and gravel. Compressed air used. No timbering used in hard clay. Progress averaged 6¾ ft per day in clay. Drills and explosives used in hard clay. Circular section lined with 4 rings of brick.

(22) Water Supply. Rock tunnel lined with brick backed by rubble. Length of 500 ft is iron lined. Average cover is 150 ft.

(23) Water Supply, Jersey City, N. J. Steel plate pipe $^5/_{16}$ in to $^7/_{16}$ in thick except at crossing of Hackensack and Passaic Rivers where the thickness is $^{11}/_{16}$ in.

(24) Water Supply. Rock tunnel lined with 13½ in of brick in the rock and 9 in in the invert, backed with a minimum of 6 in of concrete. The maximum cover is 115 ft.

(25) Water Supply, Cincinnati. Rock tunnel lined with two rings of brick backed by a minimum of 6 in of concrete. Average cover over tunnel is 130 ft.

(26) Water Supply. Rock tunnel, concrete lined 1 to 2 ft thick. Extends 6000 ft under Lake Erie, inside dimensions 12 by 11 ft 3 in. Land tunnel 4300 ft long inside dimensions 9 by 8 ft.

(27) Rock tunnel driven from 8 shafts by top heading and bench method, known as American method. Maximum progress (full section) 488½ ft per month. Four 3¼ in Ingersoll-Rand drills on 2 vertical columns and 2 on bench. 22 holes, 8 to 12 ft deep per round in heading. 175 to 200 lbs of 60% dynamite per round. Concrete lining 1 : 2 : 4, 15 to 17 in thick. Steel forms. Approximate cost to city per lin ft based on contract prices: Tunnel \$180, shaft \$285 in rock and \$350 in earth. Minimum rock cover 180. Maximum depth 710 ft.

(28) Rock tunnel driven from 6 shafts in Hudson River shale, by American method. 4 air drills in heading and 2 on bench. 22 to 24 holes per round. Muck hauled by mules and electric locomotives. Maximum monthly advance one face 523 ft. Ventilation by blowers. Concrete lining 15 to 17 in thick.

(29) Tunnel in shale and granite. 7 shafts Concrete lining 13 to 15 in thick.

(30) Tunnel in sound granite, 1100 ft below surface of river. Hydraulic gradient 400 ft above river. Shaft at either end. Concrete lining 13 to 15 in thick. Water bearing fissure sealed by building concrete bulkhead 8 ft thick heavily reinforced with rails and grout, under pressures up to 1060 lbs per sq in forced through pipes set in bulkhead and leading to fissures.

(31) Tunnel in gneiss, driven from 4 shafts. Concrete lining 15 to 17 in thick.

(32) Tunnel under New York City in gneiss, schist and limestone from 200 to 750 ft below surface. Driven from 25 shafts by American method. Electrically operated machinery generally used. Ventilation by blowers. Cost of excavation per lin ft tunnel based on contract prices varied from \$86 for 11 ft diameter tunnel to \$90 per 15 ft diameter tunnel. Lining 11 to 19 in thick of 1 : 1½ : 3 concrete. Cost of lining based on bid prices varied from \$51 for 11 ft diameter tunnel to \$52 for 15 ft diameter.

(33) Waterworks tunnel in stiff clay under Lake Erie, driven by hydraulic shield. Excavation for about half the length of tunnel done by Rotary cutting machine which was abandoned and rest of work done by hand. Maximum monthly advance 886 ft. Considerable trouble with inflammable gas. Tunnel lined with concrete blocks 11 in thick radially by 18 in wide, six segment blocks and keys to the ring, blocks weighing 1200 lbs each.

(34) Water works tunnel in rock, 3 miles under Lake Michigan and 5 miles under Wilson Avenue, Chicago. 4 shafts. The top heading and bench method and bottom heading method were tried and the former proved more economical. Maximum monthly progress one heading 630 ft Excavated rock crushed and screened and made into concrete, mixed in the tunnel and placed by pneumatic process back of steel forms. Tunnel of horseshoe section; 5883 lin ft of lake tunnel, 12 ft 3 in wide and 13 ft high. Rest, 11 ft 4 in wide and 12 ft high. Lining 12 in thick. Cost per lin ft. \$61.48 done by city force account.

There are several cast-iron siphons not included in the above. The aqueduct for the Liverpool and Manchester Water Supply have siphons consisting of from three to five 39 in and 42 in cast-iron pipes laid side by side under heads of 300 to 480 ft. The new Croton aqueduct passes under the 125th Street valley in 8 cast-iron pipes 48 in in diameter

laid side by side. The Catskill aqueduct crossing under the Narrows is a 36 in diameter cast-iron pipe.

13. Reinforced Concrete Conduits

Data regarding reinforced concrete conduits are given below, the numbers in parentheses referring to the following notes and to Fig. 41. In the Salt Lake City conduit the joints at the end of the sections were thoroly grouted in the coldest weather and the concrete was thus thrown into compression, effectually cutting off leakage. In the Jersey City aqueduct fine cracks appeared at the joints, but the leakage was not serious, and eventually they silted up. The Cottonwood and Pinto pressure pipes were built without any provision being made for expansion joints, the ends of section being left rough for the purpose of affording a good bond with the next day's work. Numerous cracks developed which were from time to time repaired, with the result that, one year after their completion, test showed no leakage in the two Cottonwood pipes; in the north Pinto pipe a leakage of 0.002 sec ft, and in the south Pinto pipe 0.03 sec ft, all tests being made under maximum head.

(1) Hydro-electric plant. Hoops and longitudinal rods forming a 4-in mesh used fo[r] reinforcement. Maximum head sustained 65.6 ft.

(2) Power pipe lines. This is a double line siphon with a maximum internal head of 75 ft and an external head not exceeding 10 ft. Reinforced with ⅝-in steel hoops spaced 3 in c to c and 10 longitudinal rods.

(3) Pressure Pipe. In a trench 4 ft wide and back-filled with a minimum cover of 30 in. Used for siphons up to a head of 105 ft. Reinforced with hoops of No. 5 steel wire spaced 12 in c to c. 7 tunnels on the line aggregate in length 1500 ft. Pipes were cast in lengths of 2 ft before being placed in trench.

(4) Flow-line water supply aqueduct. Reinforced with transverse ⅝-in twisted steel rods 12 in c to c and longitudinal ¼-in twisted steel rods 24 in c to c. Portion of the 22.99 miles of aqueduct from Boonton to Jersey City.

(5) By-pass on Catskill Aqueduct at Kensico reservoir. Maximum depth of invert below flow line of reservoir in which by-pass is located is about 53 ft.

(6) Flow-line water supply aqueduct. The reinforcement is expanded metal. Conduit entirely built in cut and cover.

(7) In Cedar Grove Reservoir. Maximum head inside 50 ft and outside 50 ft depending on whether pipe or reservoir is empty. Reinforcement is No. 10 gage expanded metal with three-inch mesh and joints lapt. 4000 ft are single conduit and 1500 ft are double conduit.

(8) Power pipe lines. Double-line siphon with maximum internal head of 31 ft and external head not exceeding 10 ft. Reinforcement is ⅝-in steel hoops placed 6 in c to c and 6 longitudinal rods.

(9) Big Cottonwood Water Supply, flow-line aqueduct. Part of conduit was built in cut and cover, part in fill and part in tunnel. The reinforcement is twisted steel bars ⅝-in to ½-in in diameter, space 6 in to 9 in c to c. Cost was about $9.80 per lin ft.

(10) Consist of a steel tube 0.118 in thick, embedded between an inner mortar coat 0.9 in thick, plastered on wire mesh, and an outer concrete shell 5.9 in thick reinforced by hoops of T iron, all in shallow trench, maximum head 85 ft.

(11) A siphon on the Umatilla irrigation system. The maximum head is 55 ft. The reinforcement is a coil of 5/16-in wire.

(12) Same irrigation system as Sosa and Ribabona. Maximum pressure head 97 ft. Shell of pipe 7.28 in of concrete faced with 0.59 in cement mortar. Reinforcement 124 longitudinal round bars 4 in apart and circumferential T bars. Concrete, 1 Portland cement: 1.28 sand: 2.56 gravel under 1¼ in and 0.58 to 1.00 part of water, all by volume. Lining 1 cement: 1 sand. Seepage loss under full head 0.14 sec ft.

14. Wooden Stave Pipe

Stave Pipe is much used in Western United States on account of the cheapness of lumber and the high cost of steel and cement. It is built in place by assembling the staves for the lower half in a cradle, after which a pipe ring is set inside and the staves for the upper half assembled on it. The staves all break joints with those adjoining and are "driven home" on the end. Bands are placed but not finally tightened until the wood is thoroly saturated. Junctions are made by cutting the last staves a little long and springing them into place.

The Staves vary between 1¼ in and 2½ in in thickness and 6 to 8 in in width and are uniform thruout the length of the pipe, the variation of head being met by variation in spacing of bands. The staves are shaped to true cylindrical surfaces on the inside and to true radial lines on edges. The outside is usually curved, but sometimes flat. A very shallow bead left on the edges crushes and results in greater water-tightness. Thin steel tongues let into the ends of the staves make tight joints and insure a smooth interior surface. The timbers most used are California redwood, Oregon and Washington fir, yellow pine and several kinds of spruces. The timber should be clear, somewhat seasoned and protected from warping.

Bands are from ⅜ in to ¾ in in diameter. They are proportioned for the initial tension on erection, plus the stress from water pressure plus the stress from swelling wood. It is generally agreed that a pressure sufficient to keep

Name and location	Dia. ins	Total length of pipe line, miles	Length of wood stave pipe, miles	Capacity, cu ft per sec	Thickness of staves, ins	Diam. of bands, ins	Band spacing, ins	Max. head ft

(1) 1895. Water Supply and Power. Oregon yellow fir. Stave pipe cost city 90 ce per lin ft. Grade 5.03 ft per 1000 ft. Leakage 0.099 sec ft. At end of 10 years 1 of all staves were replaced and 5½% of the line was reconstructed.

(2) 1892. Redwood. After 14 years service was in very good condition; up to t time no staves were ever replaced on account of rot.

(3) 1896. Redwood.

(4) Water Supply. Mostly fir used, some cedar. Average spacing of bands 3¾ in

(5) Beaver Creek, Pueblo. Redwood. One tunnel on line 1533 ft long.

(6) 1890. Texas pine. Cost of stave pipe, including erecting, $1.365 per lin ft. Tren ing and back filling $0.483 additional.

(7) Little Conemaugh River Water Supply. Washington fir. Average cost of wh line $2.60 per lin ft exclusive of trench and supports. Grade 1 to 2 per 1000.

(8) 1903. Water Supply. Washington fir. Grade 0.16 ft per 1000 ft. Cost $ per lin ft. (9) See note under (7). (10) See note under (7). (11) 1893. Redwood

(12) Santa Ana Canal. Cost of pipe $6.20 per lin ft. Cost complete $11.39 per li

(13) Santa Ana Canal. Cost of pipe $7.46 per lin ft. Cost complete $10.04 per li

(14) Santa Ana Canal. Cost of pipe $4.06 per lin ft. Cost complete $6.51 per li

(15) 1897. Pioneer Power Plant. Douglas fir. Pipe is laid in trench 8.5 ft and covered to a depth of 3 ft on top.

(16) 1874. Power Development. Southern pitch pine. Grade 43.33 ft per 100 Said to be the first wood stave pipe.

(17) Cascade Tunnel Power Plant. 1909. Washington fir. Mostly in rock trenc

(18) 1898. Power for paper mill. Redwood. Mainly laid above ground; bo portion on earth and stone spalls. After 8 years service there was no evidence of r

(19) No. 2 plant of the Madison River Power Co., Norris, Mont. 120-in pipe fini 1906, 144-in pipe finished 1908. Redwood. (20) See note under (19).

the wood saturated, or nearly so, prolongs the life of the staves, and contact with earth charged with decaying vegetable matter and crushin the exterior surface of the wood in adjusting bands shortens it. Examinat of pipes which have been in use for a number of years show that the int surfaces wear smoother and do not become fouled.

15. Flumes

Flumes are used where excavation for a canal is difficult, as on steep hill-sides, where the soil is so loose that an unlined canal is impossible, or where the canals cross rivers or deep depressions and the use of siphons is undesirable. Since much higher velocities can be used than in canals, and the frictional resistance is less, it is possible to use a much smaller area of cross-section. Concrete, iron and wood are the principal materials employed

Reinforced Concrete Flumes of varied design are used by the U. S. Reclamation Service on its irrigation projects. No. 1, Fig. 42 shows the type con-

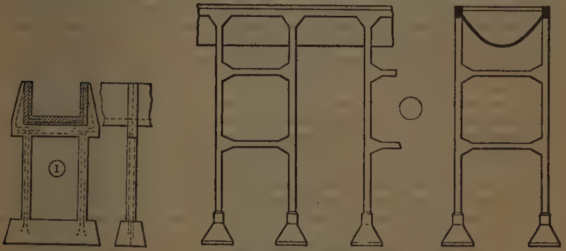

Fig. 42. Reinforced Concrete Flumes

structed in 1908. This design is more or less standard for flumes up to 72 sq ft section, the spans between bents varying from 14 to 30 ft. No. 2, Fig. 42 shows the Brooks Aqueduct, Alberta, consisting of a curved shell of reinforced concrete suspended between two girders on a reinforced concrete trestle, bents 20 ft c to c.

Wooden Flumes are most numerous on account of smaller first cost, tho they have short life. Fig 43 shows 2 by 3 ft wooden flume on trestle. The bents are 15 ft between centers, 4 in by 4 in up to 7 ft high and 6 in by 6 in up to 12 ft high. The stringers are 4 in by 10 in by 16 ft long. The sides and bottom are 2 in by 12 in with ⅝ in by 1 in splines set in edges and quarter round molding nailed in corners; the sides are spiked to the bottom by 20d nails 1 ft

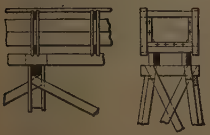

Fig. 43. Wooden Flume

Fig. 44.

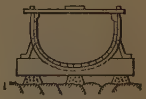

Fig. 45. Wooden Stave Flume

centers; the yoke frames are spaced 4 ft centers. Fig. 44 is a cross-section of the San Diego flume, Cal. Fig. 45 shows the wood stave flume. The greatest difficulty in construction is encountered in making the junction between the flume and the natural earth bed of the canal, since this joint must be absolutely watertight.

(1) Bear River Canal, Utah. Plate girder bridge of three spans, viz., 60 ft, 45 ft, and 25 ft. Flooring between lower flanges carries canal.

(2) Washington. Temporary flume for water supply used in hydraulic fill dam in 1909. Material used was timber.

(3) Sides and bottom are redwood. Carried on trestle. Frames spaced 4 ft c to c.

(4) Canal in Spain. Steel bridge aqueduct formed by 2 box girders with iron floor between, attached to lower flanges. 62 ft clear span.

(5) Canal. Reinforced concrete bridge on concrete piers. Framework of floor reinforcement is 19 longitudinal I beams 20 in deep and 34 ft 11 in long laid abreast. Side wall reinforcement is 2 I beams 20 in deep, 6 ft apart vertically and trussed.

(6) Kern River Power Plant, Los Angeles. Redwood, seams beveled and calked on sides and flushed with asphalt on the bottom. 1 in by 6 in battens used. Carried on concrete foundations.

(7) Aqueduct of the Lower Ganges Canal. Masonry bridge of 15 spans 60 ft clear.

(8) Canal crossing Spring Canyon. Bridge carried on three arches of reinforced concrete. Walls are reinforced with ¾-in to 1-in steel rods 6 in c to c in 2 rows. Floor reinforcement is 1-in steel rods 6 in c to c.

(9) Platte or Highline Canal. Timber.

(10) Platte or Highline Canal crossing Plum Creek.

(11) Colorado. Timber with joints calked with oakum. Constructed on rock bench.

(12) Colorado. Timber with joints calked with oakum. Constructed on trestle.

(13) New Mexico. Irrigation canal built in 1903. Concrete reinforced with T iron spaced 4 ft c to c. Supported on four concrete arches of 100 ft clear span and 25 ft rise.

(14) Power canal in Washington built in 1903. Timber, carried on trestle from 6 to 80 ft high. The maximum curve is 70° and the total curvature is 10 280°.

(15) Redwood. Carried on timber stringers and mudsills.

(16) Wooden Stave. Redwood. Held by T irons 2¼ in by 2¼ in 4 lbs per lin ft spaced 8 ft c to c and 2 intermediate ⅝ in steel binders. Supported on timber cradles and concrete piers.

(17) Washington. Semicircular reinforced concrete. Transverse reinforcement ⅝-in steel rods 4 in c to c, longitudinal 18 steel rods ¼ in in diameter 12 in c to c. Carried on reinforced concrete trestles.

CANALS

16. Navigation Canals

Canal Prisms (Fig. 46). The cross-section varies with the material past thru, the value of adjacent property, and the facilities to be given to traffic. In earth the side slopes are usually from 2 : 1 to 3 : 1 but there are many examples of steeper and flatter slopes. The Erie and Manchester canals have in places side slopes of 1 : 1, but these are protected by paving for the full height, and have failed in some cases. In cities it has often been found economical, as in the case of the Erie canal, to provide vertical side walls. In rock the sides are usually made vertical, or nearly so. The recent use of channeling machines has facilitated the formation of smooth vertical sides, with great benefit to vessels. Clearance between the keel of the vessel and the bottom of the canal varies with the form and area of cross-section of the vessel, the width of the channel and the speed desired, as the following table shows:

Canal	Depth, ft	Depth, in	Haulage	Speed, miles per hour	Clearance, ft	Clearance, in	Authority
Erie (enlarged)	7	0	Horse	1.67	1	0	N. Y. S. Eng., 1877
Upper Escaut, St. Quentin, Lateral Oise	7	2½	Horse	1.67	1	3½	Lindley
Dortmund & Ems, Ger	8	2½	Tug	3.10	1	7½	Herman
Merwede, Holland	10	0	Tug	4.66	1	6	Int. Engr. Congress
Brussels to Rupel, Belgium	10	6	Tug	3.73	0	4	
Ghent-Terneuzen, Holland	20	8	Steam	5.40	1	5	Int. Engr. Congress
Amsterdam (before last enlargement)	28	3	Steam	5.59	2	0	Int. Engr. Congress
Suez (before last enlargement)	31	1	Steam	6.20	4	1	Panama Report, 1906

The width of the canal should be at least sufficient to permit two boats meeting to pass each other, but on account of the rapidly increasing resistance to the movement of a boat as the cross-section of the canal diminishes, the width of boat canals is generally greater, so that the area of the wet cross-section may be three to five times the area of the cross-section of the boat. On the New York State Barge Canal, the ratio is designed to vary from 4.76 in earth sections to 4.51 in rock sections.

Level Sections are required for a navigation canal, since strong currents are inadmissible. Difference of level between adjacent sections is overcome by locks, inclines or mechanical lifts. Inclines or high mechanical lifts are suitable only in the exceptional cases where the slope of the valley is very steep or where they can be so located as to concentrate a large descent within a short distance. They effect a saving of water as compared with locks. Locks are usually best adapted to meet topographical conditions; in general, lifts of locks vary from 5 or 6 ft to 15 or 20 ft, but some have less than 5 ft and a few have been built with lifts of from 25 ft to 30 ft and upwards. Larger lifts require more water for lockage, reduce the time required by a boat to overcome a given elevation but tend to reduce the ultimate traffic capacity of the canal. Locks are used in most places where an incline or high mechanical lift would be practicable. If the slope of the ground is not too steep, sections of canal are placed between adjacent locks which enables some saving of water to be effected; where the topography does not permit these

Widening Prism on Curves. It has not been usual in the United States to increase the width of canals on curves. In the plans of the New York Barge Canal no increase in width was proposed for curves of 5° or less; for 6° the widening proposed was 5 ft. On the Canal du Centre in Belgium the widening was $400/R$ in meters, R being the radius of the curve. At the International Congress for Inland Navigation held at Vienna in 1886, a rule was adopted that the amount of widening should be twice the versed sine of the arc whose chord is equal to the length of the largest boat traversing the canal. This was adopted for the Dortmund and Ems Canal, the length of the boat being taken at 220 ft.

On the Ship Canal from Ghent to Terneuzen, the widening on curves was determined by the formula $4\,(R-\sqrt{R^2-200^2})$ in feet, R being the radius of the curve. On the Kiel Canal, the widening was determined by the formula $26-0.01\,R$ in meters, or $85.3-0.01\,R$ in feet. On the Kiel Canal it has been found by experience that "it is not so much a large radius that is required as a proper widening of the cross-section." This view is abundantly confirmed in the United States as regards vessels moving under steam power.

Protection of Side Slopes (Fig. 47). In earth some form of protection is usually advisable, particularly in sandy soils, to protect the slopes against wave action caused by passing boats. The extent required depends upon the character of the traffic. At the Dortmund and Ems Canal, traversed by boats drawing 6′7″ at a speed of 3.1 miles per hour, it has been found sufficient to extend the protection 2 ft under water; one of the several forms used is shown in Fig. 47. On the New York Barge Canal, the protection is extended 2′6″ or more under water. In larger canals, traversed by large ships and at higher speed, the protection is usually extended 5 to 8 feet under water, and terminated at its lower edge on a berm. Of the three figures relating to the Kiel Canal, the last one is designed for use when the canal is filled with water, and the stones cannot be laid with regularity below water level without unwarranted expense. In some cases the protection has been designed to serve the further purpose of maintaining the bank at a steeper slope than it would otherwise sustain, as in the standard section of the Erie Canal and at places in the Manchester Canal. This is decidedly objectionable for propellers, as the slope walls are liable to break the wheels and it is better practise in nearly all cases to give the earth below the belt requiring protection from wave action a slope at which it will stand.

When the protection is of stone it usually consists of a paving of rubble masonry or selected stone laid dry with as close joints as practicable in order to prevent washing thru the joints of the paving, the earth is first covered with a layer of gravel or of small broken stone. A cheaper form of revetment has been used successfully at the Soulanges Canal, and has been adopted for the New York Barge Canal where specifications describe it as consisting of three grades of stone; first one-quarter of the whole volume to be quarry waste, stones ranging in size from 9 in to 15 in in longest dimension; second one-quarter of stones from 4 in to 9 in in longest dimension; and, third, one-half of stones from 1 in to 2 in in diameter. The larger stones are bedded on smaller ones and rammed firmly in place; the remainder of the small stones are used to fill voids and form a smooth surface. No flat stones are permitted. On the eastern section of the Illinois and Mississippi (Hennepin) Canal a trench was cut in face of the embankment, extending from 2 ft above normal water level to 1 ft below it, and filled with rubble laid roughly by hand. On other sections no protection was provided until after the canal was put in use and a berm had been formed by wave-wash; stone was then brought in on barges and deposited in the trench thus formed. Bricks have been used in various forms; also concrete blocks and reinforced concrete. Where water seeps into the canal, revetments of masonry or of concrete require to be back-drained by being laid on sand or gravel or by other means.

Control of Leakage from Canal (Fig. 48). Where canals are formed in sandy soil or other permeable material, the loss of water by percolation or seepage may be so great as to endanger the adequacy of the water supply. If the water supplied to the canal carries silt the seepage will become less as the voids in the sand gradually become filled with fine particles of silt carried by the water, or with silt, sawdust or similar material thrown into the water near the points where leakage is greatest; but in such material it is usually advisable to take means to prevent or reduce seepage during the construction of the canal by interposing less permeable material, and where the canal is carried on an embankment this is usually essential to insure the safety of the work. In such a case the canal should have an impermeable lining, which is usually of clay with sand or gravel well puddled or rammed. In order to prevent shrinkage cracks above the water line and in the sides and bottom when the water is drawn out, and also to protect the puddled material from abrasion by boats, the puddle is usually covered by a layer of ordinary soil.

In the canal from the Marne to the Rhine the water-tight layer contained three parts of sand to two parts of clay, the mixture, after spreading, being sprinkled and rammed to

⅗ of its original volume. In the navigable feeder of the Arroux, Canal du Centre, France, the mixture contained 65 to 70% of clay; the material in the bottom was compacted by grooved rollers drawn by horses, and in the slopes was rammed; the material was spread in 4-in layers and reduced in volume 40% by rolling or ramming. In the Dortmund and Ems Canal, where the canal was in embankment, the material of the embankment was principally marl, and the water-tight lining was of the form shown in the figure, the thickness of the puddled material increasing with the height of the embankment. In the Canal du Centre, Belgium, a lining of concrete has been used successfully, protected on the bottom of the canal by a fill of clayey earth. This is suitable only where the bank is of firm material not liable to irregular settlement, and is liable to injury by boats. In the canal from the Marne to the Rhine concrete in banks was also covered with earth.

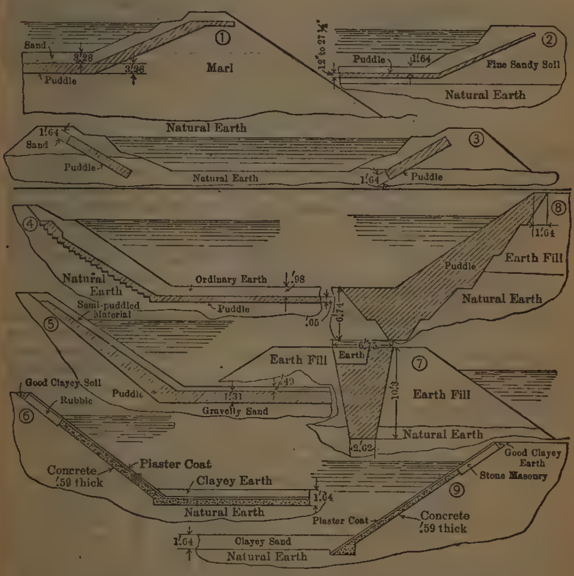

Fig. 48. Methods of Tightening Canal Prisms. (1) (2) (3) Dortmund and Ems. (4) Marne to Rhine. (5) Arroux. (6) (7) (8) (9) Canals du Centre, Belgium.

Where the bottom of the canal is subjected to up-lifting pressure when the canal is laid dry, the water-tight layer is likely to be breached; underdraining is sometimes practicable. The case may arise where the head of the inflowing water is above the bottom of the canal but below the water surface desired; each case of this kind must be studied as it arises. A water-tight lining of the sides and a silt lining of the bottom may be suitable in such a case. Where the bottom of the canal is in excavation and the material sufficiently water-tight, while the sides are embankments, seepage may be prevented by a puddle lining on the slope or by a puddle wall in the middle of the embankment.

When placed on the slope the thickness should be great enough to permit considerabl abrasion by boats without cutting thru it. This is avoided by forming a puddle wall i the middle of the embankment, but the fill on the water side is likely to become saturate and then may contribute little to the stability of the embankment, or may even reduce it Care must be taken to remove all loose or yielding material and to avoid forming a perme able joint between the original ground and the fill.

Drainage of Adjacent Territory. A canal in a river valley is so locate that its banks may be above the highest flood level. Small streams, arti ficial drains, or storm water may be received directly into the canal or pas under it thru culverts (Fig. 49). When circumstances permit, the latter i

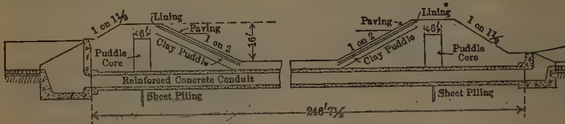

Fig. 49. Dive Culvert, N.Y. Barge Canal

preferable; the principal objections to draining into the canal are the resultin silting, which will involve continual expense, and the variations produce in the water level. Where practicable, water, if silt bearing, should be mac to pass thru a settli basin before entering t canal. If the amount water flowing into t canal is considerable, t resulting current is o jectionable. The surpl water received into t canal is discharged ov WASTE-WEIRS (Fig. 50

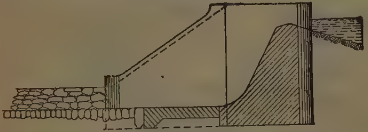

Fig. 50a. Waste-Weir, N. Y. Barge Canal

or thru WASTE-GATES. Where the requisite control can be given by a wei has the advantage of being automatic; but this may at times cause waste, si

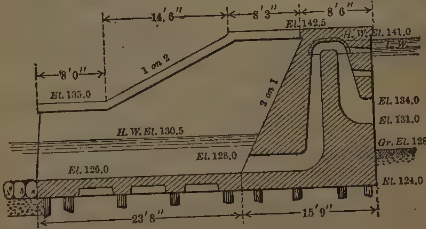

Fig. 50b. Siphon Spillway, N. Y. Barge Canal

a high wind blowing in the direction of the canal, or a succession of b moving in one direction, may cause a rise at one end of a canal level. Waste also result from the difficulty of adjusting the supply to the summit level to

varying demand for lockages; to overflow from short levels; to unequal lift at locks, etc.

In the New York Barge Canal the crests of the waste weirs are at low water elevation. Channels are provided for placing flashboards to raise the crest of the waste weir if required. On this canal a siphon spillway shown by (Fig. 50*b*) has been used.

Waste-gates are usually placed with their sills at canal bottom and are useful for draining the level when desired for repairs.

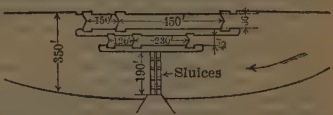

Fig. 51. Irlam Locks, Manchester Ship Canal

At the Manchester Canal, where large amounts are received into the canal at times of floods, each level is controlled by Stoney sluice gates placed in a sluiceway adjacent to and parallel with the locks. The sills are at the same elevation as the sill at the upper end of the locks; the sluice gates are each 30 ft opening, and can be raised about 20 ft. The Irlam sluices (Fig. 51) can discharge 26 000 cu ft per second.

Large streams are usually crossed by aqueducts forming part of the canal, but usually reduced in width to the requirement for a single boat. The superstructure, or "trunk," may be of wood, masonry or iron. The crossing of the Erie Canal over the Mohawk River at Rexford Flats is a good example of a trunk of wood; of the same canal over the Genesee River at Rochester is a good example of a trunk of masonry; both of these structures have been in use for many years. The one at Rexford Flats has been partially removed and the one at Rochester is still in use. The Bridgewater Canal is carried over the Manchester Canal on a swing bridge, the trunk is of wrought iron, has a clear width of 19 ft and a depth below ordinary water surface of 6 ft and a freeboard of 1 ft.

17. Water Required for Operation

Filling the Prism of the Canal. The prism of the canal may be emptied either for repairs or as a result of accident. In dealing with the question of water supply for the proposed New York Barge Canal, E. Kuichling assumed that the prism of the summit level would be laid dry once per year; also, that in addition to the volume of the prism, an equal amount would be required to saturate the adjacent soil to its normal condition, but this additional amount depends on the water-tightness of the wetted contour of the canal prism, and, if this is not well provided for, by the porosity of the adjacent ground. In the case considered by Kuichling it was contemplated to line the canal with clay where formed in permeable ground.

Evaporation and Seepage. For the New York Barge Canal, Kuichling estimated that the evaporation from the water surface would be 0.30 inch per day, to which he added 10% as a liberal provision for consumption by aquatic plants, or a total of 0.33 inch evaporation per day from the surface of the canal.

In the summer of 1900 observations were made to determine the loss by percolation from various sections of the Erie and Champlain canals. In some cases where the canal had been deepened within a short time before the gagings were made the loss was large, running up to 773 cu ft per mile per minute; in other cases, even where percolation thru the banks could be seen, the gagings indicated little loss, and, on the whole, the results were not of great value, but, rejecting the abnormal results, a loss from percolation of 100 to 150 cu ft per mile per minute was indicated.

Kuichling finally estimated that the loss from evaporation and seepage from the Barge Canal would aggregate 4⅓ in in depth per day, equivalent to 169 cu ft per mile per minute, but this was based on the assumption that clay linings would be provided in permeable soil. The thickness of the puddled material was intended to be 3 to 4 ft on the slopes on

embankments and 1½ ft in excavation where the materials were of a nature to permit seepage. The thickness on the bed of the canal was to be 1½ ft in all cases where puddle was deemed necessary. The canal was to be 123 ft wide at the water line, 75 ft at the bottom and 12 ft deep.

G. W. Rafter estimated the probable percolation from the summit level of the proposed deep waterway from the Great Lakes to tidewater at 330 to 440 cu ft per mile per minute. At the divide near Rome, N. Y., the water in the canal would be slightly below the level in the adjacent streams, and about 15 ft above at the ends of the summit level. No puddle lining was intended for the canal.

The excessive loss of 4144 cu ft per mile per minute from the Marne-Saône Canal is said to be due to fissures in the rock in which a section of the canal is excavated. A similar loss, and for the same reason, has been met in the Glens Falls feeder for the Champlain Canal. Such leaks are difficult to close after the water is once admitted to the canal. On the other hand, earth sections of canals become tighter with use. Some of the large losses shown in the table occurred when the canal was new or had been deepened within a short time.

Measurements of Loss of Water from American Canals by Evaporation and Seepage, Including, in Some Cases, Waste at Structures

* For these cases evaporation, seepage, and waste were measured. For the other cases only evaporation and seepage were measured.

Percolation, infiltration or seepage is usually much greater in amount than evaporation. The combined loss from evaporation, seepage and waste is usually measured together by current observations at two or more cross-sections of the canal, and simultaneous measurements made of waste. The loss by evaporation plus seepage is then given by subtraction and usually reported together. Evaporation can be estimated with reasonable correctness and seepage determined within a small range of uncertainty. The table on p. 1338 is condensed from Kuichling's report on Water Supply for New York Barge Canal.

The loss by evaporation, seepage and leakage from the Illinois and Mississippi Canal is stated to be less than 60 cu ft per mile per minute.

In some of the European canals where the water supply is limited, and particularly where the summit level is maintained by pumping from the lower levels, greater expense is incurred to reduce seepage than is usual in the United States. In the Dortmund-Ems Canal the loss by percolation and evaporation amounted to 32 cu ft per mile per minute of which 9 cu ft was estimated to be due to evaporation and 23 cu ft to percolation. This was rather more than had been anticipated but it is expected that it will be reduced by silting. The water-tightness of the prism was of much importance because the water on the upper levels was supplied in large part by pumping. Lindley states that the mean value of the loss by evaporation and percolation is estimated for the whole of France at about 40 cu ft per mile per minute. In a given permeable soil the amount of seepage varies with the width and depth of the canal, but no satisfactory expression of the relation has been advanced.

Leakage at Aqueducts, Culverts and Waste-Gates. The amount of leakage at these structures depends principally upon the care taken in design, construction, maintenance and operation, and can be limited to a small amount. In a report made in 1837 by W. H. Talcott the leakage of waste-weirs and aqueducts on 22 miles of the Chenango Canal (depth 4 ft) was given at 220 cu ft per minute, or 10 cu ft per mile per minute. Kuichling gives an estimate of 1.6 cu ft per mile per minute on certain old canals in France. The losses will obviously depend on the depth of water and may be assumed to vary with the square root of the depth as an approximation. Kuichling estimates for the New York Barge Canal (depth 12 ft) 12 000 cu ft per day for each culvert and waste-gate, and 96 000 cu ft per day for each aqueduct, which appears to correspond approximately with the observations of Talcott, without allowance for increased depth. With modern methods the older class of masonry should be improved upon.

Leakage at Locks. This will be at the valves for filling and emptying the lock and at the lock-gates. Seepage around the locks should be prevented by suitable construction or reduced to a negligible amount. From observations at the Chenango Canal (in 1839) W. H. Talcott estimated leakage at a canal lock of 11 ft lift at 447 cu ft per minute or 643 680 cu ft per day. Kuichling gives an estimate as low as 14 100 cu ft per day on certain small French canals. Measurements of leakage around the filling valves of the Weitzel lock, St. Marys Falls Canal, made by J. Ripley in 1899, gave a coefficient of 0.49 for use in the formula $v = C\sqrt{2gh}$ or $v = 4\sqrt{h}$ nearly. The valves were of the butterfly type, 8 ft by 10 ft, turning about the 10-ft axis. The mean width of opening around the closed valves was about 3/8 in. The valves had been in use about 18 years, and saving of water was not important. This type of valve is wasteful and should not be used where saving of water is important, altho there should be no difficulty in reducing the leakage to 1/2 the amount observed by Ripley; its advantages are in simplicity, low cost of maintenance, and facility of operating. Leakage at the gates results from imperfect fitting; in the case of the ordinary mitering gates, the gates may be too long, in which case one or both (usually one) will not be in contact with the sill when closed, resulting in an opening, approximately triangular, extending from the miter to or toward the quoin; or the gates may be too short

(usually from wear), in which case an opening of similar form will exist between the ends of the gates, extending from the sill upwards.

For the gates of boat canals, maintained in good condition, it will be sufficient to assume an opening between the sill and one gate ½ in wide at the miter and gradually tapering to nothing at the quoin. For ship canals the maximum width of opening may be doubled. While locks are being operated the head on the opening thru which water is being wasted may vary from nothing, when the filling or emptying of the locks begins, to the full lift of the lock when the operation is completed; but as a safe provision, which covers small leaks between the quoins and the gates and elsewhere, the full head is usually taken.

Using the coefficient for leakage at valves found by J. Ripley, and computing the leakage at gates as just indicated, the leakage at the Weitzel lock (60 ft wide at gates, 20 ft lift) is estimated at 72 cu ft per second, but the valves are not close-fitting. The various Commissions of the old and new French Panama Canal Company allowed 35 to 53 cu ft per second for each lock, the lifts being about 30 ft. Kuichling estimated the leakage at locks from the summit level of the Barge Canal at about 23 cu ft per second, the lock at one end having a lift of 20½ ft and the lock at the other end 16 ft. He followed the method above outlined, assuming ¼ in opening around each valve and an opening of 1 in at the miter between the sill and one gate of a pair.

Loss over Waste-Weirs. It is impracticable to adjust the supply of feed water to the varying requirements of traffic; therefore the crest of the wasteway must be fixt at such a height that the canal will always have the required depth of water, or the crest may be provided with flashboards, permitting a temporary surplus of water to be held until wanted, or the water must be wasted. Waste may also result from the action of the wind blowing toward the weir, from a succession of boats moving toward it, etc. It is customary to provide a limited amount of storage by fixing the elevation of the crest of the wasteway somewhat above the level required for traffic, but it is restricted by the cost of the corresponding increase in height of the canal banks lock walls, etc. In general, the best form of wasteway for ordinary conditions is a simple overflow weir, because its action is automatic; its length mus be fixt with reference to the allowable rise of water in the canal.

Data regarding existing or projected canals vary greatly. For the eight waste-weir on a 22-mile level of the Chenango Canal W. H. Talcott observed (in 1839) a wast of 96 cu ft per minute; for the proposed deep waterway from the Great Lakes to tidewater G. W. Rafter estimated the waste for the summit level at 150 to 200 cu ft per second = 9 000 to 12 000 cu ft per minute, but his large estimate resulted from the provision of waste-weir long enough to pass the floods of the Mohawk which was to be taken into th summit level. For the summit level of the New York Barge Canal, Kuichling assume a waste-weir long enough to control the water level within about 5 in with a water suppl sufficient for normal amount of lockages flowing in but with no lockages, and estimate the discharge over the waste-weir from this and other minor causes of waste to averag 46 cu ft per second (400 000 cu ft per day) from each end of the summit level.

Power for Operating Locks. This is usually developed by water fro the higher level. Power may be required for (A) opening and closin valves; and (B) hauling boats into or out of the lock. (A) For opening an closing of gates and valves, occupying only a small part of the time, accumu lators may be employed. At the Dortmund and Ems Canal, where the lock are 28¼ ft wide with 9.84 ft on the sills and maximum lifts of 20⅓ ft, th lock-gates and sluice valves are moved by power; the greatest amount re quired for any single operation is 7.2 H.P. At the Weitzel lock, St. Mar Falls Canal, there are two turbines of 25 H.P. each; one is sufficient to accumu late power as quickly as necessary, the other is a duplication for safet The largest gates are 39 ft high, the lock 60 ft wide at the gates; two valv for filling the lock and two for discharging, each valve 8 ft by 10 ft. The pow

required being given or estimated, the corresponding water consumption can be approximated in any given case. (B) The power required for haulage at the locks of the Erie Canal was given at about 8 H.P., the immersed cross-section of the boats being 17.5 ft × 6 ft = 105 sq ft. For the Barge Canal, and boats of 25 ft × 10 ft = 250 sq ft immersed cross-section, Kuichling proposed 20 H.P. as sufficient, the power to move a boat at a given speed being assumed to vary with the immersed cross-section.

Power Required for Lighting. For the New York State Barge Canal from 10 to 14 arc lights each of 750 c p. have been used. The United States canal at Sault Ste. Marie has 13 lights, each of 1200 nominal c p. (300 actual) for the duplicate locks, and one similar light each 400 ft, approximately, on each side of the canal. The Canadian canal on the opposite side of the St. Marys River has 8 lights, each 1 200 c p. nominal, at the locks, and one similar light on each side of the canal every 300 ft. The length of each of these canals is approximately 1½ miles. The Kiel Canal is lighted by incandescent lights placed opposite each other on the canal banks, spaced on curves at distances $R/15$ between pairs up to a maximum of 820 ft, on tangents.

Practise is not well defined as to the extent of lighting desirable, and the only practicable course is to prepare a plan for lighting believed to be the best suited to the case in hand, from which the amount of water required can be computed. The fall at the locks is usually the most convenient source of power, in which case the amount of water consumed is an element of the quantity to be supplied to the upper level, but in many cases the electric current may be supplied from a distance, between the reservoir and the canal, requiring no additional water; in other cases it may be found economical to buy current.

Under present conditions arc lighting is estimated to require 0.4 H.P. per 1000 c.p. with efficient plant management, and incandescent lighting with carbon filament 4.2 H.P. per 1000 c.p. These are approximations, and for canal illuminations the power should probably be doubled. For the New York State Barge Canal, Kuichling estimated a consumption from the summit level of 21 cu ft of water per second or 6 H.P. for four arc-lights, each of 1000 c.p.

Water Consumed for Lockages. Let Q = area of lock multiplied by lift of lock, D = displacement of vessel, N = number of locks in flight. There are four possible conditions of lockage affecting the consumption of water. Case 1: A boat ascending after another has descended will draw from the upper level, past the upper gate, $V = NQ + D$. Case 2: A boat descending after another has ascended will force into the upper level, past the upper gate, $V = D$, the draft from the upper level being $-D$. Case 3: A boat ascending following another that has ascended, will draw from the upper level, past the upper gate, $V = Q + D$. Case 4: A boat descending following another which has descended will draw from the upper level, past the upper gate, $V = Q - D$. The ascending boats draw from the summit level their displacements, and the descending boats force their displacement back into the summit level. Ordinarily no material error will be introduced if the displacements be assumed equal, therefore D may be eliminated from the formulas which become:

Case 1, $V = NQ$ (boat ascending); Case 2, $V = Q$ (boat descending);
Case 3, $V = Q$ (boat ascending); Case 4, $V = Q$ (boat descending).

If the summit level is reached by a single lock, and the number of boats passing in one direction is equal to the number passing in the opposite direction the minimum consumption of water would be given by alternating ascending and descending boats, cases 1 and 2; in Case 1, N becomes 1, and the two boats of a pair would consume $Q + O = Q$, or an average per boat of ½ Q. If the boats follow each other the average consumption per boat is Q. The actual consumption will be between these extremes ½ Q and Q since it will frequently be impracticable to delay a boat which is awaiting another from the opposite direction.

If the summit level is reached by a flight of two locks, ascending and descending boats alternating require 2 Q for the ascending boat and O for the descending boat, or an average of Q, and the same average amount if the boats follow in the same direction.

For a flight of three locks two boats alternating will require 3 Q or an average for the two of $\frac{3}{2}$ Q, and the average for all lockages will equal or exceed Q. When the number of locks in a flight exceeds two, economy in use of water for lockages results from duplicating the flights of locks, using one flight for up-bound and the other for down-bound boats, the consumption for each boat being Q.

Water for lockages may be economized by the use of side ponds receiving the water discharged from the lock chamber during the earlier part of the process of emptying and returning it to the lock chamber during the earlier part of the operation of filling. At the Dortmund and Ems Canal two pairs of side ponds are used, at different elevations, two ponds at each side of the lock and about 50% of the lockage water is saved.

Pumping is often necessary to supply the higher levels. The average cost of pumping by water power at the French canals may be taken at 60 cents to $2.90 per million gallons delivered into the canal, or 1 to 2 cents per million gallons raised 1 ft high, according to the length of delivery main. The average cost of pumping by steam power at the French canals is $6.82 to $12.18 per million gallons delivered into the canal, or $0.055 to $0.105 per million gallons raised 1 ft high, depending on the distance. The electric pumping plant for supplying Canal de Bourgogne cost $15 600. Annual cost of working and up-keep $400 or $1.75 per million gallons raised 17.3 ft, or $0.10 per million gallons raised 1 ft.

18. Speed of Canal Boats

Where steam power is used the speed is usually limited by regulations. The power required to move a boat increases rapidly as the ratio (wet cross-section of canal) ÷ (wet cross-section of boat) decreases. On boat canals the boats are usually of the largest dimensions permitted by the locks. On ship canals the tendency to uniformity is not well marked, and is affected or controlled by numerous conditions other than lock dimensions. Following are data for various canals:

Canal	Cross-section of canal			Cross-section of boat		Ratio of cross-section	Power	Speed, miles per hour
	Surface width, feet	Bottom width, feet	Depth, feet	Beam, ft in	Draft, ft in			
Erie, Original	40.0	28.0	4.0	13 6	2 6	4.03	Horse	2.00*
				14 6		3.13	2 Horses	2.00*
Erie, Enlarged	70.0	56.5	7.0	17 5	6 5	4.20	2 Horses	2.00*
Erie, Enlarged	......	......	......	17 0	5 6	4.72	Steam	2.54†
Dortmund-Ems	98.5	59.0	8.2	27 0	6 7	3.82	Steam	2.50‡
Dortmund-Ems	98.5	59.0	8.2	27 0	5 9	4.41	Steam	3.10‡
Ghent-Ter. Belg.	183.7	55.8	21.3	......	......	3.92	Steam	6.21§
Ghent-Ter. Hol.	155.0	56.0	20.7	......	......	......	Steam	5.40‡
Suez	......	......	......	......	......	3.10	Steam	6.21‡
Kiel	......	......	......	......	......	......	Steam	9.32‖
Teltow	101.0	66.0	6.6	......	......	......	Electric	2.5–3.1*
Brussels-Rupel	108.0	49.0	10.5	23 9	10 2	3.43	Steam	3.73
Merwede	107.0	66.0	10.2	34 3	8 6	3.06	Steam	4.75‡
Manchester	200.0	120.0	26.0	......	......	4.00	Steam	6.90¶

* Actual average is somewhat less. † By trial. ‡ Permitted by rules.

§ By regulations; actual speeds allowed on tangents 7.4 miles per hour. Average speed on sharp curves 3.7 miles per hour.

‖ Permitted by rules for small vessels. Large ships cannot attain 6.2 miles per hour.

¶ By regulation; enforced for large ships. Small vessels specially licensed to run 9.2 miles, but attain 11.5 to 15 miles per hour.

The New York Barge Canal with a wet cross-section of 1188 sq ft is intended for steam barges having a wet cross-section of 250 sq ft when loaded, giving a ratio of 4.75. In concluding report on the probable speed in such a traffic, E. Sweet expressed the opinion that a higher speed than 3 miles per hour would be "economically inadmissible."

In France the speed limit on canals is considered to be 1.67 miles per hour; traction by horses. On the Northeastern canals where on account of congested traffic a concession for horse traction was instituted in 1875, the contractor is bound to maintain the speed of 1.24 miles per hour for ordinary service and 1.8 miles per hour for accelerated service. Interesting experiments have been made on the French waterways on the tractive force required by various types of boats at various speeds and in various channels. The types of boats were: "Peniche flamande," — box bow and stern, only slightly rounded where the ends join the sides and bottom; "Flute," cut-away bow, rising in a curve from the keel; "Toue," pointed peaked bow and square box stern; "Prussian barge," pointed bow and stern; "Margotat," punt-shaped. The boats were towed in a river of large section (practically an unlimited cross-section) at a uniform speed of 3.35 miles per hour to determine the influence of the form of boat on tractive force required.

Type of boat	Length, feet	Beam, feet	Draft, feet	Coefficient of displacement	Gross tonnage	Traction force in lbs at 3.35 miles per hour: On boat	Per gross ton
Peniche flamande..	126	16.4	5.25	0.99	305	1530	5.03
Flute..............	126	16.4	5.25	0.95	283	785	2.77
Flute..............	126	16.4	4.27	0.95	250	695	2.78
Toue..............	126	16.4	5.25	0.97	299	590	1.97
Prussian barge.....	113	16.4	4.27	0.94	210	410	1.95
Margotat.........	72	16.4	4.27	0.82	116	310	2.67

Another set of experiments was made in various canals with the "flute" at 4.27 ft draft at various speeds. The coefficient of resistance is the factor to be applied to the tractive force required in an unlimited cross-section in order to obtain the tractive force required in the canal named. The ratio of cross-section of channel to cross-section of boat is represented by r.

	Depth, feet	Area, sq ft	r	Coefficient of resistance for speed in miles per hour: 0.56	1.12	1.67	2.23	2.79
Diversion of the Yonne at Joigny..................	8.20	450	6.39	......	......	1.38	......	......
Canal de Bourgogne.......	7.95	320	4.54	......	......	1.98	......	......
Canal de la Curé (Yonne).	6.85	250	3.57	1.92	2.13	2.38	2.75	3.17
Canal de St. Dizier at Vassy	6.80	207	2.94	......	......	3.32	......	......
Canal du Nivernais........	5.60	207	2.94	......	......	3.82	......	......

The resistance at 1.67 miles per hour in the unlimited section was 172 lbs, and in the Diversion of the Yonne at Joigny with $r = 6.39$ it was 238 lb or 38% greater; but with r reduced to 2.94 it increased 232% in one case and 282% in another, the greater resistance being in the shallower canal, a diminution of 1.2 ft in depth or 48% in clearance under the boat, increasing the resistance 15%.

Experiments to determine influence of form of boat and cross-section of canal on cost of transportation were made in 1898 on the Dortmund and Ems Canal, and in 1906 on models in the government experimental tank in Berlin comparing cross-sections of equal area, one with a greater central depth, also cross-sections of different areas, and two forms of boats moving at different speeds with a view of determining the most economical conditions of transport for assumed amounts of traffic. The effects of draft and speed

were found to be similar to those indicated by the French experiments and for the conditions assumed $r = 4.2$ to 5.3, and boats carrying 667 tons one way and $^1/_5$ as much the other way, with mechanical haulage, a speed of 3 1 miles gave economical transport.

19. Locks and Lock Gates

Locks are usually employed to overcome differences of level. In the earlier canals in the United States they were frequently built of wood, but these were soon replaced with stone masonry, the face being cut accurately to true lines and surfaces, and until within the last 20 years practically all canal locks in the United States were of stone masonry. Recently concrete made with Portland cement has come into use. Brick masonry laid in cement or hydraulic lime has been used largely in European canals, either for the entire mass of masonry or for facing, except at quoins and other exposed places, where heavy stone blocks have been built into the brickwork. Bricks for facing are of specially good quality.

In the locks of the Kiel Canal the floors and lower portion of the side walls up to the floor level are of concrete; above the floor the side walls are of brick masonry built with

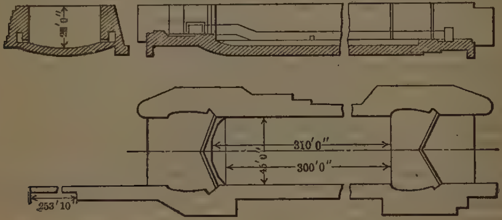

Fig. 52. Barge Canal Lock

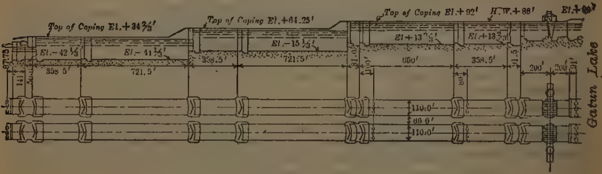

Fig. 53

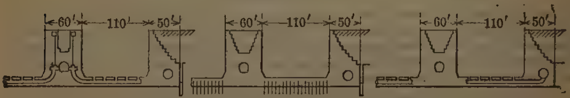

Fig. 54. Gatun Locks, Panama Canal

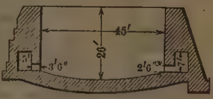
large openings filled with cheap beton of 1 cement to 8 sand. Fender courses, lock-sills, angles of gate recesses, and guide grooves for the pontoon gates are of granite. The locks of the Manchester Canal are of concrete, with brick facing above low-water

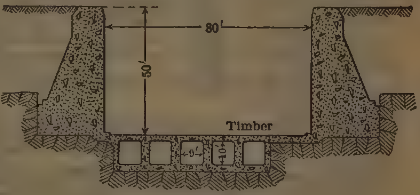
and stone copings, miter sill masonry facing of sandstone, the coping of specially hard quality, but stones in contact with gates (no timber sill) are of granite; brick and stone are used at other exposed places.

The Poe and Weitzel locks at Sault Ste. Marie are of limestone masonry. The new locks are of concrete. Fig. 52 illustrates a lock of the New York Barge Canal. Fig. 53 shows the principal dimensions and Fig. 54 the cross-sections of the Gatun locks of the Panama Canal.

Foundations and Floors of Locks. Where rock foundation is not available, the lock is usually founded on piles, and the entire foundation enclosed within sheet piling and with lines of sheet piling under the sills. In American practise the floors of small locks have usually been built of wood, but with increased width the use of timber is not advantageous. In foreign canals, lock floors are usually of concrete in the form of an inverted arch. The thickness of the floor is usually sufficient to resist the full upward pressure of water when the lock is pumped out, but in some cases weep holes have been formed in the floor to relieve this pressure.



(a) Barge Canal



(b) St. Marys Falls Canal
Fig. 55. Locks of Large Canals

Where founded on rock, the thickness of the floor is more frequently reduced and may be, in great part, omitted if the rock is especially sound and free from fissures, but usually a covering is required, either to protect the rock or to give a smooth surface. In the St. Marys Falls Canal this protection is of timber and concrete; the floors are firmly bolted to the underlying rock. With the increasing price of timber the reduced cost of Portland cement, and the introduction of reinforced concrete, the economy formerly effected by the use of timber is reduced.

Facilities for Filling and Emptying Lock. Small locks are usually filled and discharged thru valves in the gates or thru short culverts around the quoins. This causes the boat to surge, and in large locks this action prevents rapid operation. The large boat canals, and nearly all ship canals, have sluiceways or culverts formed in the side walls of the locks, provided with a valve at each end to open or close connection with either level and with openings leading into the lock chamber near the bottom of the side walls. At the St. Marys Falls Canal, the timber floors have facilitated forming culverts underneath, discharging upward thru many small openings, affording a more uniform distribution of water supply and giving the least possible disturbance to ships.

Valves in gates are usually of the butterfly type turning on a central axis. In culverts or sluices they may be plain slide valves, either of wood or metal, but with large sluices friction makes the operation of such valves difficult or slow. Stoney sluices have been used, for example, at the Manchester Canal. At the St. Marys Falls Canal butterfly valves are used for the 8 ft by 10 ft openings, but are not economical of water. Valves moving on four large wheels have been adopted for the N. Y. Barge Canal (Fig. 62). On this canal one lock at Oswego has no valves for

filling and emptying the lock chamber, it being filled and emptied by means of siphons in the lock wall.

Lock Gates. Mitering gates are in pairs, each of the two "leaves" turning about a vertical axis in a recess in the lock wall. When closed, the two leaves, usually of equal length, meet and support each other about ¼ to 1/5 the width of the lock from a straight line connecting the two axes of rotation. In earlier practise, and particularly in small locks, the gates were made of timber, but steel is coming into more general use; at the Manchester canal, as well as the Liverpool docks, greenheart timber is still used for openings up to 80 ft or more in width, and the engineers claim for it much longer life than for metal gates.

Timber gates (Fig. 56) consist of horizontal girders usually framed into strong end verticals called, respectively, "quoin post" or "heel post" and "miter post" or "toe post"; the gates are planked on the upstream face, where necessary for water-tightness. On the Canadian canals the miter and quoin post and planking are omitted and the gates built solid.

Steel gates (Fig. 57) have a strong vertical girder at each end which is usually furnished with a timber-bearing face. The intermediate framing may consist of horizontal girders carrying stresses directly from the miter to the quoin, or of a heavy girder top and bottom to which the vertical girders carry the water-pressure loads. The upstream or both faces are covered with continuous plating, and in cases of heavy gates an air-tight chamber is formed to facilitate moving the gate.

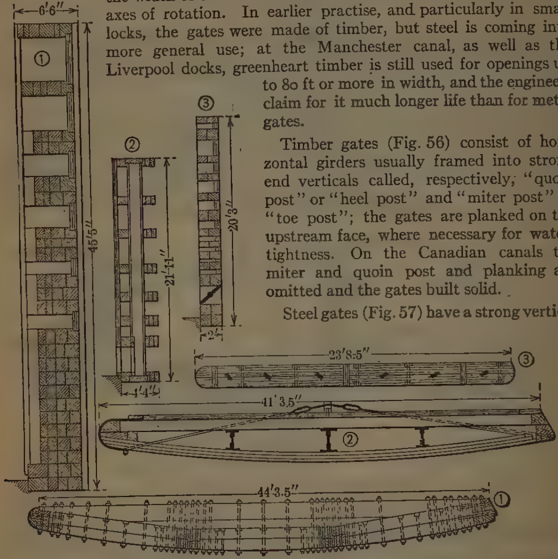


Fig. 56. Wooden Lock Gates
(1) Manchester (2) Kampsville (3) Kanawha

Fig. 58 shows one leaf of a gate for the New York Barge Canal. The gate is supported by a pivot under the quoin post and a steel strap or other device at the top strongly anchored to the side wall of the lock. In the United States and Canada, and in some foreign canals, these arrangements suffice to support the gates in position. In English practise, a heavy gate is usually supported on a roller at the miter end, which moves along a path laid in the lock floor.

Many forms of single-leaf gates are in use. On the Erie Canal the gate at the head of the lock is frequently of the form called "tumble" gate, which turns about the lower edge, falling upstream when opening and lying flat on the bottom of the lock, boats

passing over it (Fig. 59). The span (width of lock) is 18 ft and the depth of water 7 ft. Similar gates are in use at the head of locks on the Oder and Spree Canal, where the span is 29.52 ft and depth of water 8.2 ft. These gates are of wood.

On boat canals, where a limited overhead clearance is admissible, gates lifting vertically have been used, as in the recently built Teltow Canal. A lifting gate on the Coevorder Canal, Holland, has a length of 21.3 ft and a height of 5.6 ft, is of metal, and lifts vertically high enough for boats to pass under. On this canal one lock with a lift of 40.5 ft has a vertical lift gate at the lower end of the lock. Gates turning about a vertical axis at one end and closing the entire width of the lock are in use in some European canals. Following are examples: In the diversion of the Scarpe around Douai the single-leaf gates at the foot of the locks are 21.8 ft

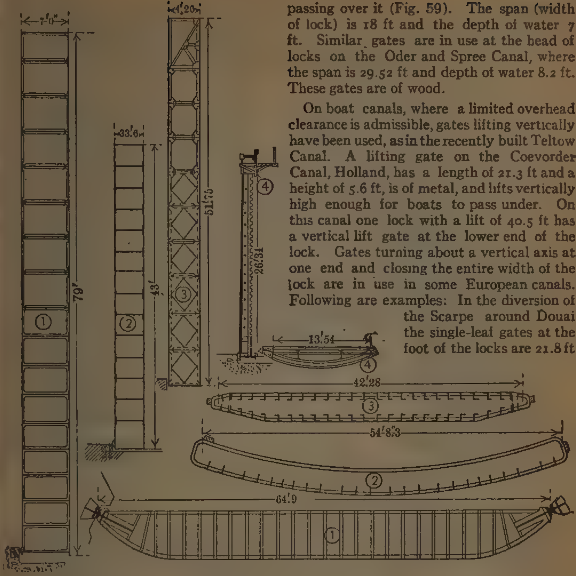

Fig. 57. Steel Lock Gates
(1) Panama (2) Poe (3) Kiel (4) Spree

long and 25.2 ft high; those at the head of the locks are 21.6 ft long and 11.7 ft high; the depth of water over the sills is 8.2 ft and the lift of the lock 13.4 ft; gates are of iron with wood sheathing and contact pieces. At Lichmis on the Dedemsvaart Canal, Holland, single-leaf gates at the head of the lock span 19.7 ft; depth of water on sill 6.6 ft; height of gate 7.3 ft; built of iron. At the Canal St. Denis a single-leaf gate is used at the foot of a lock where the lift is 32.5 ft. As a clear headroom of only 17.2 ft is required, a masonry arch is extended across the lock, and the gate when closed is sup-

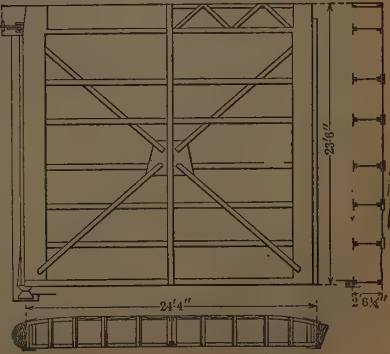

Fig. 58. Barge Canal, Steel Lock Gate

ported on all four sides; the gate is 28.7 ft long and 33.6 ft high; depth of water over sills about 10 ft. It has a frame of iron with wood sheathing and contact pieces.

Rolling gates moving transversely to the canal are in use in many places. In the locks for the Ohio River navigation at Davis Island and elsewhere (Fig. 60) which are 110 ft wide, the gates at the head and foot of the lock are alike; the lift is limited to about 8 ft and the maximum height of gate built up to this time is 18.5 ft. The gates have steel frames with wood sheathing, and are carried on wheels which run on tracks laid in the lock floor. The gates are opened and closed in 1½ to 2 minutes with steam power. In the Canal François, Hungary, the locks (two in flight) near the R. Sisza have a width of 52.5 ft and a depth of 8.2 ft on sills; the upper and middle gates are

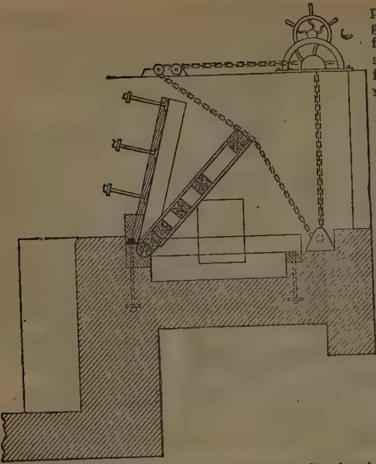

Fig. 59. Tumble Gate, Junction Lock, Erie Canal and New York Barge Canal

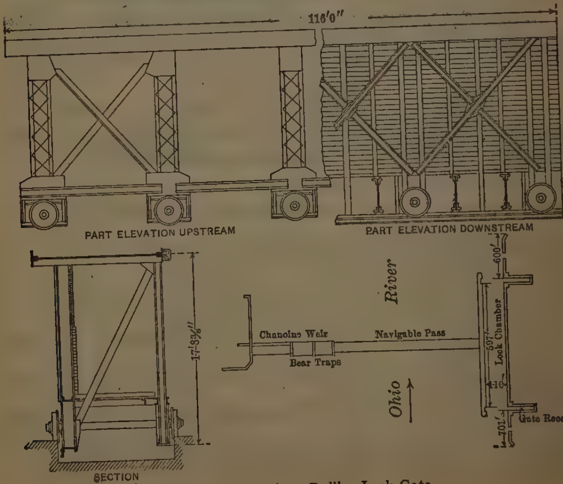

Fig. 60. Ohio River, Rolling Lock Gate

of iron and of the roller type, suspended from trucks running on an overhead bridge. The middle gate is 55.6 ft long, 30.1 ft high, and weighs 150 tons mounted. It has air chambers which lift 44 tons, leaving the net weight to be moved 106 tons; operating machinery is electric. Time to open and close the gate 3 minutes.

Operating Machinery. In the smaller boat canals the gates and valve are operated by hand. The lock gates of the Erie Canal have "balance beams" attached to the top of the gate and extending back over the side walls, and the gate is moved by men pushing against the beam. In some foreign canals a segment of a toothed wheel is attached to the quoin post and extends back over the wall and is operated by means of a windlass with vertical axis carrying a pinion which acts upon the toothed segment. At the Dortmund and Ems Canal the piston rod of a hydraulic cylinder acts upon an arm extending back from the gate, replacing the toothed gear just mentioned. At the larger locks, hydraulic machinery is in most general use. As the machinery is operated for only a small part of the time, accumulators are employed, usually in the form of a vertical cylinder, into which water is pumped, lifting a heavily loaded plunger, and from which the water is drawn when wanted. At many places, as the Manchester Canal and the Liverpool docks, the gate is opened by means of a chain attached to one end of the gate and then led around guides and rove thru two sets of pulleys, one attached to the lock wall and the other to the plunger of a hydraulic cylinder. The effect of this is to multiply the movement of the end attached to the gate when the plunger is operated. A similar arrangement effects the closing of the gate. At the Weitzel lock of the St. Marys Falls Canal a single cylinder is used to open and close each gate, a piston being substituted for the plunger, a long piston rod passing thru both cylinder heads with a set of pulleys at each end (Fig. 61). At other places winding drums are operated by three-cylinder hydraulic engines, as at the Kiel Canal. A simple and efficient machine, consisting of a hydraulic cylinder with its piston rod guided and a connecting rod attached directly to the gate and opening or closing the gate by a single movement of the piston was introduced at the Barry dock at Bristol, England, and is used at several places.

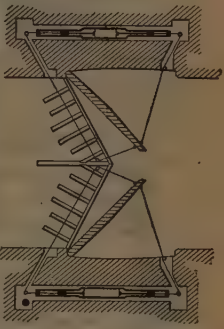

Fig. 61. Method of Operating Gates, St. Marys Falls Canal

In the smaller canals the valves for filling or emptying the locks are operated by hand power. The 8 ft by 10 ft butterfly valves at the locks of the United States canals at St. Marys Falls are opened or closed by a single stroke of a hydraulic engine, the connecting rod being attached directly to the valve—all below the lock floor. At the Canadian Canal, St. Marys Falls, the valves are operated by a long connecting rod attached to a crank arm of the valve stem. On the New York Barge Canal the valves which are counterweighted are operated by electricity (Fig. 62).

In foreign canals the water pressure used in hydraulic machinery at locks is usually 40 to 50 atmospheres. In recent years the use of electric current for operating lock machinery is increasing; two notable examples are the Canadian lock at the St. Marys Falls and the sea lock of the Amsterdam Canal.

Approaches to Locks. In canals where boats are moved by men or horses at low speed the change from canal section is effected abruptly at the ends of the lock walls but where vessels are moved by steam the danger of accidents to lock gates is greatly increased, and a long guide wall should be built at each end of every lock or flight of locks with posts strongly anchored placed at short intervals for use in checking speed by means

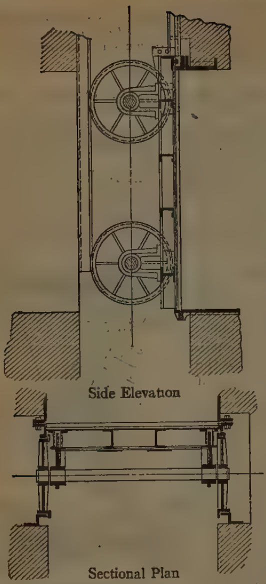

Fig. 62. Lock Valve, New York Barge Canal

of lines. Such arrangements exist a the St. Marys Falls canals, at the Nev York Barge Canal, and at the Panam Canal.

20. Lifts and Inclines

High Lifts. There are severa examples in European and Canadia canals of so-called "hydraulic lifts. This type consists of two tanks each large enough to receive boat, and supported by a plunge working in a cylinder of sufficien length to give the desired lift b one stroke of the plunger. Th cylinders of the two tanks a interconnected, so that the tank balance each other. The boat t be lifted or lowered is placed i one of the tanks, displacing it own weight of water, and thu not affecting the balance. Move ment is effected by admitting small amount of excess water to t tank which is desired to be lowere The tank has a gate at each en a gate is also placed at the end each canal level. Following a some of the details of existi hydraulic lifts:

Data	Anderton, Eng. Trent & Mersey Canal	Fontinettes, France. Neufosse Canal	La Louvieres, Belgium. Canal du Centre	Peter-borough, Canada. Trent Canal	Kirk-field, Canada Trent Canal
When built	1875	1888	1888	1904	1906
Tank, inside length	73′ 9″	132′ 10″	141′ 7″	139′ 0″	139′ 0
Tank, inside width	15′ 3″	17′ 0″	18′ 4″	33′ 0″	33′ 0
Tank, depth of water	4′ 5″	6′ 6¾″	8′ 6″	8′ 0″	8′ 0
Height of lift	50′ 2″	43′ 0″	50′ 6″	65′ 0″	48′ 5
Diameter of ram	2′ 11¼″	6′ 6¾″	6′ 6¾″	7′ 6″	7′ 6
Pressure of ram, lbs per sq in	532	....	500	600	600
Weight to be lifted, tons	250	770	1100	1700	1700
Displacement of boat, tons	120	300	400	800	800
Carrying capacity of boat, tons	80	....	....	....	....
Time to lift boat, minutes	....	....	2¼	1½	....
Time complete operation, minutes	....	....	15	12 *	....
Cost in dollars	230 000	380 000	320 000	500 000	....

* The record time of complete operation was 6 ½ minutes.

The Anderton lift, the first to be built, was operated with little trouble for several years, but finally the plunger became scored to such an extent that it was decided to remove the hydraulic appliances; each tank is now counterweighted separately, the counterweights being connected to the tank by wire cables carried over pulleys supported by an elevated frame; the operation is by electric machinery. This change was carried out in 1908.

The high lift at Henrichenburg, built in 1899 on the Dortmund and Ems Canal, consists of a single tank supported on five water-tight air-filled cylinders immersed in wells which are interconnected and kept full of water. Principal data are:

Depth of wells	98′ 0″	Length of largest boat	220′ 0″
Diameter of wells	30′ 2″	Width of largest boat	27′ 0″
Diameter of cylinder floats	27′ 6″	Draft of largest boat	6′ 7″
Length of cylinder floats	32′ 9½″	Time to lift or lower tank	2½ min.
Length of tank (useful)	225′ 0″	Time for one round trip, lifting one boat and lowering another	25 min.
Width of tank (useful)	28′ 4″	Power supplied	440 H.P.
Depth of water in tank, min.	8′ 3″	Cost, including installation	$630 000
Height of lift	45′ 11″		
Weight to be lifted, tons	3100		
Carrying capacity of boat, tons	950		

The movement of the lift is controlled by guides, and uniformity is secured by four massive vertical screws, interconnected, and working thru nuts fixt to the lift. It is stated that "a lift constructed on the open trough principle should only be adopted where the conditions for it are favorable, and a good foundation can either be found or can be prepared without any great trouble and expenditure. In conclusion, it should be mentioned that when the further extension of the Dortmund and Ems Canal is taken in hand, it is contemplated to construct a flight of locks by the side of the canal lift."

Inclined planes have been used to surmount high lifts, both in the United States and Europe. The following table gives details of several examples:

Canal	No. of inclines	Total lift, feet	Largest boat: Length	Largest boat: Width	Largest boat: Draft	Largest boat: Load, tons	Built	In use or abandoned
Morris, U. S.	23	1449.0	89.0	10′ 6″	4′ 0″	70	1831	In use
Pennsylvania, U. S.	10	2007.0	85.0	13′ 6″	.....	75	1831	Abandoned
Ches. & Ohio, U. S.	1	39.0	90.8	14′ 5″	5′ 0″	115	1876	"
Monkland, Scotland	1	96.0	70.0	14′ 4″	2′ 2″	60	1850	"
Shropshire, Eng.	1	213.0	20.0	6′ 0″	2′ 9″	.....	.....	In use
Shrewsbury, Eng.	1	73.5	20.0	6′ 0″	2′ 3″	.....	.....	"
Chard, Eng.	3	27.5 to 86.0	26.0	......	.....	60	.....	"
Grand Junction, Eng.	1	75.2	75.0	12′ 0″	3′ 4″	75	1900	"
Ourcq, France	1	40.0	92.0	10′ 0″	4′ 0″	70	1888	"
Oberland, Germany	5	66.0 to 80.3	......	......	.....	70	1860	"
Bude	1	......	20.0	5′ 6″	1′ 8″	.....	.....	"

The small boats using the Bude incline have wheels built in, and are drawn up the incline in trains, counterbalanced to some extent by descending trains or boats. On the inclines of the Morris, Pennsylvania, Shropshire, Shrewsbury, Ourcq and Oberland canals, boats are (or were) carried on trucks; on the inclines of the Chard and Monkland and Chesapeake and Ohio canals, the boats are hauled while water-borne, or nearly so, in tanks. In some cases the incline is double, the boats or tanks counterbalancing each other. Boats are usually carried endwise, but on the Foxton incline on the Grand Junction Canal, the boat is carried sidewise and is water-borne; two tanks are used counterbalancing each other.

The incline of the Chesapeake and Ohio Canal (at Georgetown, D. C.) provided for larger boats than any other yet built. In connection with the projected Austrian sys-

tem of canals to connect the Danube with the Ober, the Elbe and the Moldau, inclines have been proposed for boats of 600 to 800 tons capacity. It was announced in 1902 that the Government of Austria had decided to build an experimental incline for boats of 600 tons, investigations having indicated a saving in cost of transport by the use of inclines instead of locks, provided no unforeseen difficulties develop in actual use of inclines constructed on a scale so much exceeding any previously built.

21. Guard Gates, Safety Gates, Stop Gates

Guard Gates are arranged at the St. Marys Falls canals by extending the lock walls at each end sufficiently to receive an additional pair of gates, both opening outwardly. They could be used to protect the ordinary lock gates from approaching vessels, but are not so used, their purpose being to enable the lock to be closed quickly by unworn and perfectly fitting gates, for repairing the lock and its gates and valves. The summit level of the Charleroi Canal (supplied by pumping) is divided into short sections by SAFETY gates so that in case of a break in the canal bank the gates may be closed and the loss of water limited to about 20 000 000 cu ft. STOP gates (Fig. 63) were introduced in the Dortmund and Ems Canal which in places is carried on heavy embankments. These are on the same principle as Taintor gates, and when opened permit the passage of boats underneath. In the New York Barge Canal guard gates (Fig. 64) are placed at least every 10 miles in canal sections; these are lifting gates and in duplicate, each affording a clear opening of 55 ft and a clear head room of 15.5 ft above the water surface at high navigable stage when opened. These gates are steel and carry wheels moving on vertical tracks fixt in the masonry. They are operated by hand power. The last three devices are designed to be operated in moving water.

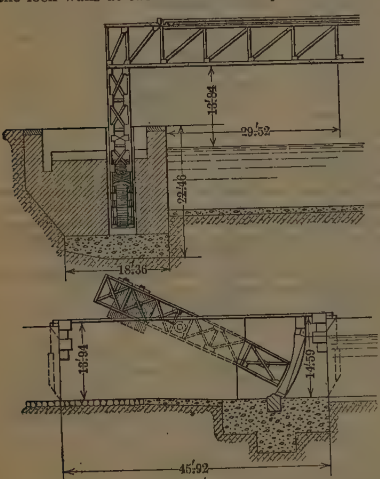

Fig. 63. Guard Gate, Dortmund and Ems Canal.

These devices are impracticable for closing a ship canal where unlimited height is required, and for such canals the safety gates are some form of movable dam. As these are to be manipulated in powerful currents, a subdivision of the structure is considered necessary, and as the emergency requiring their use will seldom arise, and if not in sight they would be more liable to be neglected and unserviceable when needed, they should be above water and readily inspected when not in use. These conditions have been met at the St. Marys Falls canals by swing bridges carrying the sectional dams. Fig. 65 shows the structure in the canal on the Michigan side of the rapids. The canal, which is in rock excavation, is separated by an island into two channels, each 108 ft wide and 25 ft deep. Each channel is closed by 16 wickets which can be lowered

separately. Each wicket will consist of two parts, a frame and a shutter movable in the frame. It is expected that the frames will be lowered first, offering only a partial obstruction to the current, and when all are properly placed, the shutters, guided in the frames,

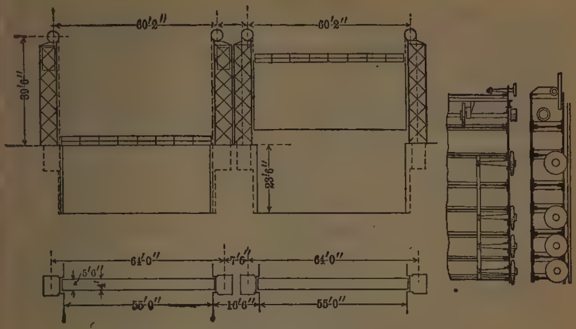

Fig. 64. New York Barge Canal Guard Gates

will be lowered one at a time. This structure is similar to the one at the Canadian Canal which was successfully operated when lock gates were carried away in June, 1909. On

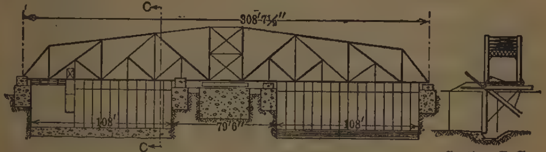

Fig. 65. Movable Dam. United States Ship Canal, Saulte Ste. Marie

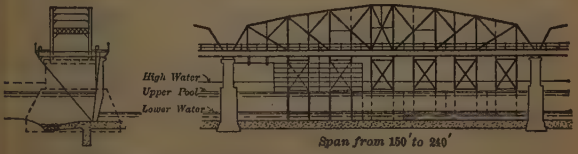

Fig. 65a. Movable Dam. New York Barge Canal

the Panama Canal a safety device is used similar to that shown in Fig. 65. It is described in more detail on p. 1360.

Nearly all the canals built by the United States Government are lateral canals, avoiding rapids in the natural waterways and providing for steamboats ar well as barges. The most important one is the St. Mary's Falls Canal which will be described as one of the great ship canals. The Colbert Shoals Canal is typical of lateral canals along navigable rivers. It avoids Big Tree and Colbert Shoals in the Tennessee River; length 8 miles, depth at low water 7 ft. Width for lower 5½ miles in earth excavation 112 ft at bottom, 140 ft at low-water surface, side slopes 2:1. Width for upper 2½ miles, mainly in rock excavation, 175 ft at bottom, about 190 ft at water surface. Lock at lower end of canal: available length 350 ft, width 80 ft. Lift, maximum at extreme low water, 26 ft. Mitering gates steel, circular in plan. Culverts in side walls for filling and discharging, 8.6 ft by 9 ft, with 11 openings into the chamber from each wall. Valves of the Stoney type. Banks 20 ft wide at top extend 9.5 ft above low-water line and are protected by Bermuda grass above that line. Side drainage received into the canal usually thru culverts. Five waste-weirs, each 100 ft long, are built into the bank on the river side, exclusive of a guide wall 7000 ft long at head of canal serving also as a weir. Crests of weirs 0.5 ft above low-water surface.

Only two canals with summit levels and intended for boat or barge navigation have been undertaken within recent years in the United States. One of these is the Illinois and Mississippi Canal (also called " Hennepin " Canal), and the other is the New York Barge Canal with its branches, the Oswego, Champlain, Cayuga and Seneca canals.

Traffic in the boat canals of the United States has been steadily decreasing with increasing competition of the railroads and this has not been checked materially by the removal of tolls and the assumption of fixt eharges and operating expenses by the state. On the continent of Europe, where the canals are generally owned by the state and free from tolls, the assumption of construction, operation and maintenance by the state enables water transportation to compete with rail, and traffic on the waterways is increasing rapidly.

New York Barge Canal. The Barge Canal is the improvement of four existing canals, and consists of (1) the Erie, stretching across the state from east to west and joining the Hudson river and Lake Erie; (2) the Champlain, running northerly from the eastern Erie terminus to Lake Champlain; (3) the Oswego, starting north midway on the Erie and reaching Lake Ontario; (4) the Cayuga and Seneca, leaving the Erie a little west of the Oswego junction and extending south, first to Cayuga lake and then to Seneca lake.

The Barge Canal is largely a river canalization project, natural water-courses being available for much of its length. With intervening lakes and adjoining rivers there is a total length of a little more than 800 miles in the State's internal waterway system of Barge Canal dimensions.

The main water supply is taken from Lake Erie, from reservoirs in the Adirondack region and from the upper Hudson River. The supply is adequate not only for the 10 000 000 tons seasonal traffic for which the canal was designed, but also for the maximum traffic which the canal is capable of handling, namely, from 18 500 000 to 20 000 000 tons per season.

The locks on all branches of the canal are of standard dimensions. The lifts range from 6 ft to 40½ ft. They are built of concrete thruout and except on rock or hardpan have pile foundations. Within each side wall runs a culvert for filling and emptying the lock. The culverts are connected with ports that open into the chamber at the bottoms of the walls. With a few exceptions the lock gates are of the mitering, girder type, carrying the principal load as beams. They are built of steel, with single skin-plates, have white oak quoin and toe posts, swing on cast-steel pivots set in the concrete, are held at the top by adjustable anchorage and bear against cast-iron quoin plates bolted into the side walls. In general a power station at each lock supplies the energy for operating and lighting the lock. A majority of these installations are hydroelectric, but at locks beside movable dams gasoline-electric stations are employed.

At about fifty cities and villages along the waterways the State has built terminals,

which provide suitable dockage, mechanical devices for handling goods quickly and cheaply, a building for temporary storage and, where possible, railway connections—al available to any shipper or boatman.

France. Practically the whole of the canal system is owned and controlled by the state. In 1905 the total length of canals in use was 3010 miles. The more importan canals have a bottom width of 33 ft or more; depth 6.6 ft to 7.25 ft.

Belgium. The total mileage of the waterways (canals and rivers) is 1345 miles The total length of the more important canals is 334 miles. The total lift at 141 lock (excluding lifts) is 1445 ft The total lift at 4 lifts (1 completed, 4 building) is 217 ft When new work or enlargement is taken up the locks are given greater lifts, up to 14 ft, and water saving effected by side ponds.

Germany. The total length of the waterways on which the traffic is of importance 6200 miles and the total lift at 359 locks (excluding lifts) is 3129 ft. In the canal connecting most directly with the French waterways the width at the water surface is abou 52 ft, at the bottom 33 ft, depth 6.6 ft: useful length of locks 126 ft, width 17 ft, adapte for use of boats on the French and Belgium canals.

Great Britain. The canals were built by independent companies, without assistan from the State. Nearly 1/3 of the total mileage has been acquired by railway companie The total length is 3811 miles (Engr. News, Apr. 16, 1890). The annual traffic on th independent canals is about 33 000 000 tons: on the railway owned canals, about 6 000 00 The greater part of the traffic is short distance, there being no uniformity of canal dime sions, making frequent transshipment necessary on thru business. Excluding the sh canals, only 10% of the total mileage has a depth of 6 ft or more, while 46% has a dep of less than 4 ft. On account of the diverse ownership a material extension or improv ment of the boat canal system is not expected.

Holland. There are 265 canals, with a total length of 2100 miles, of which abo $1/_{20}$ belongs to the State: the remaining canals are under control of provincial or municip authorities, administrative corporations, or private companies. Many of these cana are designed primarily for drainage, and some of the branch canals can be navigated on by small boats poled or towed by manual labor Power boats and tugs are used on t larger canals. On the Merwede Canal recently built, length 43¾ miles, 106 ft wide water surface, 66 ft at bottom, 10.2 ft minimum depth, the tugs tow trains of 12 boa This canal cost $8 480 000 for construction: annual maintenance, $103 000. All t canals owned by the State, and nearly all the others, are free from tolls.

23. Ship Canals

Suez Canal. Connects the Mediterranean and the Red Sea. Shorte the sailing distance from Northern Europe to India about 5000 miles; Australia about 1000 miles. Total length of canal including harbor at P Said and roadsteads at both ends 104.08 miles. Minimum depth 31.1 Width at this depth (excluding harbor and roadsteads) 108.26 ft to 118.11 widened on curves to 131 to 262 ft. There are 23 passing places where t bottom width is increased to 147 63 ft for a length of 2460 ft, reducing at ea end to standard width in a distance of 984 ft. Side slopes vary from 2 : 1 3 : 1 or flatter. The width and depth are being increased gradually. C of the work up to the end of 1908 was $122 275 000. Expenses during 19 were about $8 668 000 and net profits about $12 850 000

On account of the tides and effect of the wind in the Mediterranean and Red s currents are produced in the canal reaching 1⅛ miles per hour between the Bitter La and Port Said, and 3 miles per hour between the Lakes and Suez. The speed of ves is limited to 7¾ miles per hour on the 28-mile tangent beginning at Port Said, an 6 2 miles per hour elsewhere in canal sections. A high speed is permitted in the la The average time actually consumed in passing the canal is from 18 to 19 hours.

Corinth Canal. Connects Gulf of Corinth with Gulf of Ægina. Is at level. Shortens sailing distance from Adriatic ports about 175 miles, from Mediterranean ports about 100 miles. The canal is 3.91 miles lo

The great central cut is 2½ miles long with a maximum depth of 286 ft from surface of ground to bottom of canal. The canal is 26.64 ft deep and has a bottom width of 68.9 ft. The sides have a batter or slope of 1 horizontal to 4 vertical (1 : 4). Unless vessels move very slowly they strike the sides of the cut frequently. The traffic is small.

Manchester Canal. Connects Manchester with the River Mersey at Eastham near Liverpool. It is 35½ miles long; when opened for navigation (1894) its depth was 26 ft; ruling bottom width 120 ft. Side slopes in earth from 1 : 1 to 3 : 1, in rock 1 : 5. For a distance of four miles from Manchester the bottom width was 170 ft. The depth of water on the lock sills was made 28 ft, and the canal was deepened to the same.

The Manchester level is 70 ft above mean tide at Eastham, and is reached in five lifts, varying from 9 ft 6 in to 16 ft 6 in; the smallest lift is at Eastham and overcomes the difference of level between mean tide and mean high water.

At the Eastham terminus there are three parallel locks having the length and width, respectively, of 600 ft by 80 ft; 350 ft by 50 ft and 150 ft by 30 ft; the lengths given are from quoin to quoin. At the other lock sites there are only two parallel locks, respectively, 600 ft by 80 ft and 350 ft by 50 ft.

Each set of locks is paralleled by a sluiceway, with sluice gates of the Stoney type 20 to 30 ft wide (30 ft except at Eastham), and with sills at the same level as the upper sill of the adjacent lock. Each 30-ft gate has a discharging capacity of about 6500 cu ft per second. There are three to five (excluding Eastham) such outlets in each sluiceway, so that in times of flood strong currents may be set up for short periods. The smaller sluiceway at Eastham is supplemented by extensive sluices in the bank of the canal in the level immediately above. The speed permitted is 6 miles per hour for the largest vessels, rising to 12 miles or more for smaller vessels and tugs. The time required for passing thru the canal varies from 5 to 8 hours.

Kiel Canal. Connects Baltic and North seas. It is 61.31 miles long, 36.08 ft deep, 144.32 ft wide at bottom, 333.74 ft and upward at water surface. The width is increased on curves at bottom. The canal has 11 passing places, four of which are 984 ft wide at bottom to serve as turning places; the others are 439 52 ft wide at bottom, length 1968 to 3608 ft. There is a lock at each end of the canal with ebb and flood gates at each end of the lock. Normal water level in the canal is mean tide in the Baltic. There is also in each an intermediate pair of ebb gates and one pair of flood gates, permitting use of a shorter lock chamber. The locks have a useful length of 984 ft, width 147 ft 8 in, depth on sills 45 ft.

The speed allowed by regulations is 9 3 miles per hour, but the largest vessels cannot attain this. The time required to pass thru varies with the draft, from about 8 hours for the smaller vessels to 13 or 14 hours for the larger.

Amsterdam Canal. Connects the North Sea at Ymuiden with Amsterdam and also with Zuyder Zee. Its principal purpose is to make Amsterdam a seaport. Its length from the North Sea locks at Ymuiden to the Zuyder Zee locks is 17.4 miles, and from the North Sea locks to the entrance to Ymuiden Harbor about 2 miles, making a total of 19.4 miles. Depth 32.14 ft below "ordinary water-level;" width at bottom, 164 ft on tangents increased to 196.8 ft on curves. Side slopes generally 3 : 1 with a berm of varying width and depth.

The new great lock at Ymuiden is intended to accommodate vessels of the maximum length of 721.6 ft, width 82 ft, draft 30 18 ft. It has intermediate gates to permit the use of a shorter lock for small vessels, and ebb and flood gates, making 6 pairs in all. The operating machinery is electric thruout, and it is the second ship-canal lock to be so equipped.

The speed permitted varies with the draft of vessel; it is 6.52 miles per hour for vessels drawing 19.68 ft or more, 7.45 miles per hour for vessels drawing 13.12 to 19.68 ft, and 9.32 miles per hour for vessels drawing less than 13.12 ft.

Petrograd and Cronstadt Canal. Connects deep water in the roadstead in the Gulf of Finland with one of the delta mouths of the River Neva at Petrograd, and it is intended to make Petrograd a seaport. It consists of a channel about 17¾ miles long dredged in the open water of the bay and across the Neva bar and protected by dikes for a distance of about 6 miles at the upper end. Its depth was made 28 ft. Bottom width from 213 to 275½ ft in the diked portion and 355½ ft in the portion not diked.

Cape Cod Canal. Sea level canal connecting Cape Cod and Buzzards Bays; shortens the sailing distance from Boston to New York by 66 miles and avoids the dangerous Cape Cod Coast. Highest part of ridge cut through was 29 ft above mean sea level. Material chiefly sand. Length of canal proper 8 miles, 25 ft deep at low water 100 ft wide at bottom side slopes 1 on 2. There are 5 miles of approach channels having bottom widths of 250 ft and 300 ft and side slopes of 1 on 3. Mean range of tide at one end 8.9 at the other end 3 6 ft. This tidal difference produced velocities as great as 5 ft per sec. Completed in 1915.

St. Marys Falls Canals. These are lateral canals avoiding St. Marys Rapids in St. Marys River between Lakes Superior and Huron. There are two canals one on the American side of the river and the other on the Canadian side. The fall in the rapids varies from about 17 to 21 ft with the varying stages of the lakes. and is overcome by one lift in each of the canals.

The American Canal is about 1.6 miles long with four parallel and adjacent locks at the downstream end. The canal consists of two channels, the Poe and Weitzel locks serving the old south channel, and the new third and fourth locks serving the new channel to the north. The Weitzel lock is 515 ft long from quoin to quoin, 60 ft wide at gates 80 ft wide in chamber and has from 15 to 17 ft of water on the sills. The Poe lock is 800 ft long, 100 ft wide, and has 20 to 22 ft of water on the sills. The two new locks are each 1350 ft long, 80 ft wide, and have 24½ to 26 ft water on sills.

Upstream from the Poe and Weitzel locks, is a narrow island on which is located the pivot pier of a swing bridge carrying the wickets and machinery of a movable dam, the purpose of which is to close this portion of the canal in case of a break at the locks permitting a free flow. (See Fig. 65, p. 1353.)

The Canadian canal is 1.4 miles long, 141 ft 8 in wide at bottom, 150 ft at water surface and about 22 ft deep. The single lock is 900 ft long from quoin to quoin, 60 ft wide and has 20 to 22 ft of water on the sills, depending on the varying stages of the lakes.

Canadian Canals from Lake Erie to Tidewater at Montreal

* One is a guard lock. † Minimum. ‡ Variable. § Under construction 1919

The two canals actually constitute one system. No charges are made to vessels passing, which usually take the canal having the smaller number of waiting vessels. Hydraulic power is used at the American canal; the Canadian canal is operated electrically, and was the first ship canal to be provided with such operating machinery. A boat can be passed thru the lock in either canal in 8 to 11 minutes, but on account mainly of fleet lockages, the average time for a lockage is about 33 minutes in the American canal. In the Canadian canal, where fleet lockages form a smaller proportion of the total time, the average is about 20 minutes.

The time necessary to pass thru the canal depends largely on the amount of traffic and the congestion resulting, and has varied in the American canal from 4 hrs 58 min in 1895, when only one lock was in operation, to 1 hr 10 min in 1900, when two locks were in use. With increased traffic since that date the time has increased to 2 hrs 40 min.

Panama Canal. Connects the Atlantic Ocean (Carribean Sea) with the Pacific, crossing the Central American Isthmus in Lat. 9° N. and Long. 85° W. at approximately its narrowest and lowest point. It reduces the sailing distance from New York to San Francisco by 7873 miles (5262 miles as compared with 13 135 miles via Magellan Straits) with a similar saving in distance to many ports, in South America and the Orient. The canal is 50 miles long between deep water in the two oceans. The average time of passage is 12 hours, the shortest recorded time is 6 hours 30 minutes.

Its construction was began in 1882, by the French, whose rights were acquired by United States for $40 000 000 in 1904, when a Canal Zone 10 miles wide was secured from the Republic of Panama, for $10 000 000 and a perpetual rental of $250 000 per annum. The canal was completed by the U. S. Government in 1914.

The canal is a lock canal with a summit level normally 85 ft above mean tide in the two oceans, the maximum tidal range being 22 ft at the Pacific and 2 ft at the Atlantic end. Its most distinctive feature is Gatun lake, an artificial body of water, 164 square miles in area, which forms the summit level. The lake provides wide and deep channels which permit vessels to travel at high speed for over half the distance between the two oceans. Its formation involved the building of a huge earth dam for closing the valley of the Chagres at Gatun and of three expensive groups of locks, but on the other hand, the depth of the summit cut at Culebra was reduced decidedly, and a large amount of excavation eliminated so that there was a decided saving in the total time and cost of construction in comparison with a sea level canal. As practically no excavation was required in the deeper portion of Gatun lake the work of building the canal, resolved itself essentially into the excavation of the sea level sections, and of the cut through the Continental Divide, the building of the Gatun and some smaller dams and the construction of the locks and spillways. Some details of the several parts of the work are given below:

Beginning at the Atlantic End, the successive sections of the Canal are the following: (1) A sea-level channel 7 miles long and of 500 ft bottom width, extending to the locks and dam at Gatun. (2) Gatun lock flight with 3 lifts of about 28 ft each. (3) Gatun lake at Elev + 85 forming the summit level which extends across the Continental divide through the Culebra (Gaillard) Cut to the lock at Pedro Miguel.—The total length of channel in the summit level is 32 miles of which 16 miles is 1000 ft wide, this section having a depth of 45 to 75 ft—4½ miles is 800 ft wide, 4 miles is 500 ft wide, and 8 miles (in Culebra Cut) is 300 ft wide. (4) Pedro Miguel lock with a 30 ft single lift. (5) Miraflores Lake (area 1.6 sq miles) at Elev + 55 with a channel 500 ft wide 1½ miles long and 45 ft deep. (6) Miraflores Locks, a flight having two lifts of 22 to 33 ft each, according to the tidal stage, and finally (7) A sea level section 500 ft wide and 7 miles long to deep water in the Pacific.

It will be noted that, except in the locks, the channel has a minimum width of 300 ft and a minimum depth of 45 ft. Where there is a change in the direction of the Canal axis, instead of connecting the tangents by curves, the channel was widened so as to allow vessels to turn readily

Locks. The principal dimensions of the locks are shown in Figs. 53 and 54. They have a clear width of 110 ft, a usable length of 1000 ft, and a minimum depth on the sills of 41 ft 4 in. There are twin chambers, with a central wall 60 ft thick between them, which is extended 1000 to 1200 ft beyond each end of the lock—to act as a guide wall for vessels.

For filling and emptying there is one longitudinal culvert 255 sq ft in cross-section (equal to a circle 18 ft in diameter) in the middle wall and in each sidewall connecting with transverse culverts of elliptical section built in the lock floor, which are each 41 sq ft in area and discharge upwards into the lock chamber through 5 circular outlets of 12 sq ft each. These laterals extend across the lock at intervals of about 35 ft connecting alternately with the culverts in the side and middle walls. The main culverts are controlled by rising stem gate valves of the Stoney type, located close to the upper, intermediate and lower lock gates. They are 8 ft wide and 18 ft high and are placed in pairs separated by a dividing wall. As a safeguard, a duplicate set is provided close to each pair of valves. The valves are, each, opened and closed by a single valve stem, which extends through a horizontal cast-iron bulkhead, placed just above the valve, and fitted with a stuffing box. The stem connects with a guided cross head, which is raised and lowered by 2 non-rising screws driven through reducing gears by a 50 H.P. electric motor. The time of operation is one minute. Each lateral culvert leading from the middle wall is fitted with a cylindrical valve 78 in in diameter, placed vertically, which is opened or closed in 10 seconds by a 7 H.P. motor.

Lockgates. The lockgates are double-skin steel gates of the mitering type with air chambers. The sill angle is 26° 33′ 54″. There are duplicate operating gates at both ends of Pedro Miguel lock and at the upper chambers in the lock flights and an intermediate set in all the chambers except the lower ones at Miraflores. These subdivide the locks into usable lengths of 550 and 278 ft. A reverse guard gate is provided in the lower approach to each log. There are in all 46 gates of 2 leaves each, weighing nearly 60 000 tons. The leaves are uniformly 65 ft long and 7 ft thick and vary in height from 47 to 82 ft and in weight from 395 to 745 tons. The horizontal girders which are spaced from 3 ft 8 in to 5 ft apart have straight parallel sides and curved ends. See Fig. 57. The bearings along the quoin and miter posts and in the hollow quoins are polished steel plates. Their joints have proved to be absolutely watertight. There is a wooden clapping sill with a rubber seal.

The gate-moving machinery is of a novel type developed and first used on the Panama Canal. A horizontal strut is used, hinged at one end to the top of gate, and at the other to a crank pin fixed in a horizontal wheel 19 ft in diameter, (the so-called "bull wheel") which is supported on the lockwall. This is turned by a 25-H.P. motor through a series of reducing gears, the time for opening or closing a leaf being 2 minutes. The special merit of the design is the fact, due to the kinematics of the mechanism, that it gives the leaf a relatively slow motion at both ends of its travel, where the hydraulic resistances are greatest.

Safeguards. The following safeguards are provided in the locks: (1) The duplicat lockgates mentioned above. (2) A novel system of chain fenders placed in the upp and lower approaches to all the locks and also just above the intermediate and low gates in Pedro Miguel lock and in the upper chambers of the other two locks. The consist of 3-inch anchor chains stretched across the locks at the top, which are raise and lowered by vertical hydraulic cylinders in the walls. These chains serve to chec vessels that may strike them, by paying out under strain, the amount of pull bein regulated by relief valves on the cylinders. It has been shown by actual tests that vessel of 18 000 tons displacement, moving at a speed of 2½ miles per hour, can readily brought to rest in a distance of 55 ft, without injury to the vessel or chain. (Electric towing locomotives, traveling on rack railways on the walls on both sides of t lock chambers, which are used in the case of all vessels for moving them during th passage through the entire length of the lock flight. They exert a pull of about 25 o lbs and move at a speed of 1 or 2 miles per hour. (4) Emergency dams at the upp end of each lock for shutting off the flow of water in case of a serious accident to t lockgates, which has resulted in establishing a connection between the upper and low levels. The dams are of the swing bridge type, similar in design to the movable da at the St. Mary's Falls canal, shown in Fig. 65. At Panama, there is an independe dam, (supported on the side wall) for each twin lock flight. The arm spanning the 'c is 164 ft 3 in long, while the other arm, which is 98 ft long, carries a heavy concrete count

weight and the operating machinery. The wicket girders are 60 ft long and spaced 9 ft 2 in apart. There are 5 wickets, in each vertical bay, which roll down along the upstream flanges of the girders. In operation, the flow of water is to be gradually shut off by building up the wickets in horizontal tiers from the bottom. In still water, the dam has been swung, and all the girders and wickets put in place, in 26 minutes.

All the machinery in the locks is operated electrically. The current which is 3 phase at 25 cycles is generated at 2200 and 6600 volts in an hydro-electric station at the spillway in the Gatun dam operating under a head of 77 ft. Its present capacity is 13 140 kw to be ultimately increased to 22 140 kw. There is also a reserve steam turbine plant of 7500 kw capacity near Miraflores. The current is distributed at 6600 volts to transformer rooms in the lockwalls at Gatun, all motors operating at 220 volts. It is carried across the isthmus at 44 000 volts on an overhead transmission line supported on structural steel frames along the line of the Panama Railroad.

The machines for moving the lockgates, valves and chain fenders are located in small rooms in the lockwalls just below the coping level, which are all connected by continuous longitudinal tunnels.

The principal machines in each of the three groups of locks are normally operated from a central control house on the middle wall. This contains a horizontal control board or table, which resembles a miniature ground plan of the lock, with models of the different gates, valves, etc., which open and close when the actual gates are being operated. Local control is also provided in the several machine rooms. The principal gates, lockgates and chain fenders are interlocked so as to guard against errors in operation.

In the operation of the locks, several novel and important hydraulic features have been observed:

(1) A very unequal discharge from the several orifices in a given lateral culvert, the flow being greatest from the outlet farthest from the main culvert. This results in forcing a vessel in the lock strongly towards the wall from which filling is taking place and has made it necessary to use both culverts throughout the process of filling, thus obtaining a very uniform distribution and permitting a maximum rate of changing levels of 7.5 ft per minute with safety.

(2) An "over travel" of the water levels, due to the acceleration of the water in motion through the culverts. Owing to the great length and cross-section of the locks, this action, not taken into account in the ordinary formulæ, is important, as it shortens the time of filling by about two minutes.

The coefficients of flow are approximately:

For filling—using side and middle wall culverts, $C = .65$
using side wall only, " " $C = .82$
For emptying—using side and middle wall culverts $C = .67$
using side wall only, " " $C = .73$

The time for filling (for a length of lock of 900 ft) is 7 to 8 min, using both culverts, and 12.5 to 13.5 min, using the side wall culvert only.

Dams. The Gatun dam is shown in cross-section in Fig. 13, No. 12. It is about 1½ miles long and polygonal in ground plan. The maximum bottom width is 2300 ft. The central portion of the cross-section, except near the top, was hydraulically filled, by pumping a mixture of sand and clay from the bed of the Chagres by 20-in suction pumps, working in two lifts. The hydraulic fill was confined on each side by rock-fill dams, built for the purpose, which form a part of the main dam. The remainder of the cross-section is dry filling, earth and rock, brought partly from the Culebra Cut, partly from borrow pits close to the dam. There is no core wall. The total volume of Gatun Dam is 22 958 000 cu yd, of which 12 229 000 cu yd was dry filling. Its cost, exclusive of the spillway, was $9 871 635. The much smaller dams, at the Pedro Miguel and Miraflores locks, are of a similar character.

Spillways. Lake Gatun is regulated entirely by a concrete spillway, built on a rocky ledge, which divides Gatun dam into two approximately equal parts. The total watershed drained is 1320 sq miles, the annual rainfall 120 in with a runoff of 62%. The yearly evaporation of the lake area is 60 in, while there is no appreciable seepage.

The maximum observed momentary discharge of the river was 175 000 cu ft per sec, the maximum for 33 hours, 137 500 cu ft per sec, and for 48 hours 120 000 cu ft per sec. The spillway has a capacity of 180 000 cu ft per sec, with the lake at +87. It is circular

in plan with 14 clear openings of 45 ft controlled by electrically operated Stoney ga
19 ft high. The crest is at +69.

A similar spillway but straight in plan, with 8 openings of 45 ft, is provided adjac
to Miraflores lock, as a safeguard in case of a serious accident to the Pedro Miguel lo
Its capacity is about 92 000 cu ft per sec.

Capacity of the Canal. The maximum number of complete lockages at both e
of the canal possible with an unlimited water supply is about 48 in 24 hours, co
sponding to the passage through the canal of 60 commercial vessels of average s
With the present provisions for water storage, the practicable number of lockage
much lower, varying with the power demands and the rainfall in different years.
average years 21 lockages will be possible even when operating the power plant at its
projected capacity of 22 140 kw. In very dry years, the number would be still smal
but the capacity of the canal can be largely increased by using the auxiliary steam p
for part of the year, or by providing additional storage by reservoirs on the upper Chag

Excavation. The earth and rock excavation formed the largest single item in
canal construction, its cost amounting to nearly half the total cost of the canal. To J
30, 1918, the total excavation was 267 834 201 cu yd, of which 130 465 874 cu yd
dry excavation, the rest being removed by dredging and hydraulic methods. A
from a portion of the lock excavation and a few short channel sections elsewhere,
dry excavation was confined almost wholly to the 8¾ miles of the Culebra Cut, w
included all the most difficult work. The prism section is shown in Fig. 46. The
cavation below the berm was wholly in rock as was fully 70% of all the excavatio
the cut. The established slope above Elev + 95 was 2 on 3 which was generally m
tained except in the deepest portion close to the Continental divide. This section,
over ⅞ mile long, was the scene of the serious slides, which delayed the opening o
canal and subsequently stopped navigation for many months. These slides have
practically overcome by flattening the slopes to approximately 1 on 7 by dredging
the channel was filled with water in October, 1913. The material removed from
slides to June 30, 1918, was about 56 000 000 cu yd.

The wet excavation, mainly in the sea-level sections, the lock pits and the slides,
carried on by an elaborate plant, comprising suction, ladder and dipper dredges of v
types and great capacity. Hydraulic sluicing was also resorted to on some parts o
work.

Aids to Navigation. In addition to the light houses at the entrances to the c
a complete system of range lights, beacons, and buoys, mark the channel clearly
by day and at night. The tangents in the lake and sea-level channels are define
range lights, vessels going in opposite directions using different ranges giving co
200 to 250 ft apart, a somewhat novel arrangement. In the Culebra Cut, be
placed at frequent intervals on the banks, take the place of range lights. Ther
also numerous gas buoys at the sides of the channel.

Cost of Construction of Panama Canal to June 30, 1918

Prism Excavation	$137 674 924.79
Locks and Dams	92 768 591.66
Breakwaters	9 098 018.41
Aids to Navigation	650 139.87
Power Plants and Transmission System	5 417 309.72
Atlantic Terminals	5 248 350.47
Pacific Terminals	14 394 256.12
Permanent Townsites	2 414 087.09
Buildings and Playgrounds	15 740 443.64
Sanitary Fills, etc.	718 947.64
Water Works and Sewerage Systems	3 285 837.85
Real Estate	2 776 121.35
Rebuilding Panama Railroad	9 800 626.46
Concessions from Republic of Panama	10 000 000.00
Purchase of Canal from New Panama Canal Co.	38 728 484.05
Miscellaneous	154 649.28
Total	$348,870 782.40

Terminals. Both terminals are protected by rock-fill breakwaters, giving ample anchorage grounds and equipped with concrete and steel piers for the transfer of freight. At the Pacific end, there is a concrete drydock with a clear width of 110 ft and a usable length of 1000 ft close to which large repair shops have been built. There are very complete coaling plants at each end of the canal, the one at the Atlantic end having a maximum storage capacity of 100 000 tons of submerged and 350 000 tons of dry coal. The corresponding figures for the Pacific Plant are 44 500 and 167 000 tons.

Total Cost of Canal. The total amount charged to Canal construction to June 30, 1918, is given on bottom of p. 1362; but a considerable additional sum expended since 1914 for dredging out the slides and for many other purposes should properly be charged to capital account. In the figures given, an overhead charge is included, covering general and administrative costs, expenses for hospital and sanitation, etc. An additional sum of $30 000 000 was appropriated for fortifications.

24. Power, Drainage, and Irrigation Canals

Cross-Sections. Unlined canals in earth have usually a large trapezoidal section, at least when first built. The side slope must be fixt with reference to the character of the soil in which the canal lies. It is usually assumed that the slope should be a little flatter than the angle of repose of the earth in water. In very light fine soil the slope may be as great as 3 or 4 horizontal to 1 vertical; in clayey loam or coarse soil or ordinary firm soil 1½ or 2 horizontal to 1 vertical; in firm clayey gravel or hardpan or firm clay 1¼ or 1 horizontal to 1 vertical. Experiment with the earth of the locality may be necessary, to fix the best side slope.

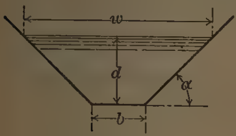

Fig. 66

Trapezoidal Sections. Having the side slope fixt, the relation of depth to breadth may be chosen. The efficiency of canals used as aqueducts, other things being equal, is directly proportional to the square root of the hydraulic radius. Let b, d and w be as in Fig. 66, A the area of cross-section, p the wetted perimeter and r the hydraulic radius. The values of b and d which will furnish a section of the maximum hydraulic radius for a given value of A, are given by the formulas:

$$b = \frac{A}{d} - d \cot \alpha \qquad d^2 = \frac{A \sin \alpha}{2 - \cos \alpha} \qquad p = b + \frac{2d}{\sin \alpha} \qquad r = \frac{A}{p}.$$

The following table, computed by these formulas, gives the values of d, b, p and r in terms of A, which will furnish sections of maximum hydraulic radius, and consequently maximum efficiency, for various slopes in common use.

Slope	α	d	b	p	r
1 on 3	18° 26′	$0.548\sqrt{A}$	$0.178\sqrt{A}$	$3.647\sqrt{A}$	$0.274\sqrt{A}$
1 on 2	26° 34′	$0.636\sqrt{A}$	$0.300\sqrt{A}$	$3.145\sqrt{A}$	$0.318\sqrt{A}$
4 on 7	29° 45′	$0.662\sqrt{A}$	$0.352\sqrt{A}$	$3.021\sqrt{A}$	$0.331\sqrt{A}$
2 on 3	33° 41′	$0.689\sqrt{A}$	$0.417\sqrt{A}$	$2.902\sqrt{A}$	$0.345\sqrt{A}$
4 on 5	38° 40′	$0.716\sqrt{A}$	$0.502\sqrt{A}$	$2.794\sqrt{A}$	$0.358\sqrt{A}$
1 on 1	45° 0′	$0.740\sqrt{A}$	$0.613\sqrt{A}$	$2.704\sqrt{A}$	$0.370\sqrt{A}$
3 on 2	56° 19′	$0.759\sqrt{A}$	$0.812\sqrt{A}$	$2.636\sqrt{A}$	$0.379\sqrt{A}$
7 on 4	60° 15′	$0.760\sqrt{A}$	$0.882\sqrt{A}$	$2.632\sqrt{A}$	$0.380\sqrt{A}$
2 on 1	63° 26′	$0.759\sqrt{A}$	$0.938\sqrt{A}$	$2.635\sqrt{A}$	$0.379\sqrt{A}$
Vertical	90° 0′	$0.707\sqrt{A}$	$1.414\sqrt{A}$	$2.828\sqrt{A}$	$0.354\sqrt{A}$

The Semi-Circular Section has the greatest hydraulic radius for a given area of cross-section, but it is only practicable when lined with concrete or steel. For a given A, the formulas are

$$d = 0.798\sqrt{A} \qquad p = 1.773\sqrt{A} \qquad r = 0.564\sqrt{A}.$$

For small canals the equations above will often fix the best dimensions, but there are numerous considerations which may modify the section. If the canal is very large the excavation may be enough cheaper for a shallower canal, so that the necessary greater sectional area may be removed more economically than the smaller section of equal capacity. This will depend much upon the methods of excavation and the type of machinery used. Again, losses from seepage increase with depth, so that where such losses are liable to become important, or where the bottom of a deep canal would reach an open impervious stratum, it may be wise to adopt a shallower section than would otherwise be economical. On the other hand, for canals on side hills, a still deeper section of greater area may be more economical.

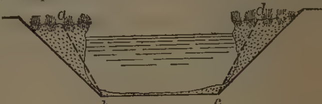

Fig. 67

Small canals are subject to a reduction of cross-section by encroachment of vegetation on the banks, and silting. Jeffreys, in Professional Papers on Indian Engineering, says: "Whatever slope is adopted in construction it is found that this cannot be maintained after the channel has been in use some time. A distributary at the close of an irrigation season invariably assumes the shape seen in Fig. 67. When the time for clearance comes around the engineer in charge, if he is wise, will not attempt to restore the original section. . . . The custom in the Ganges Canal distributaries is to trim off the slope at ½ to as shown by dotted lines a-b and c-d."

The canal may be all in cutting, or all in embankment, or part in each. Each type has its advantages and disadvantages, depending on the local condition. In some localities canals in cutting may be cheaper in maintenance and suffer less loss from seepage; drainage from the surrounding territory may be more easily handled. In other localities there may be danger of reaching an open pervious stratum in cutting which may require lining to prevent excessive loss.

Irrigation Canals all in embankment are sometimes necessary to command the surrounding land or for short lengths to avoid long detours. It is easy with this type, if for any reason it becomes necessary to avoid absorbing the drainage of the country, to pass that drainage across the line of the canal in culverts. The disadvantages are the danger that the banks may break, the higher cost of construction, inspection, and maintenance, and, usually, the greater loss by seepage, which in some cases is further objectionable by forming stagnant pools on the neighboring land. This type of canal generally costs more than either of the other two types.

The advantages of the type in which the section is part cutting and part embankment are that it is usually the cheapest and quickest constructed, that for irrigation it is high enough to command the neighboring land, and that the head of water against the embankments is usually small enough to reduce seepage thru the banks to little or nothing.

Limiting Velocities. Loss of head is to be avoided as much as possible in power canals, while in irrigation and drainage canals the velocity will often be limited only by the ability of the earth of the banks and bed to resist erosion. The velocity should be great enough to prevent the growth of weeds and the deposit of silt, and not so great as to cause erosion. The experiments of Du Buat give velocities in ft per sec next to the bed of the canal which will begin to erode various materials as follows: 0.25 for soft clay, 0.50 fine sand, 0.70 for gravel as large as peas, 2.2 for gravel one inch in diameter, 3.3 for pebbles 1½ inch in diameter, 4.0 for heavy shingle.

Seepage. Sometimes power canals, and usually irrigation canals, are located on hillsides well above ground water level, so that seepage f

unlined canals often amounts to 25%, and sometimes 50%, of the total water entering their headworks. For example, from 20 irrigation canals in operation, taken at random, including canals in France, Belgium, Italy and the United States, the average loss from seepage expressed in depth times area of the water surface of the canal was 3.8 ft depth per day. Omitting two which were between 6 and 7 ft per day, the average was 1.5 ft depth per day. In gravel the loss was from 3 to 7 ft depth per day; in sandy soils 1 to 2 ft; in sandy loam and firm compact alluvial soil 0.2 ft to 1 ft depth per day. These canals varied in depth from 2 to 8 ft.

The common remedies for loss by seepage are silting, puddling and lining with concrete. Excessive losses are likely to be in some short length. Good results are reported to have been obtained by producing stagnant water, which is then made turbid by dumping pulverized clay or other fine material. If the canal water is normally turbid, slack water may be formed by a temporary weir and silting encouraged at the leaky length. A more effective method, but more expensive, is to puddle the bottom and sides with clay when the canal is drained. It may be necessary to protect the puddle from erosion by a layer of coarser material. Where the saving will warrant the expense, the canal may be lined with concrete, as has been done in the case of numerous canals in California.

Canal Linings. Power canals in earth are frequently lined either with timber or concrete to reduce the friction and assure permanency of the cross-section. The timber lining consists of mud sills laid at right angles to the direction of flow and planed plank flooring spiked to the mud sills. The

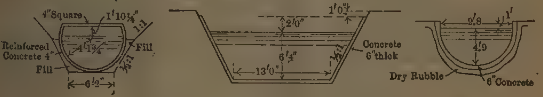

Fig. 68. Three Types of Concrete Lining.

mud sills may rest upon and be held down by bearing piles or be held down by rods to masonry anchors. Fig. 68 shows linings used in the west.

If the ground is very firm, concrete may be laid upon it without other support; in very soft ground bearing piles may be necessary, care being taken, however, that the concrete is in contact with the ground. The concrete should be deposited back of very smooth forms in order to get a smooth surface. For irrigation canals the concrete-lined canal not only costs less to maintain, and prevents loss of water by seepage, but the first cost is often less than for an unlined canal, for the allowable velocities may be from two to four times as great and the section correspondingly smaller.

For the Tieton Canal (left-hand cut of Fig. 68) the reinforced concrete lining was molded in steel forms in sections 2 ft long which were later transported on cars to the canal and set in position by derricks; each section weighing about 1800 lbs was 4 in thick, of gravel concrete reinforced by ⅜ in corrugated rods 4 in apart. Each section was stiffened by a 4 in by 6 in crossbar reinforced by two ⅜ in rods. The molds were removed after about 3 days and the section allowed to harden for at least 30 days, during which time it was frequently sprinkled. The sections were set in place about 1½ in apart and immediately backfilled with earth which on the lower quarter was selected and tamped in from the ends with the greatest care; above this the backfilling was placed from above. The 1½ in space between sections was later filled with rich concrete of fine aggregate which would pass a ½ in ring. The joint was rubbed smooth on the inside before the joining concrete was completely set. The canal has a fall of 8.71 ft per mile and was designed to have a capacity of 300 second feet. A test in the completed canal gave a value of .012 for the coefficient n in Kutter's formula. The gross cost, exclusive of excavation, of 13 000 ft of the concrete lining was found to be $5.80 per foot.

SHAFTS AND BORINGS

25. Timbered Shafts

Timbered shafts are sunk vertically by mining much the same as a heading is driven horizontally. A frame of four waling timbers joined at their ends, forming a rectangle, is laid out on the ground. Outside are driven vertica polings or sheeting; inside, as the sheeting is being driven, the earth is excavatec to a little above or a little below its lower end, depending upon whether the ground is soft or hard. As soon as the excavation is from 2 to 5 ft below one frame a new frame is placed, and so on to the depth of the length of the sheeting; a new frame is then set with clearance for a new set of sheeting. If the shaft is to be shallow it may be started large enough at the top so that the sheeting may be vertical, and the shaft reduced in size by the thickness of the timbering at the bottom of each set of sheeting, which may be from 10 to 20 ft long, as in Fig. 69*a*. If the shaft is to be deep, the sheeting will ordinarily be 5 or 6 ft polings, as in Fig. 69*b*.

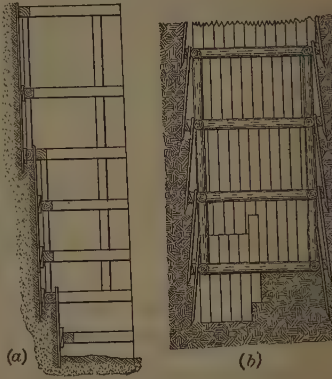

Fig. 69. Timbered Shafts

The main thing to be avoided in shaft sinking is the starting of a general movement of the earth. The great danger is that cavities will be left or formed back of the timbering or that the timbering tho not slack will have to deflect to develop resistance and a small progressive movement of the earth will be started which may extend to the surface. T precautions are, if possible, to allow no cavity to form, securely pack any accidental c and to wedge all timbering tight against the sheeting so that it will develop resistance bef the sheeting begins to move. Perhaps the greatest danger is in water-bearing ear where leakage is liable to bring into the shaft earth in such small amounts as not to noticeable but which may form cavities back of the sheeting in time.

In rock shafts the principal use of timbering is to prevent the falling of loose pie from the sides of the shaft, endangering the workmen below. If the rock is fairly go the timbering is usually kept from 10 to 30 or 40 ft behind the excavation. It is not uncommon practise to place the permanent lining, usually of concrete, in short leng 40 or 50 ft above the bottom of the shaft as the work of excavation progresses.

The method of open excavation and timbering or otherwise lining the shaft as sink progresses is no doubt cheaper, where practicable, than any other method that has b devised, but when quicksand or other soft material is encountered or where rock yield too much water is encountered, the method may be either impossible or impractica For such cases various devices have been used, notably caissons sunk by the aid of c prest air, drop shaft, freezing process, and under-water boring.

Shafts by caissons are frequently used in tunnel construction for railroa The depth of comprest air work is limited by the pressure at which w becomes either two expensive or too dangerous. After a depth of 70 ft be water is reached the cost of labor in comprest air increases very rapidly account of both greater wages and shorter hours. Very little caisson w has been done under heads of over 100 ft.

26. Drop Shafts

Drop shafts are sunk by building a heavy lining, usually circular, upon the surface, and then excavating the earth inside, allowing the structure to settle slowly into the ground. Drop shafts have been used in a great variety of places, from small wells a few feet deep to mine shafts 20 ft in diameter and over 500 ft deep. The shell or lining may be of timber, masonry, brick, reinforced concrete, cast iron or steel.

Several very large drop shafts of moderate depth in water-bearing soil have been built circular of brick masonry provided with a cast-iron shoe or cutting edge at the bottom. A large number of small drop shafts, having steel plate shells, have been sunk for foundation work. Most drop shafts for deep mines have had shells of cast-iron rings with, in some cases, steel shoes for cutting edges. The excavation in some cases has been by hand, but, usually, drop shafts are in water-bearing strata, often in quicksand, and the water is allowed to fill the interior while the earth is removed by under-water excavators, such as chain-bucket dredges, grab buckets, and sand pumps.

In moderate depth shafts the weight of the lining is usually sufficient to overcome friction on the sides. In the case of deep shafts this is not the case, and the lining must be weighted with pig iron or sand or be forced down by jacks. Water or air jets which may be forced up along the exterior surface have been used to reduce friction on the exterior, but it has frequently been necessary to abandon the sinking of the first shell and proceed with a lining of a smaller diameter sunk inside the outer lining, which will be subject to friction only below the depth of the bottom of the exterior lining.

The cost of drop shafts is often less than sinking by comprest air, the freezing process, or the boring method. The method is, however, less sure than any of these. In the drop-shaft method the lining is very liable to be distorted, and in some cases ruptured, due to drawing in material from outside the lining, forming cavities, which results in unequal pressures.

27. Freezing Process for Shafts

About 60 shafts, mostly in northern Europe (France, Germany, and Belgium), were sunk up to 1910 by the aid of the freezing process. The general features of all cases are indicated by Fig. 70. Vertical pipes are sunk, usually forming a circle in plan, completely surrounding the site of the proposed shaft; inside each pipe is placed a smaller pipe, called a circulating tube, opening into the outer pipe at the lower end. These circulating tubes are all joined together at the top by a pipe known as the circulating ring. The freezing pipes are joined together at the top by a similar ring called the collector ring. Cold brine at a temperature of from $-10°$ to $-30°$ Fahr is then pumped into the circulating ring and down the circulating tubes, back up the freezing tubes to the freezing machine.

The freezing pipes are put down by one of the well-known boring methods. Originally the casing of the bore hole was used for the freezing pipe. On account of the difficulty of closing the lower end of the pipe and making all joints of the casing water-tight, in all later work the freezing pipes are put together and tested on the surface and then lowered into the bore hole, after which the casing is withdrawn. The freezing pipes are from 4 to 6 inches in diameter, the circulating pipes from 1 to 1½ inches.

In the center of the shaft an equilibrium pipe is usually sunk. This pipe is kept open, as a vent, for the escape of water forced out of the interior mass by the expansion of the freezing material; it is sometimes necessary to keep this open with a steam pipe, because rock or clay strata will freeze much faster than quicksand and possibly congeal to the equilibrium pipe and freeze it before the lower sand strata are frozen.

It is very difficult to keep deep bore holes for the freezing pipes from departing from the vertical. Long freezing pipes are very likely to spring a leak from contraction at low temperatures. Both these considerations have led to the attempt to do the shaft in shorter lengths, say 150 ft in height. The time required for freezing a solid wall about the shaft site will vary with the character of the strata, size and distance apart of the freezing pipes, and the temperature at which the brine is maintained. The freezing

usually continues from 4 to 10 months or longer. After an ice wall has been formed around the site of the shaft, the shaft may be sunk by hand methods and lined as the excavation progresses or it may be sunk as a drop shaft.

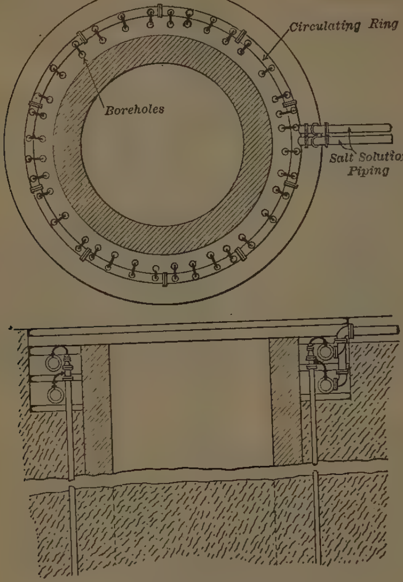

Fig. 70. Freezing Process for Shafts

28. Shaft Sinking by Borings

The Kind-Chaudron System for sinking shafts in water-bearing r
strata is almost identically the same method as ordinary well drilling ex
that it is on a very large scale. In Fig. 71 a very large chopping bit or tre
is seen at *a*, which may be from 10 to 15 ft in diameter, and weighs f
30 000 to 50 000 lbs, and which cuts a hole the full diameter of the sh
b are rods, usually of wood, each about 65 ft long, connected by iron li
c is a bar in a swivel joint and screw connection by which the tool is rot
and lowered slightly between the blows, *d* is a walking beam which a
nately lifts and drops the trepan, and *e* is a steam cylinder which operate
walking beam. The shaft is completely filled with water during sin
A small trepan is used alternately with the large one, and bores a pilot
usually about 1/3 the diameter of the shaft, into which the choppings
the large trepan fall and are removed by a grab bucket.

After the shaft is drilled, sometimes to a depth of 1300 ft, a water-tight cast-iron
or tubbing is then sunk inside the bore and sealed at the bottom. The sealing

bottom is accomplished by building what amounts to a great stuffing-box. The packing used is moss.

In sinking the tubbing, which sometimes weighs several million pounds, the first rings are suspended in the top of the shaft from beams. Rings are added on top until the tubbing, which is provided with a bottom, reaches the water surface; the whole thing is then partially and later completely water-borne, after which it is sunk as the rings are added by admitting water to the interior. On reaching the bottom the great weight bearing upon the moss in the packing rings presses it against the sides of the rock and makes a water-tight joint. There is then an annular space above the moss box between the tubbing and the rock, which must be filled with either grout or concrete. After this is placed and set, the shaft is pumped out, the false bottom removed, and sinking continued in the impervious strata below.

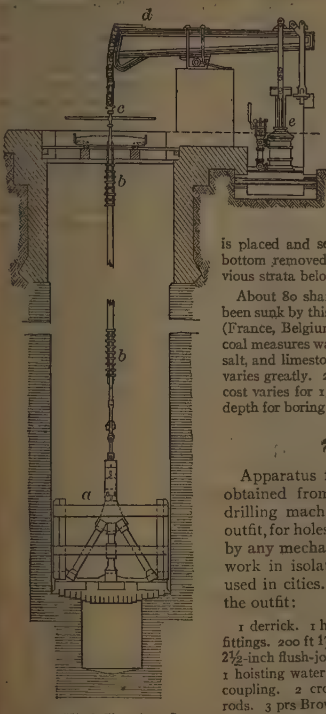

Fig. 71. Kind-Chaudron System

About 80 shafts from 300 to 1300 ft in depth have been sunk by this method, nearly all in northern Europe (France, Belgium, and Germany), where to reach the coal measures water-bearing strata of marl, shale, rock salt, and limestone must be past. The rate of sinking varies greatly. 25 feet per month is a fair average. The cost varies for 15 ft shafts from $500 to $1000 per foot depth for boring and lining with cast iron.

29. Wash Borings

Apparatus for making wash borings can be obtained from companies which make rock-drilling machinery. However, a very efficient outfit, for holes 150 feet deep or less, may be made by any mechanic, which is not only adapted to work in isolated localities but has often been used in cities. The following is an inventory of the outfit:

1 derrick. 1 hand force pump with suction hose and fittings. 200 ft 1⅞-inch drill rods with couplings. 200 ft 2½-inch flush-joint casing. 1 bushing to 2½-inch casing. 1 hoisting water swivel 1⅞ inch. 1 hoisting plug with coupling. 2 cross chopping bits 6 inches long to fit rods. 3 prs Brown's pipe tongs; 2 No. 3, 1 No. 4., 1 pr. No. 3 Brock's chain tongs. 2 Coe's monkey wrenches, 15 and 10 in. 3 Stillson wrenches, 10, 14, and 24 in. 1 15-lb crowbar. 1 pair sister hooks for 1¼-inch rope. 1 16-inch iron hoisting sheave for 1¼-inch rope, with strap and hook. 50 ft 1¼-inch manila rope. 40 ft ¾-inch three-ply water hose. 150 ft 1-inch pipe with couplings. 1 blasting battery with 500 ft No. 20 wire, and supply of exploders and 40 percent dynamite. 1 tool box. 1½-gal oil can. 1 squirt can. 1 pail and cup. 1 pick. 1 spade. 1 ax. 1 hatchet. 3 1¾-inch sand pumps. 2 1¾-inch earth augers to screw into rods. 4 sets reducers 1½-inch to ½-inch. 1 portable forge, small anvil, and small set blacksmith's tools.

The derrick is illustrated by Fig. 72. When set up, the drum and attached wheel are used as a hoisting winch. When folded and brought horizontal, the wheels become a truck on which the whole apparatus is moved to the next hole.

The drill rods are usually 1⅞ inch, exterior diameter, extra heavy pipe, in 5 to 10 lengths, with square female threads on each end and coupling of about 6 inches lo of the same pipe with square male threads at each end. The casi (for shallow holes usually 2½ inch external diameter pipe) may either "flush joint" or "drive cas- ing." The drive casing consists heavy pipe with ordinary sleeve couplings. The flush-joint casing of heavy pipe, each length of which screws into the next, making t joint flush, outside and in. The chopping bit may be screwed in the drill rods, and is sharpened like a ro drill, but is provided with holes to allow t water, forced down the drill rods, to pass o under the bit. A chop- ping bit should never used unless a full force of water is passing thru

The process of sinking holes w flush-joint casing is usually about as f lows: The der- rick is set and a hole is made, usua with a crowbar, to admit a length of casing set a few inc into the ground; into this is serted a 10-ft length of with chopping bit on the lo end and a hoist- ing water sw

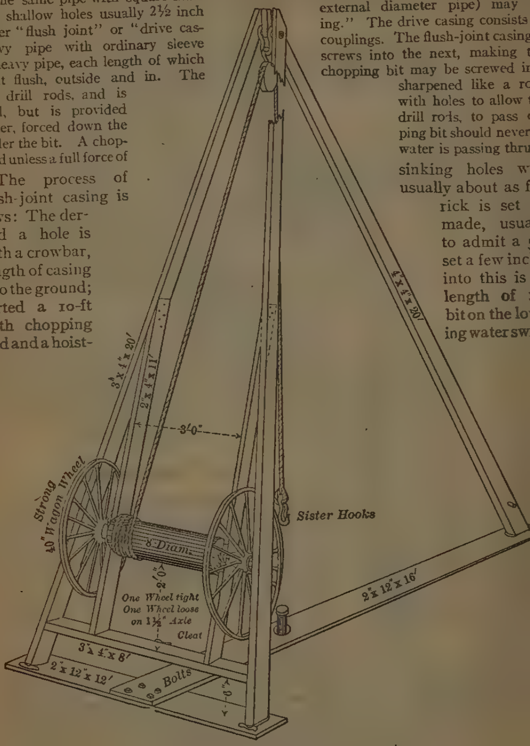

Fig. 72. Derrick for Wash Borings

on the upper end, which is connected to the derrick rope and by hose t force pump. Large pipe tongs are then clamped to both the casing anc Water is turned on, and as the material is washt from inside the casin latter is turned by the pipe tongs and gradually settles into the ground. A length is added to both casing and rods, and then the washing and tu are repeated.

Careful measurement should always be kept so that the relative position of the b of the casing and drill rods is always accurately known. In soft clayey silts and holes may be sunk to a hundred feet or more in depth in this way with very little t

but conditions are seldom so favorable. If hard sand and gravel are encountered, the drill rods are churned as well as turned, by which the material may be broken up, pulverized, and washt out with water and the casing allowed to descend. In general the drill rods work below the bottom of the casing. If loose sand or gravel is encountered, there is likely to be trouble by the binding of the casing. If the sand is a thin stratum it may be possible to wash or even blast out a cavity in it which will allow the casing to pass thru into the next possibly more favorable stratum. Another expedient is to withdraw the rods, cap the top of the casing and attach the water supply to the casing, then to twist or drive, if drive casing is being used, while the water, which is being forced down inside the casing and up the outside, reduces the friction between the sand and outside of the casing. If a casing becomes badly bound so that no further progress downward can be made, it may be necessary to abandon the hole, or having started with a large casing to put a smaller casing inside the first when the latter becomes fast, in which case the friction will only begin at the bottom of the first casing. If the required depth cannot be reached with the second casing, a third and sometimes fourth will be required. When a bowlder or other obstacle is encountered a charge of dynamite is lowered to the bottom of the hole, the casing raised 5 ft or more, depending somewhat on the size of the charge, a good rule being 5 ft for one pound and 2 ft for each additional pound of dynamite used, one-half to two cubic feet of sand is then poured down the hole, the charge exploded, the casing worked down again as quickly as possible, and if the bowlder is a small one it may be found to be shattered so that the casing may be advanced thru it. A single shot often makes no gain when the third or fourth will begin to break the bowlder and show progress, but on bedrock 7 or 8 shots will make practically no progress. If after blasting several times in this way no progress can be made, the conclusion is generally drawn that either bedrock or a very large bowlder has been encountered, and if the purpose of the boring requires it, the hole is continued with a core-boring apparatus. A core boring is the only sure test to determine whether or not bedrock is reached.

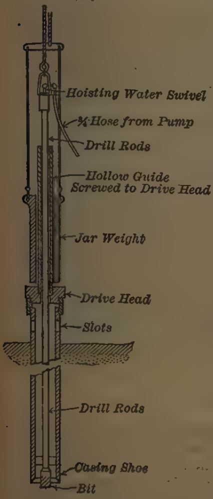

Fig. 73. Drive Casing

For Drive Casing the bottom is provided with a heavy steel shoe or cutting edge, and instead of being simply twisted down as in the case of the flush joint casing, it is driven by using the jar weight (Fig. 73); at the same time the chopping and washing is being done with the drill rods. Working with the drive casing is somewhat slower than with flush-joint casing, but in some cases, such as where considerable depth of loose sand and gravel is encountered, it is preferable. In hard ground the process is to bore or chop with the drill rods a hole some distance ahead of the bottom casing, then withdraw the rods 10 or 12 ft above the bottom and drive the casing down as far as it will go.

Fig. 73 shows one form of apparatus in place, where drive casing is used. There are many possible variations of this; the jar weights are of various sizes and shapes; a second drive head or collar is often screwed to the top of the hollow guides for use in pulling the casing. The jar weight hammers upward against this collar; at the same time the casing is turned with pipe tongs if possible. It is sometimes necessary, however, to clamp a yoke on to the casing itself and hoist on this yoke with jacks. When flush-joint casing is used, the drive head is seldom necessary, and the joints of the casing will not stand much driving.

To Obtain Samples of the material past thru by the drill the wash water is caught in a bucket after it rises to the surface thru the casing, and

the sediment is allowed to settle. Water should not be allowed to continu running into the bucket after it is once full, for it will wash out the clay an leave an unrepresentative sample. Such samples are often misleading a to the true nature of the material in place. A drive sample may be obtaine by attaching to the bottom of the drill rods a sample barrel consisting of pipe open at the bottom and provided with a small vent hole in the side nea the upper end but plugged at the top to prevent the weight of water in th rods from forcing out the sample. This may be lowered and driven int the material which is removed from the sample barrel after being raised t the surface. Samples obtained in this way are much better than wash sample but have the disadvantage that they have been considerably compacted in th taking, and unless the sample barrel is driven only a short distance into th material it may be doubtful from just what elevation the samples com When the material is sand, samples may be taken or the casing cleane out by using an ordinary sand pump which is simply a length of pipe pr vided with a foot valve. This is churned up and down in the hole un filled with sand and water.

An auger may be screwed to the bottom of the drill rod and lowered into the hole a bored into the material at the bottom. If the material is not clean open sand it w remain in the helix of the auger and come to the surface with it. In soft clayey ma rials it is often possible to use drive casing in connection with an auger instead of usi water and the wash method. A hole is bored ahead of the bottom of the casing, wh may then be driven down after the auger has been lifted well above the bottom.

The cost of wash borings is variable, depending on the character of the material pe trated. At present (1919) all costs are unstable and pre-war costs give the best co parison. To these the prevailing factor may be applied to give present day pric For holes up to 200 ft. deep in soft ground, such as silt and clayey sands the c of well-managed work was $0.25 per foot and less under very favorable conditio Where the ground was running sand or hard earth without boulders, the price ran fr $0.50 to $1.00 per foot depth. Where boulders or other obstructions were encounte the cost was from $1.00 in ordinary cases to $4.00 or $5.00 per foot. The above pri were for favorable conditions on the surface and enough work to perfect an organizati If the location were unfavorable, say in a swamp where staging would have to be bu or if water were not available, or if the conditions were otherwise difficult, the cos overcoming the difficulties would have to be added. For jobs involving only a few ho the cost of moving the apparatus to the ground and organizing the work may m than double the above prices. For deep holes, say between 800 and 1,500 ft. deep, cost is much increased. A larger plant with steam or other power must then be use

Subaqueous borings are made upon the ice, or from a platform built on piles, or use of a floating pile driver or from a catamaran.

30. Core Borings

The Diamond Drill consists of a short length of soft iron tube calle "bit," into the lower edge of which black diamonds are set. This bi screwed into the bottom end of another tube called a "core barrel," wh in turn is screwed to the hollow drill rod. A casing is sunk thru the overly earth to the rock surface by wash boring; inside this the drill rods w bit attached are placed and then rotated and prest down by the dril machine; at the same time water is forced down thru the drill rods and and comes to the surface outside the drill rods, carrying with it the r ground to a powder by the diamonds and bit. At intervals the drill are pulled out of the hole, the core removed from the barrel, the bit inspec and the operation repeated. Diamond drilling, and especially the ar setting the diamonds in the bit, can be learned only by experience. All can be done here is to call attention to some of the difficulties and met

of overcoming them. The first care should always be that an ample supply of water is being forced down the drill rods to the bit at all times; the second is to use every precaution to see that the space outside the drill rods does not become clogged by either borings or sand washing in around the top or bottom of the casing.

The difficulty most often encountered arises when seamy rock is met. Sometimes it happens that the water forced down the drill rods flows away thru seams, carrying drillings with it. If drillings are carried into a seam sloping upward, they are likely to run back into the hole and pack around and bind the drill rods when the flow of water is shut off. Small pieces from the wall of the hole of seamy rock are likely to fall in and wedge the drill rods. A single bad seam may often be stopt by pouring sawdust or horse manure into the hole; the escaping water carries this into the seam and clogs it. The second method is to drop balls of soft neat cement mortar down the hole and after it has hardened proceed with the drilling. It is usually wise to treat all seamy rock in this way and drill carefully and remove drill rods relatively often. It is sometimes possible to blast or chop with a chopping bit and sink the casing thru a loose seamy layer of rock. Frequently the hole is reamed out with a special tool and the casing driven down thru the seamy rock.

It is a good rule to let the water run a little time after stopping the drill to clean out the hole and take careful measurement of the position of the bit. In lowering the rods again, if the bit does not reach the original position, the water should be turned on, and if then it will not sink to position without drilling. the bit should be raised and the hole cleaned out with a chopping bit to a smooth clean bottom.

Shot Drilling is done in much the same way as with diamond drills, and about the same rules apply; the difference being that instead of diamonds being set in the bottom of the bit, hardened steel balls are fed down with the water inside of the drill rods, and are rolled around under the edge of the rotating bit and wear out an annular ring the same as cut by diamonds. It has an advantage over diamond drilling because the apparatus is less expensive both to buy and to operate. It takes a much larger core, which is a great advantage in well drilling, and for prospecting usually gives a better sample because the large core is not so liable to break and crumble. On the other hand, shot drilling is usually slower than diamond drilling and it has been mostly used for vertical holes.

The cost of diamond drilling varies greatly with circumstances. In the softer rocks like limestone, for holes 200 ft deep or less, taking 1¼-in cores from 1¾-in holes, the rate of actual drilling will vary from 1 to 3 ft per hour. Delays will average from 50 to 200 percent of time of actual drilling, and moving from hole to hole will usually take one or two days. Pre-war costs varied from $1 to $3 per foot. The present (1919) costs will be more than double these prices. For harder rocks, such as granite, the cost will be 50% greater than for limestone.

31. Test Pits

Test pits are sunk to determine the character of the earth as a preliminary to more expensive operations. If deep, the method of work is the same as already described for timbered shafts. One test pit is usually considerably more expensive than several wash borings, but it is worth much more in the reliability of the information which it gives. A combination of test pits and wash borings often yields the greatest amount of reliable information for a given outlay; the borings may locate the strata with sufficient exactness, while one test pit to every ten or twenty borings will show the character of the strata.

As the earth is excavated from the test pit, the different kinds of material should be placed in separate piles, and the bowlders and smaller stones in each kind separated. It often happens that workmen in digging a test pit will pile the dirt in a single pile and cover up all the bowlders. While the walls of a test pit generally show the character of the material, they do not give a correct idea of the amount of bowlders likely to be encountered.

TUNNELS

32. Tunneling in Earth by Mining

The Elementary Operation of Mining is illustrated in Fig. 74. Starting with the face of earth which is to be mined, sharpened boards P, called polings, supported by the cross timber C, are driven into the earth. Under the protection of the polings the earth is excavated. The excavation is advanced beyond the end of the first polings by erecting another cross roof timber, C_2, and starting new polings and repeating the operation indefinitely. The mining of soft ground is largely a multiplication of this elementary operation. The sides of the excavation may be treated in the same way; small headings may be enlarged to full-sized tunnels by opening the sides by the same process. In principle this elementary operation covers all conceivable requirements of protecting the sides and roof of a working where pressures are within the strength of the timbering. But there is always exposed a face F which must remain unprotected, at least for a short time, and here is where mining troubles begin.

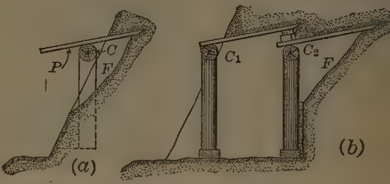

Fig. 74. Mining in Earth

The angle at which an exposed earth face will stand depends: first, upon the nature of the earth, in general, clay standing steeper than sand, and coarse sand steeper than fine sand, and a mixture of clay with coarse sand or gravel being better than either alone. Second, upon the amount of water present. Dampness will increase cohesion, but as complete saturation is approached the angle becomes flatter. If sand besides being completely saturated has an unbalanced head of water, that is, if the head or pressure of water in fine sand exposed to the air is greater than the air pressure, then it is quicksand and will take nearly a horizontal slope. Whatever the material, its thoro draining is of the greatest importance for successful mining. Third, the length of time exposed. Time is an important element in tunneling. Some of the most unstable materials will stand even vertical for a little while, so that a small vertical face may be exposed and a breast board quickly placed. Clayey earth sometimes may move so slowly that the excavation may be made without the protection of the poling, which may later be simply put up against the roof and supported by timbering which will be thoroly loaded later. Fourth, the area of the face exposed. A small area exposed will often stand vertical for a long time when a larger one would cave quickly. Fifth, the distance below the earth surface. By the ordinary accepted theory of earth pressures the horizontal thrust of earth is a function of the vertical pressure or distance below the surface. But when small areas are exposed, dry or only damp earth will arch across the area, so that depth does not usually appreciably affect the angle at which the exposed earth face will stand until some time has elapsed. The arching cannot be depended upon in wet running material. Sixth, the amount of agitation the earth has received. Earth which may be stable in its natural state may be very treacherous after it has been moved. The fear of starting a general movement of the earth makes miners thoroly pack all voids back of supporting timbering and use the greatest care to prevent the starting of a run.

Timbered Headings. In all methods of soft-ground mining the face is opened with a heading varying in cross-section according to the material penetrated from a one-man burrow to full width and 7 or 8 ft high and any length (Fig. 75). The heading timbering consists of posts P, caps C, poling boards p, and breast boards b. If the ground is stiff the face of the heading is cut down straight at nearly the forward end of the polings and new posts and a cap are set. If the ground is soft a small excavation, say two feet

high, under one or two polings is made and a short board is quickly set vertical under the end of the polings and acts as a combined breast board and prop for the poling. This is repeated under all polings. As soon as all short vertical breast boards are placed a new cap is set supported by short posts. The remainder of the face is then worked down, usually with horizontal breast boards, to the bottom of the heading.

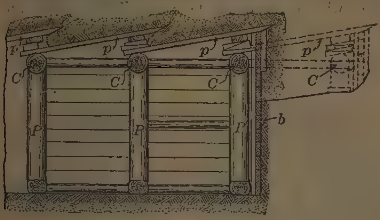

Fig. 75. Timbering Headings

33. Methods of Soft-Ground Tunneling

Small bores are driven by simple headings, large ones are worked in a variety of ways which have been classified in general according to the country in which the method originated, as English, Belgian, German, Austrian, and Italian. Obviously the classification tho widely accepted is far from strict, because each method has many variations, nor has the use of any of the methods been confined to the country for which it is named.

English Method. The entire section is removed in short lengths, usually from 12 to 20 ft, in advance of the permanent lining already built, as shown in Fig. 76. The masons and miners alternate in the possession of the face, and the work of excavation and building the masonry is uninterrupted until each is complete for the length. A small drift in wet material is commonly driven at the bottom of the tunnel prism from end to end of the

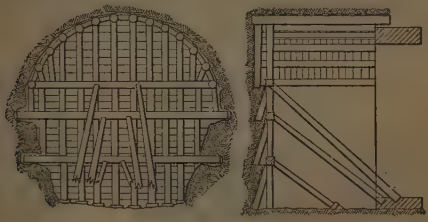

Fig. 76. English Method

tunnel, both for the purpose of furnishing good drainage facilities and for the establishment of the alinement below ground; also it allows the tunnel to be attacked at several points. The main attack on the face, however, always begins at the top of the section with a heading which in stiff material is often taken out without timbering but in softer material is timbered. Two roof bars are then placed in this heading with their forward ends resting on posts and their rear ends supported on the completed masonry lining. Transverse polings are then driven over these bars. The heading is then widened out under the transverse polings for the length of the roof bars, vertical breasting boards placed under the transverse polings and new side bars are placed; when the ground is stiff enough the polings are not driven over the side bars

but placed against the earth roof after excavation as in Fig. 77. This operation is continued down the sides as far as required by the nature and pressur of the ground, sometimes to the bottom, while at the same time the face i securely breasted and back-strutted to the completed lining. The miner now give way to the masons, who construct the length of lining within th completed timbering, and the operation is repeated. If the roof bars ar not too firmly gripped by the overlying material, the lagging is blocked u on the masonry and the roof bars are barred or pulled forward by jacks an used over again.

This method as a whole is best adapted to very firm material, but has been used wit success where the ground was heavy and wet. The Saltwood tunnel on the South eastern Railway between London and Dover was built thru greensand, which whe disturbed was a quicksand and not workable by the English method without being draine A small bottom drift driven thru from end to end drained off the water, care being take to confine the sand, and the main construction proceeded by the usual English metho The advantages of the system are the large open area in which the masonry lining ca be built up in one operation and the facility with which the spoil cars can be handle The disadvantages are that the excavators miss alternate shifts while the masons are work, thus delaying the work, and that the timbering is partly carried on fresh masonr The fact that the full section is excavated at once limits the use of the method to fair firm material.

Belgian Method. The upper half of the tunnel is excavated much th same as in the English method except that the excavation is frequentl carried considerable distance ahead of the masonry, and as the method most often used in firm ground, the transverse polings are frequently n driven over the roof bars, but instead are placed as in Fig. 77, against th earth roof after the excavation has been made for a side roof bar.

A cut is then excavated thru the center half of the tunnel to the invert, leaving a ber on either side to support the arch of the tunnel lining. From this center trench narro cuts are made at intervals to the side and the masonry arch is underpinned; the cuts a widened and the underpinning extended until a complete side wall is built, and final the invert arch is turned. The main advantage of this method lies in the fact that is possible in firm material to push the work from many points of attack, the successive developments of the tunnel, the heading, its enlargement, the masonry arch, the underpinning operations, etc., all being carried on simultaneously at different points along the tunnel. When the work is carried on with this system of successive development the timbering is arranged as in Fig. 77, to permit the ready access of the spoil cars to the furthest workings. This method is adapted to firm material, but may be used, with considerable risk however, in the heavier soils by shortening the timbered section, in which case it loses its chi economy mentioned above. The disadvantage of this method is that the arch is fir carried on earth and then on timbering, both liable to unequal settlement with the co sequent risk of fracture in the key. If it becomes necessary in very stiff material to blasting, danger to the temporarily supported arch is increased.

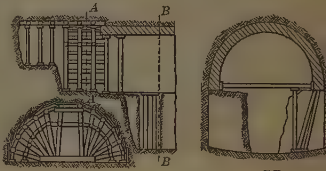

Fig. 77. Belgian Method

German Method (Fig. 78). The invert is put in last, but the rest of t lining is built from the bottom up, but without removing the center core earth. In its most characteristic form the method consists in driving tw bottom headings, one at the foot of each side wall. In these the side wa are built as high as the roof of the heading will allow. On top of these hea ings two others are driven and the side walls brought up to their roofs, a

so on until the two side walls are joined in a center heading at the top. Practically the number of headings one on top of the other is limited to three, with a top center heading which is widened out to the upper side headings. Usually only two headings on each side have been used, which brings the sides up to the springing of the arch; above this the entire section is taken out by widening out a center top heading down to the side heading by the same plan as in the Belgian method.

The most notable example in America of a tunnel done by this method is the Baltimore Belt Line tunnel. There only one heading on each side was driven; the center top heading

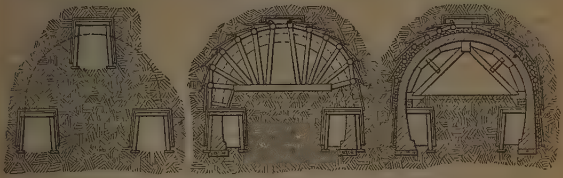

Fig. 78. German Method

was widened out down to the spring line and pits sunk down from this large upper working to the side walls which had been built in the side bottom headings. The sequence of operations is shown in Fig. 78. The chief advantages of the German method are the saving in timber due to large cores of earth being used to brace against; the cheapness with which the central core, a relatively large mass of earth, can be removed; the fact that only small areas are opened, thus increasing safety in soft materials, and the fact that the masonry is built continuously from the bottom upward. The disadvantages are that the restricted area available for removing spoil from the small headings causes a great amount of inconvenience and interference with the masons and timbermen; ventilation in these small passageways is very difficult; and there may be danger in some cases of movement of the center core when used as an abutment for strutting.

Austrian System (Fig. 79). The essential feature is a center cut from top to bottom of the tunnel with timbering as in *A-A*. The cut is widened out

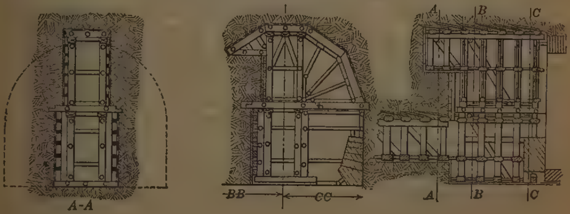

Fig. 79. Austrian System

from the top as indicated in section *BB* and timbered with segmental arch timbering up to the time the sills are placed above the horizontal diameter and is supported by the central frame. The poling boards over the segmental arch timbers are all driven parallel to the axis of the tunnel, and the widening out is done in short lengths, working practically the full face. The variations

in the method, depending largely on the character of the material, are prac cally all in the method of making the central cut. A top heading may driven, which then may be cut down in short lengths to the invert of t tunnel, or a bottom heading may be driven, then the top heading, then the co between the two removed in short lengths, the short posts of the top headi being replaced by long ones resting on the cap timbers of the bottom headi

Mr. Rziha, the eminent Austrian engineer, who did much to develop the system a who is its principal advocate, recommends the bottom heading to be first driven fr end to end of the tunnel, then enlarging this to about half the height of the tunnel a placing in it all of the lower half of the timbering required in the center cut, section C Fig. 79. The upper half of the center cut is then taken out in a top heading and timbers placed as in Fig. 79. The excavation of the remainder of the full section is th done, being kept from 10 to 20 ft ahead of the masonry. The masonry lining is beg at the bottom and carried up continuously, the reaction of the timbers being transfer to the masonry as they are reached. The advantages of the method are that the timb ing is strong, that the timbers are in short lengths and easily handled, and that the w may be attacked at a number of points and each operation carried on continuously. disadvantage is its expense.

The Italian Method (Fig. 80) was especially developed for very s and treacherous ground and is strictly an emergency method. The succ

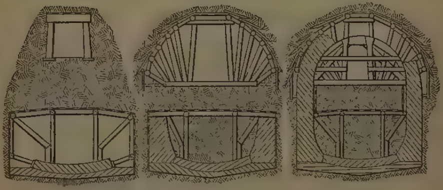

Fig. 80. Italian Method

of the system depends on the fact that only small areas are opened and material can thus be well controlled. A bottom center drift about ⅓ height of the tunnel is started and driven a very short distance, 6 to 10 after which it is enlarged to full width of the tunnel, very heavy and ti timbering being used. The invert and as much as possible of the side w are constructed in the drift, and the open area is backfilled with earth. center top heading is then driven and enlarged to full width and about ⅓ height of the tunnel, leaving a bench the full width of the tunnel and someth less than ⅓ the height. This upper section of the tunnel is very hea timbered and braced; connection between the upper section and the maso walls already built is made by trenching thru the bench, after which the s walls are completed and the arch turned as one operation. The cen bench and the backfilled earth are excavated inside the completed tunnel.

The chief advantage of this method is that the workings are so small as to be rea braced and maintained in very treacherous ground. The disadvantage is the exces cost. Modern shield methods would now be used for all tunnels for which this me was designed, except possibly where only a short length of very treacherous groun encountered.

American Method (Fig. 81). Here the segmental arch timbering and posts only are used and no interior struts. It has been much used in rock; it is specially adapted to fairly firm material. In rock a top head is driven and timbered with posts and caps. A short length is widened

down to the springing line of the arch, the sills are placed and the segmental timber arches erected between the posts and caps, which may then be removed. In earth the face is opened by a top heading, which is poled and timbered in the usual way. In the space between two bents of the heading timber the crown segments of the timber arches are set in position and held in place temporarily by secondary posts or by strips of scantlings spiked to the main posts as shown in Fig. 81. A short length of from 2 to 6 feet, depending on the nature of the ground, section *A-A*, is then widened out without polings or other roof support and the segments adjacent to the crown segments are put in position and held by iron dowels and a short prop. If the segmental timbers are not set close together, lagging is inserted above the timbering and cavities between the lagging and the earth are packed. The widening out for the next timber is done in the same way down to the sill. After the two sills are placed the roof timber is completed and the bench is then removed.

Fig. 81. American Method

During each operation the sill timbers are underpinned by any one of the several different methods. If the material is very firm a longitudinal cut is made in the bench, leaving a berm on which the sill rests, and the counterforts are excavated at intervals under the sill and posts placed. If the material is too soft for this, pits are sunk at intervals, and first short posts and later, if excavation has proceeded, long posts are placed to support the sills. If the material is firm enough, as for example rock, the sills or wall plates are set in niches at about the springing line and no posts are used. The number of segments in the arch varies from 3 to 7 or even more. It can be used successfully in firm material which will stand for a short time without support. This type of timbering has been used in American tunnel practise as a semi-permanent lining, but is usually replaced within 10 to 15 years by masonry. The chief advantages of this method are in the large open area within which the masonry lining can be built continuously from invert to crown and the saving of timber.

34. Tunneling in Rock

Top Heading and Bench Method. Tunneling in rock by the top heading and bench method, shown in Fig. 82, is the prevailing practise in America. The heading usually comprises the upper 7 or 8 ft of the tunnel prism and is driven with compress air drills mounted on vertical columns by one gang, while a second gang with tripod drills works on the bench. In the more recent practise the bench is kept quite close to the heading, so that the mucking of both heading and bench is done together, the blasting being so arranged that considerable of the heading excavation is shoveled into spoil cars by hand, or, if the tunnel is large enough, by air-operated steam shovels. What remains in the heading is handled directly to cars with wheelbarrows and a movable platform at the bench.

Fig. 82. Top Heading and Bench Method

Bottom Heading Methods in Rock Tunnels. There are two general types of bottom heading methods in use in Europe. The first is the method used notably in the Loetschberg and Simplon tunnels, in which a bottom heading is driven in advance; at intervals, in the Simplon every 164 ft, small upraisers or shafts are excavated to the top of the tunnel and top headings driven in both directions and enlarged laterally. The next step is the removal of the bench between the top and bottom headings and finally the side benches. The bottom heading is kept clear for the muck cars by closely timbering its roof. In the second type, a bottom heading is driven in advance and at intervals break-ups are made to the crown of the arch. The material of the full upper portion of the tunnel is shot down upon a heavy timber platform which acts as a roof for the bottom heading.

Outside Pioneer Heading Method. By this method a heading is driven entirely outside the main tunnel which is to be built. From this heading drifts are driven to the center line of the main tunnel and from the ends of these cross drifts, headings are driven along the main tunnel, usually on its centerline. As soon as one of these center headings reaches the working being carried on from the main portal, radial holes are drilled from it to the limits of the cross section of the main tunnel. These holes are loaded and the rock is shot down in front of a steam shovel working inward from the main portal.

The advantage of the method is that the drilling operations do not interfere with the work of the shovel because the drillers and the air mains to the drills all enter from the side heading.

Drilling Diagrams. Fig. 83 shows the method of spacing the drill holes in the headings of several rock tunnels. The practise of setting drill holes normal to the face of the heading is nearly universal in Europe and was used in America prior to the inauguration of the center cut system in the Hoosac tunnel. The depth of holes used in European practise is seldom more than 4.5 ft while in America 6 to 10 or 12 ft depth prevails. In general, the higher speed has been attained in the European practise,

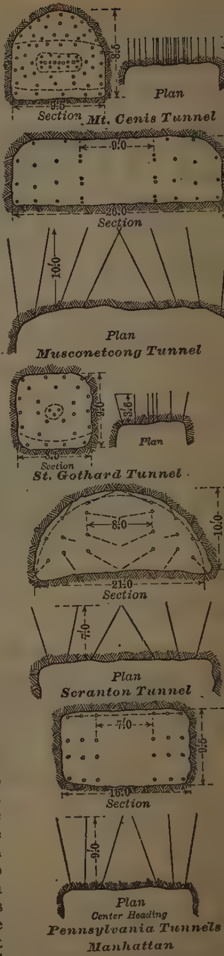

Fig. 83. Drilling Diagrams

with a great number of holes normal to the f ce and from 3 to 4.5 ft deep, but the amount of powder and the cost of driving are greater than where the center cut with deep holes is used. It is not entirely evident, however, that the arrangement of drill holes accounts for the difference, as the higher speeds in the European practise were made where large drills mounted on a heavy c rriage were used instead of the smaller drills mounted on columns as is usual in America.

Mucking is the universal term for removing the blasted rock, called muck, from the tunnel. It is usually done by laborers with shovels. Steel plates are often laid on the floor before the blast; from these the muck is shoveled more easily. Many mechanical muckers have been devised, but none have come into general use except the small steam shovel operated by comprest air.

35. Data Regarding Tunnels

In the following notes the numbers in parentheses refer to the tables on pages 1382 and 1383 and to the numbers within the circles in Fig. 84.

(1) Box, Great Britain. Oölite rock, forest-marble, and Lias marl. Lined with brick 27 in thick at springing line.

(2) Blechingly, Great Britain. Blue clay of Weald. 11 shafts. Maximum progress 792 ft per month, 187 ft per month average for completed work. Hand drills and gunpowder. Lined with brick varying from 22½ to 27 in thick.

(3) Saltwood, Great Britain. Greensand (quicksand before being drained). 12 shafts. Average progress completed work 238 ft per month. Lined with brick in horseshoe section; thickness varies between 22½ and 27 in.

(4) Moncreiffe, Great Britain. Poor rock. Widened and relined in 1902, 88% lined with brick arches 18 in thick on 9-in brick walls.

(5) Lydgate, Great Britain. ¼ of length on curve. Clay, strong shale, rock with veins of shale, limestone, fire clay, and coal. Thickness of arch in shale 2 ft, in rock 1 ft 6 in. 5 shafts. Progress for completed work 52 ft per month. Hand drills used in rock and strong shale; clay and loose shale axed out.

(6) Netherton, Great Britain. Carries a canal. Marl, coarse sand, rock, hard shaly clay, coal, Lias ironstone and fireclay. 17 shafts. Average progress for completed work 294 ft per month. Hand drills used. Lining 22½ in thick in horseshoe section.

(7) Bergen No. 1, Erie Railroad, N. J. Dolerite (very hard trap). Hand drills used. 20% lined with brick arch and stone masonry side walls.

(8) Buckhorn Weston, Great Britain. Kimmeridge clay and veins of loose wet rubble, 5 shafts. Average progress 168 ft per month. Lining 27 to 32 in thick.

(9) No. 6 Union Pacific Railroad, California. Granite. Average progress 1.6 ft finished tunnel per working day, using 4 working faces.

(10) Sand Patch, Pennsylvania. Red sandstone and shale varying from hard to soft. About 50% lined with sandstone masonry.

(11) Mont Cenis. From France to Italy. About ¾ mile on curve. Limestone, calcareous schist, quartz, carbonaceous schist, gneiss and schistose sandstone. Maximum depth below surface 5277 ft. Maximum rock temperature was 80° Fahr. No shafts. Maximum progress one heading 297 ft per month, average for both headings completed 231 ft per month. Cost $272 per lin ft. Hand drilling used for first four years with holes 1.5 ft deep, subsequently 3-in cylinder comprest air drills with holes 3.5 ft deep were used. After first four years 70 to 80 drill holes 1.2 in in diameter in heading averaged 67 lbs gunpowder per round, or about 3.8 per cu yd. Mucking done by hand; horses for hauling. Gas for lighting. Ventilation at first by exhaust from drills, then blowers and bratticing were installed, and finally exhaust bells. 2 rounds were fired in 24 hours. Time of drilling 6 to 8 hours, loading 1.5 to 2 hours, mucking 3 to 5 hours. Lined with side walls of stone and arch which is stone for ½ length and brick for the rest; the thickness is 31½ in.

(12) Baltimore, B. & P. R.R., Maryland. 20% on curve. Soft rock, clay, sand, and earth. 16% tunnel, 84% cut and cover. Hand drills and black powder used. Brick arch 22 in thick; limestone side walls 54 in thick.

(13) Clifton, Great Britain. Mountain limestone, conglomerate, and red sandstone. 2 shafts. Average progress of completed headings 196 ft per month, using 6 faces. 92% by hand drilling, 8% diamond boring machine. Partly lined with 5-ring brick arch on stone masonry walls.

S = Straight, C = Curve, Q = Straight and curved, B & M = Brick and stone masonry, B & C = Brick and concrete, B & S = Brick and artificial stone bricks, T C & M = Timber, concrete, and stone masonry, C & M = Concrete and stone masonry, B C & M = Brick, concrete, and stone masonry.

A = American method, B = Belgian method, E = English method, G = German method, H = Top heading and one bench, K = Top heading and two benches, L = Bottom headings, from which small shafts at intervals are driven to top of tunnel and full width top headings are excavated in both directions. The bench is removed between the top and bottom headings and the lower section of the tunnel is enlarged to full width, M = The full tunnel prism is removed as one operation, O = Cut and cover method, P = Top heading and enlargement, no other particulars are available, R = Bottom headings followed successively by their enlargement laterally and upward, V = Cut and cover and English method, W = Top heading and one bench and English method, X = Belgian and English method, Y = Top heading and one bench and cut and cover method, Z = see description of methods in the notes on pages 1387–1389.

Costs are taken from published accounts in which the elements composing the figures are seldom recorded.

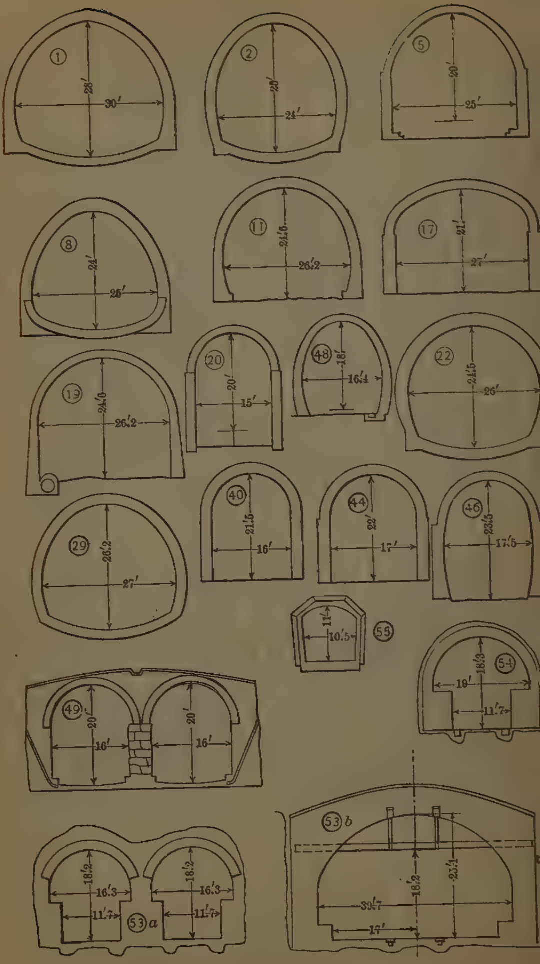

Fig. 84. Sections of Tunnels

(14) Church Hill, Virginia. Miocene clay with infusorial shells. 22-inch brick arch on masonry side walls.

(15) Musconetcong, N. J. Soft ground, limestone and syenitic gneiss. English method in soft ground; top heading and bench method used in rock. 3 shafts. Maximum progress in one heading 144 ft per month, average for whole work 181 ft per month, using 8 faces. 5-in cylinder Ingersoll compress-air drills and dynamite used. 36 drill holes in heading, 10 in bench. Depth of holes 11 ft. 270 lbs explosive per round in heading, 107 in bench. 6 drills in heading, 2 on bench. Spoil loaded into barrows, wheeled to traveling platform at bench, and dumped into chutes over cars. A derrick on the platform handled large bench excavation. Average time of drilling and loading for one round 32 hours. 20% lined with 7 or 8 ring brick arch on masonry walls.

(16) Hoosac, Massachusetts. Hard granitic gneiss, conglomerate, and mica schist. Maximum cover 1800 ft. English method in soft ground. Top heading and bench method in other material. 1 shaft. Maximum progress for 1 heading 184 ft per month, average per month for all faces 194 ft. Holes 2.1 ft deep were drilled by hand during the first 12 years, using 16 lbs of explosive per lin ft of tunnel. During the last 10 years holes 11.5 ft deep were drilled by 12 compress-air drills at each face, and 33 lbs of powder per lin ft of tunnel were used. Spoil loaded into cars, wheeled to traveling platform at bench. Derrick on platform handled large bench excavation. Lined with brick in poor rock.

(17) Bergen No. 1, D. L. & W. R. R., New Jersey. Dolerite (very hard trap). Rend-rock powder used. Brick arch on masonry side walls.

(18) Osakayama, Japan. Soft rock with clay veins. Lining is 2, 4, or 6 ring brick arch on brick side walls. Hand drills. Fans for ventilation.

(19) St. Gothard, Switzerland. Straight except about 500 ft. Gneiss, mica schist, serpentine, and hornblende schist. Maximum depth below surface 5576 ft. Maximum rock temperature 88° Fahr. No shafts. Average progress of single heading 225 ft per month. Sommelier drills used for a few years, then Ferroux 2¼-in cylinder and McKean 4-in cylinder drills with compress-air. Enlargement by hand drills. 6 drills, mounted on a carriage, bored 24 to 26 holes in each heading 2.6 ft to 4.2 ft deep. 29 lbs, 75% dynamite, explosive per round, or about 5 lbs per cu yd, were used in each heading. Horses used in headings, compress-air locomotives in full-size sections. Oil lamps for lighting. Exhaust bells for ventilation. Time of drilling 3 to 5 hours, mucking 3 to 4 hours. Brick arch on rubble masonry walls varying between 17.7 and 29.6 in thick. Altho in rock, was built by the Belgian method.

(20) Mullan, Montana. Treacherous rock. Relined with masonry in 1892. Costs, including engineering superintendence and interest: concrete $8 per cu yd; brick $17 per cu yd. Total relining $50 per lin ft, brick arch 20 in and concrete side walls 30 in thick.

(21) Arlberg, Austria. Mica schist and gneiss more or less rich in quartz. Maximum rock cover 2300 ft. Maximum rock temperature 64° Fahr. No shafts. Maximum progress for 1 heading 641 ft per month, average for single headings 408 ft per month. Ferroux compress-air and Brandt's rotary hydraulic drills used. With Ferroux drills 4.8 lbs of powder per cu yd and with Brandt 4.0 lbs. Lining is mostly between 19.7 and 37.4 in thick, 6% of length not lined.

(22) Severn, Great Britain. Conglomerate, limestone, carboniferous beds, marl, gravel, and sand. Lining of vitrified brick 27 to 36 in thick.

(23) Vosburg, Pennsylvania. 138.5 ft on curve, the rest is on tangent. Red, green, and black shales and red and blue sandstone. Short length earth roof. American system of timbering used. No shafts. Average progress single heading 137 ft per month. In the heading 4 Rand or Ingersoll 3⅛-in cylinder drills bored 12 to 18 holes 9 to 10 ft deep. 3.13 lbs rack-a-rock were used per cu yd excavated. 2 drills and Altas powder were used on the bench. 10% of all the drilling was done by hand. The average amount of explosive used was 1.71 lbs per cu yd of all excavation. No special provision was made for ventilation. Mostly arched with 3 rings of brick. About ⅛ arched with stone 18 to 24 in thick. Side walls of stone 30 to 36 in thick. Stone used is black limestone.

(24) Stampede, Washington. Soft basaltic rock. No shafts. Maximum progress of single heading 274 ft per month, average for two headings 413 ft per month. About 9% with hand drills, the rest with compress-air drills. 31 lbs of Giant and Hercules 45% and 60% dynamite were used per lin ft of tunnel. 20 to 23 drill holes 12 ft deep in heading, 18 in bench. Spoil from heading hauled to chutes at traveling platform at bench by mules. Removed in cars from chutes by small locomotives. Electric lighting. Ventilation by exhaust fans. Concrete side walls and brick arch.

(25) Ronco, Italy. Argillaceous schist with considerable water. 6 shafts. Average progress one heading 231 ft per month, average of completed tunnel 123 ft per month. Brandt rotary hydraulic drills and Ferroux compress-air drills. 0.48 to 0.68 lbs 75% to 78% dynamite used per cu yd. Sheeles system of ventilation. 2 exhausts coupled.

(26) Belt Line, Baltimore. Howard Street Tunnel. Sand with seams of loam, clay, and gravel. 5-ring brick arch.

(27) Little Tom, Norfolk & Western R.R. Seamy gray sandstone disintegrating on contact with air. 1410 ft originally lined with timber. Later relined with brick. Arch made of four rings of brick. Cost of relining complete was $33.50 per lin ft.

(28) Cowburn, Great Britain. Material about ⅓ shale, ⅔ rock intermixt with thin beds of shale. Quite dry. Average progress for single heading, dry shale by hand drilling 299 ft per month, rock by hand drilling 111 ft per month, rock and shale by machine drilling 270 ft per month, rock by machine drilling 199 ft per month. ⅓ excavated with hand drills, rest with Larmuth compress-air drills. 17 lbs gelignite used per lin ft. 2 drills in heading. Horses used in headings and locomotives in finished sections. Ventilation by fan. Arch entirely brick. Side walls ⅔ length stone masonry and ⅓ length brick.

(29) Totley, Great Britain. Hard and soft black shale, coal, fire clay, sandstone, and grit rock. 4 shafts. Average progress machine-drilled heading 242.4 ft per month. 3¼ and 3½ in Schram percussion drills and 3-in Larmuth. Average number drill holes in heading 13.4. Holes 6.2 ft deep. 38 lbs gelignite per round. 2 drills in heading. For clearing heading of fumes and dust, a jet of compress air and spray of water were used. The arch is entirely brick and the walls are brick for 70% of length and coursed masonry for 30% of length.

(30) Niagara Falls Power Co., New York. Limestone and shale with slaty seams extremely wet. Progress 304 ft per month with 5 headings. Rand compress-air drills, 4 to 6 per heading. Dynamite. Electric lighting. Ventilation by exhaust from drills. Lined with from 4 to 6 rings of brick.

(31) Busk, Colorado. Gray granite, disintegrated in places. Maximum progress of single heading 202 ft per month, average completed tunnel 190 ft per month. 3½-in cylinder Ingersoll compress-air drill. Holes 12 ft deep. Electric lighting. Blower for ventilation. 78% lined with timber.

(32) Panir, India. Limestone, clay, and soft sandstone. Average progress single heading 145 ft per month, average whole work 95 ft per month. 4-in cylinder Climax compress-air drill bored 25 holes in heading 3.8 ft deep and 1¾ in in diameter. Dynamite and gelignite were used. The time for drilling one round was 5 hours. 520 ft is one-half lined and 2690 ft is three-quarters lined.

(33) East River Gas, New York. Gneiss, mica schist, veins of decomposed feldspar, and black mud. Maximum progress 101 ft per week on New York side in rock, average 69 ft per week in good rock in each heading. Compress air 15 to 48 lbs per sq in used while in soft material. Good rock not lined; soft material lined with cast iron—see table of cast-iron lining in tunnels, p. 1398.

(34) Tequixquiac, Mexico. Sandstone with lime, soapstone, and conglomerate. Very wet. Progress 18 ft per day in heading. Timbered. Lined with 20-in arch of brick and 18-in walls of artificial stone blocks. Hand drills and dynamite. 6 drill holes in heading 6.5 ft deep. 6 lbs of explosives per round in heading.

(35) Ampthill 2nd, Great Britain. Kimmeridge clay. Progress averaged 6 days to complete 1 length of 12 ft. 1½ lbs tonite per lin ft. Horseshoe section, walls, and arch lined with 33 in of brick; invert 27 in brick.

(36) Cwm Cerwym, Port Talbot R.R. Slight curves at end. Shale, hard clift, fire clay thin veins of coal, and about 500 ft of pennant rock. Originally lined with brick without invert, afterward relined without interrupting heavy traffic. Concrete blocks in invert and cast-iron segments above.

(37) Catesby, Great Britain. Clay. 9 shafts. Average progress for finished work 330 ft per month. Lined with brick 22½ to 31½ in thick.

(38) Boulder, Montana. 150 ft curved at one end. Material penetrated 80% seamy blue trap rock and 20% syenitic bowlders and debris. Originally lined with timber. Later relined with 20-in coarse granite rubble in walls and 4 rings of brick in arch.

(39) Palisades, New Jersey. Hard trap rock with many seams in places. 1 shaft. Average progress 186 ft completed tunnel per month. 24 holes in heading drilled by four Ingersoll-Sergeant 2½-in compress-air drills. 6 drills on bench. A derrick car was used t

handle large stones from the bench. Horses were used at first, dummy locomotives later.

(40) Cascade, Washington. Medium hard gray granite, seamed and wet. Temporary 5-segment timbering used. Maximum progress using two headings 527 ft per month. Maximum progress in single heading 301 ft per month. Average two headings 350 ft per month. Six 3¼-in Rand compress-air drills bored 24 to 28 holes 12 ft deep in heading. 8 drills on bench. Spoil run out in wheelbarrows to a traveling platform at the bench and dumped thru chutes into cars. A six-ton derrick mounted on platform handled large bench excavation. Ventilation by exhaust fan. Electric lighting and electric motor haulage.

(41) Sherman, Wyoming. Solid granite. Top heading and two benches. Heading progress 4.92 ft per day. Drill holes 9 ft deep. 6 drills on 3 columns in heading.

(42) Graveholtz, Norway. Quartzy granite or gneiss. Average progress of finished headings was 263 ft per month. Hand drills used at one end for 2½ years, after which Brandt boring machines and compress-air drills were used. Only about 3% lined.

(43) Barrientos, Mexico. Hard granitic porphyry with clay seams. No shafts. Heading progress 367 ft per month, completed excavation 245 ft per month. 3 Ingersoll Sergeant compress-air drills bored 14 holes in heading 10 to 12 ft deep. 29.3 lbs of 60% dynamite used per lin ft. 3 drills on bench. Small cars were loaded and run to platform at bench, where they were dumped into larger cars. Lined with concrete blocks 28 to 31 in by 60 in deep by 7 ft 8 in long.

(44) Scranton, Pennsylvania. Sandstone and shale. 2 shafts. Maximum progress in single heading 261 ft per month, average all headings 387 ft per month. 3¼-in cylinder compress-air drills and 70% dynamite. 1305 ft not lined, 2717 ft 5-segment timber lining and 725 ft concrete and stone masonry.

(45) Chicago Telephone and Express Subway, Illinois. Stiff blue clay. Full-size excavation. Excavated with spades and draw knives. Compress air used, 9 lbs per sq. in Floor 30 ft below street. Lined with 10 in of 1 : 3 : 5 concrete.

(46) Gallitzin, Pennsylvania. Sandstone and shale, also some limestone, fire clay, and slate. No shafts. Average progress of completed tunnel 164 ft per month. 16 holes in the heading and 11 on the bench 10 feet deep were drilled respectively by 4 and 2 Ingersoll-Sergeant compress-air drills. 2.5 lbs 40% forcite were used per cu yd. An air-operated steam shovel following up at the bench handled the excavated material. Horses were used in the headings and dinky locomotives in the full-size tunnel. Electric lighting. Time of drilling was 8 hours, two rounds being fired per day. Concrete arch 22 in thick and concrete and rubble side walls increasing from 38 in at spring line to 54 in at bottom.

(47) Alfreton 2nd, Great Britain. Gray sandstone, rock, shales, and fire clay with seams of coal. Worked from 5 shafts with no portal headings. The average time of mining a 15-ft length was 19.7 days. Lined with 28 in of brick.

(48) Simplon, Italy to France. Short curves at ends. Mostly very hard gneiss and calcareous rock, also short lengths in green cipolin, disintegrated slate, clay, and mica schist. Maximum depth below surface 9118 ft. No shafts. Maximum progress single heading 685 ft per month, average both headings 440 ft per month. In bottom headings Brandt rotary hydraulic drills, enlargement by hand drills. 83% dynamite and 64% blasting gelatine used in opposite ends of tunnel. 10 to 12 drills holes 4.5 ft deep, 3½ in in diameter, in heading. 2.8 lbs explosive per cu yd. 3 drills in the heading. Time of drilling one round 2.75 hours and the time of loading, firing, and mucking was 6 hours. Steam and compress-air locomotives for hauling. Blowers and water sprays used to keep the tunnel air clean. Both gas and oil for lighting. Lined with coursed masonry of various thicknesses.

(49) Capitol Hill, Washington, D. C. About ⅛ on curve. Gravel and fine sand overlaying hard blue clay. Very wet. 1600 ft in open cut and 2400 ft in tunnel. Separated by lining into twin tunnels. Each tube excavated separately. 2 side drifts at bottom and crown drift excavated in one tunnel. Crown bars 24 ft long placed in top drift and supported by radial struts. As top heading was widened segmental timbering was placed under the crown bars and carried down to posts on concrete footings in the side drifts. The radial struts were removed and the core of earth between the side and crown drifts was excavated with a steam shovel. The lining was placed in this portion of the tunnel and the excavation of the other tube was proceeded with, the timbering for it abutting against the crown bars of the first tube. The arch is brick backed by concrete

of a total thickness of 36 in. The side walls are concrete 72 in thick and the core-wall is stone 48 in thick.

(50) Haversting, Norway. The cross-section is about 270 sq ft. Gneiss with varying amounts of feldspar and quartz. Total progress both ends 114 ft finished tunnel per month. Hand drills. Horses for hauling.

(51) Bergen No. 2, D. L. & W. R.R., New Jersey. Very hard trap rock. Ingersoll-Sergeant compress-air drills. 29 holes in heading 7 to 8 ft deep. 8 holes in bench. Electric lighting. Air-operated steam shovel for mucking. Lined with concrete 24 in thick.

(52) St. Paul Pass, Idaho to Montana. Laminated quartzite with some talc layers. Average progress two headings for four months 576 ft per month. 3½-in cylinder Ingersoll-Rand compress-air drills, 8-in heading and 5 on bench. An air-operated steam shovel used at bench. Excavated material hauled by electric locomotives. Fans for ventilation. Electric lighting. Lined with five-segment timber arch.

(53a) Pennsylvania R.R., twin tunnels under Manhattan from Sixth Avenue to East River. Hudson schist. Two sets of twin tunnels averaging about 4730 ft long. At east end 350 ft excavated as 4 single tunnels and the remainder was excavated as two tunnels from 42 to 52 ft wide and separated by lining into four single tubes in sets of two. 2 shafts for each set of tunnels but no portals. Three methods of excavation used in wide tunnels: double heading, center heading, and full-width heading. Bench was usually 10 to 15 ft behind the face. The maximum progress of a single heading was 206 ft per month, the average for all six headings was 451 ft. The average length of tunnel completed per month was 257 ft. The number of holes drilled varied greatly with the width and location of the headings and averaged between 8 and 9 ft in length. In single headings 4 Ingersoll-Rand 3¼-in drills mounted on 2 columns and in full-width headings 10 drills mounted on 5 columns were used. 1.9 lbs 60% forcite were used per cu yd of all excavation. Air-operated steam shovel followed at the bench. Electric motors for haulage. Blowers for ventilation. Electric lighting. Lined mostly with concrete. Small sections in wet rock have brick arch and concrete side walls. Minimum thickness of lining 22 in.

(53b) Pennsylvania R.R., three-track tunnels under Manhattan. 218 ft long on west end of one set of twin tunnels and 683 ft long on the other. Hudson schist. Sand in the crown at places. Part done in open cut. Lining in open-cut sections concrete thruout with a minimum thickness of 59 in and in tunnel brick arch 56½ in thick on concrete side walls.

(54) Pennsylvania R.R., Bergen Hill Tunnels. Mostly hard trap rock, also 940 ft in decomposed sandstone, shale, feldspar, calcite, and sandstone. The maximum progress of a single heading was 145 ft per month, the average progress was 3.13 ft per day at each face. 8 Rand 3⅝-in drills on 4 columns drilled 32 holes 12 ft deep in the headings. The holes tapered from 2¾ or 3 in at the top to 1¾ or 2¼ in at the bottom. 1 ft of steel was used up for every 10 cu yds of excavation. An average of 5 lin ft of hole was drilled per cu yd at the average rate of 2.66 ft drilled per hour of the machine at the face. An average of 2.9 lbs of 60% forcite was used per cu yd of all excavation. The average time of each attack was 36 hours. Air-operated steam shovels handled the muck. Fan for ventilation. Electric lighting. Lined with concrete with a minimum thickness of 22 in.

(55) Gunnison, Colorado. Irrigation Canal. Mostly black shale and metamorphic granite; other materials penetrated, clay, water-bearing gravel and sand, sandstone, limestone, coal, and marble. 1 working shaft. Maximum progress of single heading 824 ft per month, average length of tunnel completed 566 ft per month. Sullivan 3-in and 2½-in and Leyner 2½-in cylinder compress-air drills were used. Jeffrey coal augers were used in shale. 40% gelatine dynamite used. 18 to 22 drill holes 6 ft to 7 ft deep in the heading. 4 drills in the heading and one on the bench. Blowers for ventilation. It was necessary to drive an inclined shaft for ventilation. Electric lighting. Lined with concrete 16 to 26 in thick.

(56) Arthurs Pass, New Zealand. Badly fissured sandstone and shale, 3% grade, not much timbering. 2 to 3 Ingersoll-Sergeant 3¼ in drills on a 4½ in cross-bar without arms in heading. 10 to 16 holes 4½ ft to 6½ ft deep per round and 4 to 6 lbs of Nobel's gelignite per cu yd in heading. Electric haulage. Side walls of concrete poured in place, arch roof of concrete blocks 12 in radial by 9 in by 18 in along tunnel, mortar joints. Over break of hand-packed stone.

(57) Fu-Chin-ling, Manchuria. Hard limestone. No timbering. Lined with cu

limestone on sides with a 3 ring brick semi-circular arch of 8 ft radius in roof. Cost $75.00 per ft lined and ready for track.

(58) Loetschberg, Switzerland. Limestone, slate, gneiss and granite. Greatest thickness of overlying rock 4692 ft. No shafts. Temperatures 75° to 110° F. Maximum progress of single heading 1013 ft per month. 4 to 5 Ingersoll-Rand 3⅝ in drills on carriages in bottom heading and on columns in top heading. In the headings there were 12 to 14 holes 4 ft to 5 ft deep and 85% dynamite was used. Lighting by individual acetylene lamps. Due to an inrush of water, sand and gravel which filled 5900 ft of the excavation and buried 25 men 0.85 miles of the old working was abandoned and the alignment changed.

(60) Pirahy, Brazil. To divert water from Pirahy river to power company's reservoir in adjacent valley. Mostly solid gneiss. Bottom heading 13 ft wide by 8 ft high. Best month 512 ft. Very little timbering. About 1000 ft of concrete lining, the rest unlined. Five 3¼ in Ingersoll-Rand drills at each face on an 8 in horizontal bar operated by a Carter tunnel carriage. Total construction period less than 23 months working from portals and 4 shafts.

(61) Laramie-Poudre, Colo. Irrigation tunnel. Granite syenite and quartzite. Leyner pneumatic hammer drills. 20 holes 7 ft to 9 ft deep per round. 100% blasting gelatin in the bottom of the cut holes and 50% and 60% dynamite for the rest of the blasting. Holes fired and fuse cut to proper length to discharge them in pre-arranged order. Muck hauled out by hoist and by mules. Average monthly advance 473.7 ft for 19 months.

(62) Mount D'Or France and Switzerland. Limestone and marl. Swiss heading averaged 566 ft advance per month for 25 months. 4 Meyer type air drills mounted on a bar and 12 to 15 five-ft holes per round in heading. Water up to 20,000 c.f. per min. encountered. Lining placed immediately behind the excavation. Compress air locomotives.

(63) Astoria-Bronx, New York. For gas mains under East River. Gneiss and dolomite. About 250 ft below mean sea level. Much trouble with water. Rock seams grouted thru pilot drill holes driven in advance of excavation, grouting under pressures up to 500 lbs per sq in and using a total of 118 000 bags of cement. Working once flooded by leak of 12000 gals per min. Tunnel then bulkheaded and whole heading grouted back of bulkhead. Work then advanced by small heading thro grout with pilot drill holes for grouting as before.

(64) Rogers Pass, B. C. Quartzite and schists. Not much water. No shafts. Thickness of overlying rock 5690 ft. A pioneer tunnel 7 ft by 8 ft was driven from each end parallel to the main tunnel and about 50 ft away. The central mile of this pioneer tunnel was not excavated. 3 and 4 light hammer drills on a horizontal bar per heading and 21 to 28 holes per round. Maximum monthly advance for a single heading 932 ft. From the pioneer bore cross cuts to the main tunnel were made at intervals of 1500 ft to 2000 ft and headings 11 ft wide by 9 ft high carried each way along the tunnel center line. This central heading was then enlarged to full section at one operation working in from each portal. Steam shovels and air locomotives used in mucking. The best monthly advance for one shovel was 1030 ft. Only partly lined with concrete.

(65) Twin Peaks, San Francisco. For 2-track street railway. Clay, sand and sandstone. Heading 8 ft by 8 ft. 65 000 cu yd of reinforced concrete lining placed by pneumatic process through a maximum length of 4,000 ft of pipe. 8 lbs hydrated lime was used per 100 lbs cement.

(66) Roosevelt, Colo. For underdraining Cripple Creek mining district. The tunnel at its inner end is over 1800 ft below the surface and takes the ground water from the surrounding mines. Maximum discharge 17 000 gals per min. Part in granite and remainder in hard volcanic rock. In granite it cost $27.27 per lin ft. Sec about 75 sq ft. In volcanic rock cost $20 to $25 per ft. Sec about 80 sq ft. Two Ingersoll-Leyner drills on a horizontal bar, about 30 holes per round. Muck hauled to shafts by mules.

(67) Rove, France. Rhone-Marseilles canal tunnel. Dolomite and limestone. "Holed through" Feb. 1916. 2 side drifts 9.8 ft by 10.7 ft are driven at bottom, enlarged to give room for track and drainage and small heading at the crown. Side headings enlarged upward and connect with crown heading. After this the lining is placed and the core removed.

36. Shield Tunneling

A Shield (Fig. 85) consists of a circular steel box or ring generally provide with a transverse diaphragm. The forward end of the ring, or cutting edg projects into the earth to be excavated, while the rear end or tail projec backward a little distance over the completed lining, which usually consis of rings of cast iron. To the shield are attached powerful hydraulic jacl

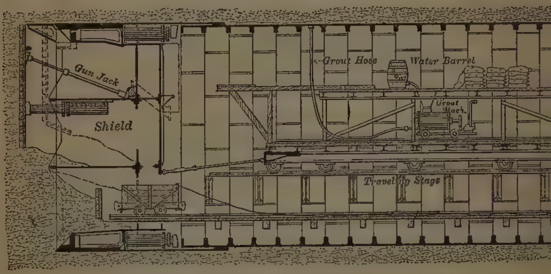

Fig. 85. Shield Tunneling

which react against the completed lining and shove the shield forward as t earth is excavated. As soon as the shield is advanced a short distance t jack plungers are withdrawn, a ring of lining built, and the operation repeate

Methods of Work. In clay or other firm material which will sta alone for a short time the full face is simply excavated to about the length one shove in front of the cutting edge without poling or breasting and t shield quickly shoved forward. If the earth is not hard enough to inju the cutting edge, only the center of the face is excavated for a depth equal length of shove and the cutting edge is allowed to break in the rest. softer clay the cutting edge and working floors may be always buried; o the back of the working chamber in front of the diaphragm is kept clear earth. In still softer material the shield is sometimes shoved against the ea face, part of which is allowed to flow thru the openings in the diaphra of the shield and the rest is pushed aside. In sand or gravel the face is u ally breasted with timber, which is held by struts against the shield. Th struts must be collapsible so that the shield may be shoved up to the fa A favorite form is simply two pieces of pipe which telescope as the shi is shoved, the resistance being regulated by set screws in the larger pi Hydraulic rams attached to the shield have been used for this purpose.

Numerous London shields have been provided with sliding platforms operated hydraulic rams. When driving the shield for the Waterloo and City tunnel, Lond thru sand and gravel pot holes were raked out in front of the cutting edge and filled v soft tempered clay. This formed a continuous ring of soft clay into which the cutt edge was shoved. The full face was then excavated under cover of the shield.

Where the material to be tunneled is part earth and part rock the full-sized tur above the rock is usually poled and excavated and the face breasted as in ordinary mi for a length of one or two shoves in front of the cutting edge, the rock in the same ler is then drilled, blasted and removed, and the rock bottom smoothed off to the form the bottom of the shield with concrete in which steel rails are imbedded; the shiel then advanced for that short length and the operation repeated.

The General Design of the different types of shields used for tube tunnels up to the year 1910 is shown in Figs. 86–89. The working chamber in front of the diaphragm has been small as in Fig. 86 or large as in Figs. 87, 88, 89,

Fig. 86. Shield, Central London Tunnel

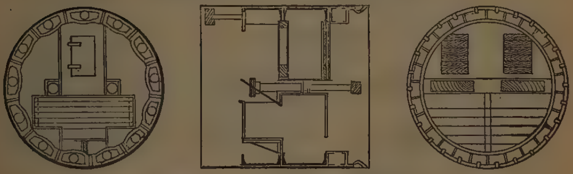

Fig. 87. Shield, Greenwich Tunnel

depending upon the character of the material and the methods of excavation. The diaphragm has openings for the passage of men and materials, and may be designed to be closed by locks or doors or be always open. Under either condition the diaphragm should be designed to lend stiffness to the skin, and since, when closed, it may take a part or even all of the water or earth pressure at the face, a system of transverse girders is introduced as reinforcement. Some of the later shields working in London clay had practically no diaphragm because the material was well known as being uniform, and not water-bearing. The shields for the Blackwall tunnel, Greenwich (Fig. 87), and Pa. R. R. East River tunnels (Fig. 89) were built with a double diaphragm, the doors of which when closed formed air locks between the working chamber and the tail for the passage of men and materials. These locks were never used, and the lower plates in all cases were removed during the course of the work to give easy access from the tunnel to the face.

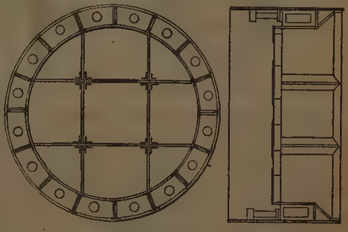

Fig. 88. Shield, Hudson Tunnel

The cutting edge at the extreme forward end of the shield in the earlier shields was the edge of the skin plates stiffened by brackets, but in later practise with few exceptions was a heavy ring made up of cast-steel segments beveled on the forward edge. Costly delays have resulted from damage to cutting edges caused by unexpected bowlders and rock ledges. The reaction of the hydraulic jacks must be transmitted to skin, cutting

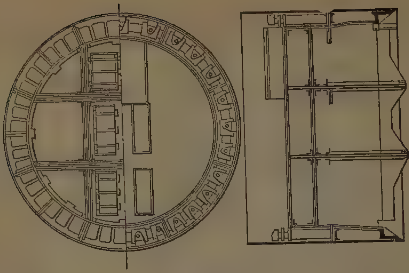

Fig. 89. Shield, East River Tunnel, P. R. R.

edge, and partly to diaphragm. These requirements have developed the circular box girder, a form of which is shown in Fig. 90, attached to the skin, bearing on the cutting edge brackets and carrying the connections of the transverse diaphragm girders. The box girder is provided with cells into which the jacks are placed, the location being convenient for substitution and repairs.

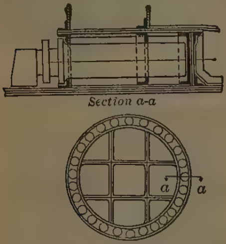

Fig. 90. Circular Box Girder

Fig. 91

Shield jacks are all connected with a battery of valves under the hand of the operator so that he may advance or withdraw any one or any combination of jacks at his will. A number of spare jacks should be provided and they should be designed so that they may be easily and quickly removed as they are sure to need repairs and delays are very expensive.

Most shields for work in sand are provided with a hood or extension of the upper part of the cutting edge. The tail of the shield should be long enough to exend about 6 inches beyond the joint between the second and third rings before the shove, to facilitate repairs to jacks and shield, and, more particularly, so that, should a segment of the tunnel lining be broken during the movement of the shield, it may be replaced at the conclusion of the shove without exposing the earth. The inside of the tail at the extreme end is provided with a bead of narrow steel plate, Fig. 91, which more nearly closes the annular space between the tunnel lining and the skin of the shield and yet allows the shield to be pointed at an angle large enough to pass around curves or regain direction when off line or grade.

37. Data Regarding Tunnel Shields

Elements in the Design of a shield which are known are merely the depth below the ground and water surface. The meager information as to the character of the material to be penetrated, generally obtained from wash borings, and the absolute uncertainty of the nature of the forces involved make its rational design impossible; the only guide is precedent. The following tables give the principal dimensions and important facts about several shields which have been used under a great variety of conditions. The numbers in parentheses in the first column of the first table refer to the notes below where additional data are given.

Number and name of tunnel	No. of sh'lds	External diam. ft	External diam. ins	Skin, ins thick	Length ft	Length ins	No. of j'ks	Inside diam. of jacks, ins.	Max. thrust, tons c	Wt. of sh'ld, tons c	Distance driven, miles

a Height 22′ 3″; width 37′ 6″. *b* Hand-operated screw jacks. *c* Tons of 2000 lbs. *d* Driven a very short distance. *e* Includes 2 foot hood. *f* Includes 2 foot 2 in hood. *g* Includes hydraulic equipment which weighs about 40 tons on 60th St shield and 28 tons on other shields. *h* Per jack.

(1) Thames. 1825-42. London clay. Max. progress 2 ft, average 0.5 ft per day.

(2) Tower. 1869. London clay. Maximum progress 9 ft. per day.

(4) City and South London. 1886. Mostly clay, also several lengths of water-bearing sand and gravel. The average progress of each shield was 333 ft per month during ⅓ of work.

(5) Mersey. 1888. Clay, coarse ballast and running sand. Maximum progress was 57 ft per week.

(6) St. Clair River. 1889. Almost entirely in soft damp clay. The maximum progress per month was 382 ft and the average 231 ft per month.

(7) Hudson. 1879 1905. Mostly in silt; at New York side some sand and short length in rock. From May, 1890, to August, 1891, the average progress per month was 126 ft in the first tunnel; in the second tunnel the average progress per day was 15.3 ft.

(8) Glasgow Harbor. 1890 One-third in clay with bowlders, the rest in sand and gravel. The average progress in sand was 2 ft per day.

(9) Glasgow District Subway 1891-95. Clay, sand, gravel, and quarry waste. The average progress was 100 ft per month.

(11) Blackwall. 1892. London clay, sand, and ⅓ in open gravel. The maximum progress was 12½ ft per day. The average progress under the river was 98 ft per month.

(12) Siphon de Clichy. 1892. Open water-bearing sand. The maximum progress was 10 ft per day and the average 6 5 ft per day.

(13) East River Gas. 1892 Short lengths in decomposed schist and black mud.

(15) Waterloo and City. 1893. Clay and ballast. 10 ft per day was the average progress while the work was in full swing.

(16) Siphon de la Concorde. 1895. Clay and sand.

(17) Central London. 1896. London clay and silty sand.

(19) Siphon de l'Oise. 1896. Sand.

(20) Baker St. and Waterloo 1898. About 350 ft was in gravel under the Thames River, the rest was in London clay. The average progress per month was 117 ft in gravel and 137 ft in clay.

(21) Greenwich. 1898. Mostly in clay with the crown in close gray sand; about ⅓ length is in close gray sand and a small part in ballast. The maximum progress was 260 ft per month and the average 148 ft.

(22) Lea. 1901. Mostly peaty clay and open ballast.

(23) Battery, East River. 1901. 500 ft almost entirely in rock; 1500 ft in fine sand with some clay, the rest was coarse sand. Rates of progress follow: In normal air above water line in sand and gravel average 140 ft per month; under river in rock, fine sand and clay, and sand and gravel, 91 ft per month.

(24) East River, Pennsylvania R.R. 1903-09. Land portion in rock, soft top in places. Under river 18% in fine sand stretched with clay, stiff clay, sand and bowlders 35% sand and bowlders, sand and clay and fine sand; 22% all in rock and 25% in rock with sand, gravel, and bowlders in the crown. Rates of progress were: Best day's work 17.5 ft. Average for month in earth 176 ft, in rock and earth 56 ft, and in rock 61 ft.

(25) North River, Pennsylvania R.R. 1903-09. Mostly in silt, also short length in sand and in rock. The maximum month's progress was 545.2 ft. The averag progress in rock was 58 ft per month and in silt 2.39 ft.

(26) Brackenagh. 1903. Water-bearing glacial deposit and running sand.

(27) Rotherhithe. 1904. Clay, conglomerate sand and gravel.

(28) Kingsway. 1904. Clay. Average progress 5.0 ft per day.

(29) River Dee. 1904. Alluvial clay and bowlders. Average progress per da 4.5 ft.

(30) Charing Cross and Hampstead. 1904. London clay. Max. progress 180 ft pe week.

(31) Great Northern and Strand. London clay.

(32) N. Y. Subway. 1916. B. R. T. system from North 7th St, Bklyn to 14th S Manhattan. Shaft at each side of river. 2 land shields, 2 river shields from each sha (8 shields in all). Tunnel part in rock and part in sand and part in clay. Averag progress per month river section, in earth 147 ft—in earth and rock 44 ft. Land sectio in earth 168 ft.

(33) N. Y. Subway. 1914-1919. B. R. T. system from Montague St, Bklyn Whitehall St, Manhattan. Shaft on each side of river. From Brooklyn shaft tw shields driven each way. River shields met rock tunnel driven without shields und river from Manhattan shaft. Material on Brooklyn side sand with some clay. Avera progress per month river section, in earth 192 ft, in rock and earth 80 ft. Land secti in earth 209 ft. Max. progress per month, river section 345 ft, land section 454 ft.

(34) N. Y. Subway. 1914-1919. B. R. T. 2 shields driven under streets of Brookly at a depth of from 43 ft to 75 ft. All above tide water. Extension of the Whiteha Montague street tunnel. Material sand. Compressed air not used.

(35) N. Y. Subway. 1914-1919. I. R. T. Shafts on each side of river. 2 shiel in each direction from Brooklyn shaft; 2 shields toward river from Manhattan sha

Material sand on Brooklyn side. Tunnels part in rock, part in sand on Manhattan side. Average progress for month, river section, in earth 184 ft in earth and rock 74 ft. Land section in earth 167 ft.

(36) N. Y. Subway. 1916–1919. B. R. T. from North Jane St, Queens to East 60th St, Manhattan. One shaft on each side of river and shaft in rock on Blackwells Island. From Queen's Borough shaft, 2 shields were driven under east channel of East River, pushed through rock tunnels, previously excavated under Blackwell's Island and continued through earth under west channel to rock on Manhattan side. Average progress for month, river section in earth 188 ft, in rock 119 ft.

38. Roof Shields

Roof shields for masonry-lined tunnels have been used with success principally in France and to some small extent in America. In use they are peculiarly adapted to the drier soils, usually under streets where open-cut methods are not permissible, tho they have been used, as in the East Boston tunnel, in connection with comprest air for subaqueous tunnels. They are usually semielliptical or semicircular in form and consist of a skin of steel plates riveted to girders which at their lower extremities are tied together with a transverse girder and mounted on rollers. Hydraulic jacks supported by the ribs and bearing against the completed masonry or the arch centers move the shield forward. The two general methods of using roof shields are: first, to excavate the area of cross-section of the shield, build the masonry arch, and subsequently underpin with the side-wall construction; second, to drive timbered headings in advance and construct in them the side walls on which the shield is later supported or rolled.

(1) Commenced 1895. Contract price $55.45 per lin ft. Semielliptical shield. Average progress 14 ft 9 in per day of 24 hours, maximum 29 ft. Material penetrated of loose sandy nature.

(2) Commenced 1897. Average progress 9 ft per day of 24 hours. Material penetrated: 450 ft compacted clay and sand, 100 ft loose sand and gravel. Height = over all.

(3*a*) Commenced 1898. Material penetrated mostly made ground, old masonry walls and foundations. Average progress 3.4 ft in 24 hours, maximum 22 ft.

(3*b*) Material penetrated, see No. 3*a*. Average progress 10 ft in 24 hours.

* Height = From springing line to crown unless noted. † Length = Distance over all.

(4*a*) Employed on elliptical section. Commenced 1898. Material penetrated: ma ground, decomposed limestone, marl, and foundation walls. Average progress 8.2 ft day, maximum 101.7 ft per week.

(4*b*) Employed on circular section. Started 1898. Material penetrated, fine sand a gravel. Average progress 9 ft per day.

(4*c*) Employed on circular section. Started 1898. Material penetrated, made grou sand, foundation walls, etc. Average progress 7.2 ft per day. * Height over all.

(5*a*) Two shields of this type employed on 1st section, 1 on 8th section, and 1 on 1 section. Started 1899. Material penetrated, made ground and soft sand, with so marl. Average advance 13 ft per day on 1st section, 10 ft on 8th, and 12 ft on 11th.

(5*b*) One shield of this type employed on 2nd section, two on 3rd section. Star 1899. Material penetrated, sand and gravel, some water-bearing. Maximum adva 29 ft per week.

(5*c*) Two shields employed on 4th section. Started 1899. Material penetrated, s and gravel. Shields proved unsatisfactory.

(5*d*) One shield of this type employed on 6th section, one on 7th section. Mat penetrated, sand, gravel, and marl. Average advance 6.5 ft per day. Shield pr unsatisfactory.

(6) Started 1901. Material penetrated, blue clay and bowlder clay, with some sa and silty permeable clay. Air pressure, 18 to 20 lbs average, 25 lbs maximum; cu ft per man per hour. Average progress 4.8 ft per day.

39. Cast-Iron Tunnel Lining

The Lining for shield-driven tube tunnels has usually been cast i The reasons for its use are that it can be most quickly built; as soon as ere it furnishes a reaction for the shield jacks; it offers greater assurance water-tightness, and being thin for its strength saves excavation. For aqueous work done in comprest air all of these considerations are weig The number of segments forming a ring and the width of the ring de on the economic weight that can be handled. Sometimes in small tur up to 13 or 14 ft in diameter iron lining has been built by hand, but hydr erectors attached to the shields or to traveling platforms are generally u The length of shield which can be conveniently used is another factor go ing the width of segments, the length of the tail being affected correspond by increases in this width. Fig. 92 shows the cast-iron lining used in Pa. R.R. tunnels under the East River, N. Y. There has been bui comprest air at least one shield-driven tube tunnel lined with brick.

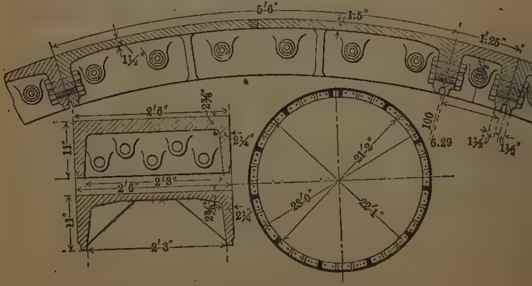

Fig. 92. Cast-Iron Lining, East River Tunnel

the construction of the 39th Street sewer at Chicago, segmental timbering formed a lining inside of which the brick was built. The timber was used to receive the reaction of the shield jacks.

The design of the cast-iron lining depends as much on the requirements of building as upon the stresses involved, and the best guide is a study of precedents. The following table gives principal dimensions and details of iron lining in existing tunnels.

* Height 5′ 7″; width 4′ 11″. † Steel lining. C = Circumferential, H = Ho

Stresses in tunnel lining can only be approximated by theoretical because they originate in earth pressures and the law of action of ea sures is only imperfectly known. While the designer should depend judgment and precedent than upon theoretical analysis, such an anal be helped by indicating the nature of the stresses.

Let C_1, C_2 (Fig. 91) be the line of centers of resistance (locus of centers of shell is homogeneous) of a unit length of tunnel shell which is taken circular b any other form. Let p_1, p_2, p_3, . . . to p_n be all forces acting upon the shell. T

satisfy the condition that the forces on opposite sides of any diameter must be equal and opposite, otherwise there would be movement. For example, the reactions and active forces, if any, on the bottom must balance the loads on top. It is assumed in Fig. 94 that the loading and the shell are symmetrical about the vertical axis A-B, which will usually be the case. The analysis would be similar in any case.

The load diagram a_1, a_2, a_3 . . . is constructed in the usual way by laying off the forces p_1, p_2, p_3 . . . to scale parallel to their direction. The position of the pole o is found by laying off on a_1 a_n the thrusts T_1 and T_n, which are found by taking moments of the horizontal components of p_1, p_2, p_3, . . . about C_1 or C_2. Then a_2, a_3, a_4, etc. are connected with the pole, and the line of thrust T_1 T_n is constructed in the usual way by drawing T_1, T_2, T_3, . . . parallel with oa_1, oa_2, oa_3, . . . But an infinite number of such lines of thrust may be drawn. The correct one may be found by trial from the consideration that as the tunnel shell is a closed ring the sum of the positiv bending moments must be equal to the sum of the negativ moments. The bending moment at any point, say at M, is oa_7 times e. The bending moments at equal small intervals around the ring for any line of thrust may be computed and summed up. A few trials will determine the correct line of thrust.

40. Waterproofing and Grouting

Grummets. Bolt holes being slightly larger than the bolts which are placed in them, permit water to seep into the tunnel unless a tight calking material is carried around the bolt hole or some form of grummet is placed under plate washers at the head and nut. Three principal types of grummets have been used. In the Baker Street and Waterloo, the North River Pennsylvania, the Battery, and for a time in the East River Pennsylvania tunnels rings of hemp saturated in red lead and oil under plate washers were used. In the East River Pennsylvania, where the bolts had rolled threads, the diameter of the threaded portion being larger than the diameter of the shank, greater success was attained by wrapping strands of hemp saturated in red lead and oil around the shank. In the Greenwich and Rotherhithe tunnels lead washers were used, and when the bolts were tightened the lead washers were forced into conical bolt holes.

Calking. The practise since 1890 has been to cast a small depression in the flanges at its inner edge which matches a like depression in the adjoining

plate and forms a calking groove when the plates are bolted together; [illegible] Fig. 92. Into this is calked either soft lead or a rust mixture or sometin[illegible] Portland cement. The grooves have usually been from ¼ to ¾ in wide a[illegible] about 1½ in deep. For lead it is desirable to make the groove much n[illegible] rower, say ⅛ in wide, but this is difficult to cast.

The rust mixture is usually one part by weight of sal ammoniac mixt with 400 pa[illegible] of iron filings. The sal ammoniac is best dissolved in enough water to dampen the [illegible] filings which are then calked into the groove and well compacted either by hand t[illegible] or pneumatic hammer. The finer the iron filings the better. Rust mixture call[illegible] is not successful if there is water coming thru the joint during calking. Even when [illegible] joints are made absolutely water-tight slight movements of the flanges, such as are li[illegible] to occur from contraction in winter or in adjustment of bolts, are liable to cause a s[illegible] amount of leakage. The following table shows the practise in some of the more im[illegible] tant tunnels:

Name	Date	Max. head water, feet	Kind of calking
Antwerp	1879	26	Groove in flange outside of bolts. Rop[illegible] tarred hemp.
City and S. London	1886	75	In joints between rings oakum in gr[illegible] covered with cement. Longitudinal joint[illegible] filled with soft wood packing and the [illegible] filled with cement.
Mersey	1888	54	Face of flange beveled. Portland cement [illegible] tar, just damp, in groove.
St. Clair	1889	78	Canvas coated with resinous compound bet[illegible] rings, creosoted oak packing 5/16 in thic[illegible] longitudinal joints.
Blackwall	1892	80	Rust joint material — 1 lb sal ammoniac t[illegible] lbs iron borings. In wet joints lead [illegible] hammered into groove.
Baker St. & Waterloo	1898	70	Pine packing between rings outside ½ of [illegible] rust joint material inner ½. Calked ar[illegible] bolts. Rust joint material in shallow g[illegible] on longitudinal joints.
Greenwich	1898	70	Rust joint material in grooves into which[illegible] lead had been hammered.
Battery, East River	1901	94	Lead in grooves.
East River, P.R.R.	1903–09	93	20 per cent calked with rust material — [illegible] sal ammoniac to 400 lbs iron borings. [illegible] cent calked with lead and pointed [illegible] portland cement.
North River, P.R.R.	1903–09	98	Sides and invert — 2 lbs sal ammonia[illegible] sulphur, and 250 lbs iron borings; arch[illegible] sal ammoniac, 3 lbs sulphur, and 125 lb[illegible] borings.
Rotherhithe	1904–09	97	Lead hammered into groove and covere[illegible] rust joint material.
East River, N. Y. Public Service	1910–19	116	The caulking for all the cast-iron [illegible] tunnels was done with leadwire over [illegible] a Portland Cement pointing was pla[illegible] fill the groove. The caulking groove was ¼ in wid[illegible] 1¼ in deep. Lead wire elliptical in section (max. [illegible] ½ in, min. diam. ¼ in) has bee[illegible] throughout the entire work.
14th St. / Whitehall St. / Old Slip / Lawrence St. / 60th St.			

Grouting. The shield being larger than the tunnel lining leaves an annular space which should be filled immediately after the shield has past. This is especially necessary at the sides to prevent the lining from spreading. A grout of about equal parts of hydraulic cement and sand is generally used.

Waterproofing. Most subaqueous tunnels have had cast-iron or steel shells which are waterproof of themselves; the exceptions are those that are in nearly impervious clay, which prevents any quantity of water reaching the tunnel lining, and such tunnels as the Severn, which has brick lining and is kept dry by pumping. Numerous tunnels and subways in water-bearing ground are of masonry lining waterproofed by pitch in some form.

The most generally used form is a combination of pitch, usually applied hot, with sheets of some fibrous material used as binders; for this purpose burlap, building paper, and so-called felt have been used. These binder sheets are usually saturated with pitch by the manufacturer, and are applied to the outside of the wall in from 2 to 6 thicknesses, each layer being given a coat of hot pitch as it is placed. The specification for such work in the Pennsylvania R.R. land tunnels in New York call for "straight run coal tar pitch which will soften at 60° Fahr and melt at 100° Fahr, being a grade in which distillate oils, distilled therefrom, shall have a specific gravity of 1.05." Felt was coated and saturated with asphaltic products, and it was required that the wool in the unsaturated felt should be not less than 25% by weight and that the felt should weigh 0.05 to 0.06 lb per sq ft unsaturated and 0.12 to 0.14 lb saturated. Another type of waterproofing consists of an outside course of asphaltic brick laid in soft pitch or a mastic of soft pitch and fine sand.

41. Compress Air

The Shield and Compress Air generally go together, but there have been several exceptions. A portion of the Pennsylvania tunnels in Long Island City were mined, timbered, and lined in compress air without use of shields, and the builders of the telephone tunnels in Chicago used compress air but no shields. The amount of air required is very variable in different tunnels and at different times in the same tunnel. In the East River tunnels of the Pennsylvania R.R. in open sand with a clay blanket 10 to 20 ft deep and 350 ft wide dumped upon the river bed, the capacity of compressors required was about 80 400 cu ft free air per min. The average used was about 3500 cu ft per min per heading. In the Rotherhithe tunnel under the Thames it was specified that the minimum amount of air pumped into the tunnel should be 8000 cu ft of free air per man per hour.

The great difficulty in water-bearing sand or gravel when compress air is used arises from the impossibility of balancing the water pressure at more than one elevation, with the result that if the water pressure is balanced at the bottom of the tunnel there is an excessive escape of air at the top, which is expensive, and there is always danger that a "blow," or sudden outrush of air, will occur at the top, which endangers the workmen and may cause delay by flooding the tunnel. If the water pressure is balanced at the top, the bottom may be so wet that the sand is unstable and difficult to handle. As a compromise the water pressure in such materials is usually balanced by the air pressure at about the center of the shield, and blows are guarded against by breasting and plastering the face with clay and depositing a clay blanket on the river bed above.

42. Subaqueous Tunnels Built from Surface

In cases where the top of the tunnel is desired to be close to the bed of the river thus giving insufficient cover for shield work, or if the tunnel is short making the plant installation required for shield work proportionately excessive, tunnels have been built successfully from the surface.

(1) Detroit River Tunnel, Detroit to Windsor. Trench was dredged to grade in the stiff clay of the river bottom. Twin steel tubes of 3/8 in pl 23 ft 4 in diam and 262 ft

Compress Air Data

Tunnel	High water to invert, max., ft	Min. cover, ft†	Max. air pressure, lbs per sq in	Average air pressure, lbs per sq in	Cubic feet free air supplied

* The shield cut into the permanent clay blanket placed on the river bed. The clay blanket is protected from washing by a rock revetment on the sides and top.

† Does not include clay blankets.

‡ Requirement for all contracts was 10 000 cu ft of free air per min per heading; except in one case where one power house supplied 8 headings, the requirement was reduced to 8000 cu ft of free air per min per heading.

6 in long connected by structural steel diaphragms at 12 ft c to c and provided with bulkheads were sunk in position on prepared foundations. Sections were connected up by divers with special bolting system. A timber form or sheathing was fastened to outer edges of the diaphragms. Concrete was placed by tremie between this sheathing and the tubes—completely encasing the tubes. This concrete was 3 ft thick on the sides and 4 ft 6 in thick top and bottom. Reinforced concrete lining having an interior diam of 20 ft was placed inside the steel tubes. (See Fig. 95). Distance from water surface to top of rail in mid-channel 66 ft. Current in river over 2 miles per hour. Total length of river section 2667 ft. Built 1906–10.

(2) Chicago River Tunnel. Single length of two parallel steel cylinders with a longitudinal dividing wall; lined with reinforced concrete and sunk on prepared foundation in a trench dredged in the river bottom. Tubes of ⅜ in steel plate, stiffened by plate and angle gussets above and below the central wall every 7½ ft. Concrete lining 2 in to 40 in thick. Central wall 3 ft thick. Length of tubes 278 ft, width 41 ft, dep

24 ft. Weight when sunk 8000 tons. Backfill and cover sand. Connection to shore tunnels made by cofferdam. Built 1910–12. (Fig. 96.)

(3) Paris Subway under Seine, Pont Mirabeau crossing. The River portion 644 ft long and made up of 5 sections 116.8 ft to 144.4 ft long. Each section was a pneumatic caisson consisting of a structural steel frame covered inside and out with steel plates and filled with concrete, with a double track tube of similar construction above the working chamber. Over-all width 29.9 ft, over-all height 30.1 ft. These sections were sunk in position 15¾ in apart, this space filled with tremie placed concrete through which an opening of required tunnel section was later excavated. A tunnel having a total caisson length of 1313 ft was built under the Seine by a very similar method in 1906–7.

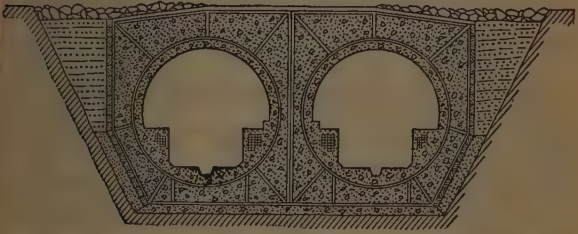

Fig. 95

(4) Harlem River crossing, New York Subway, Lexington Avenue Line. Four track tunnel built very much the same as the Detroit River tunnel noted above. The sections as assembled had an over-all width of 76 ft and height of 24½ ft. Four of the sections were 220 ft long and the remaining one was 200 ft long. Contract price $1500 per lin ft for 4 track structure. Built 1911–12.

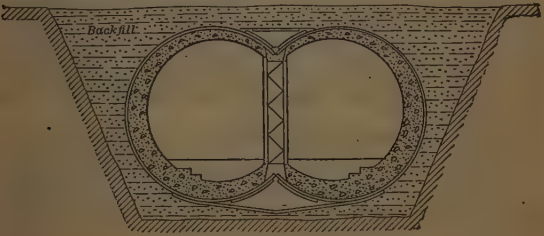

Fig. 96

(5) Harlem River Tunnels, New York Subway, Lenox Avenue Branch. Twin tube sections 610 ft long of cast iron lining, inside diam 15 ft Across the river trench was excavated, bottom of which was a little below the middle of the finished tunnel. Two lines of heavy sheet piling were driven outside the line of the finished tunnel and cut off at the springing line of the arched roof. A floating timber box was then built in which the arched roof of cast-iron segments was erected and covered with concrete with proper internal bracing and bulkhead ends. The floating box was sunk from underneath and the roof left floating like a diving bell. This with steadying tackle was sunk and left resting on the sheet piling and bearing piles previously driven in the trench. After

divers connected this to the section already in place, the lower half of the tunnel built in comprest air. Built 1903–4.

43. City Subways

The Cut-and-Cover Method is usually cheaper than tunneling at dep less than 30 ft and may be the more practicable method when the cove shallow, as often with city subways for rapid transit. Attempts to exca by shield within a few feet of street surfaces have not met with entire suc because of disturbance to pavements and pipes. Where traffic will not pe an open cut, the pavement is taken up, if necessary at night, and replaced a timber deck under cover of which the subway is built. Where wide cut is objectionable, side-walls and interior supports are sometimes built in tre and roofed, after which the core is removed and the bottom placed. W there is groundwater, its level frequently may be lowered by draining to su and pumping carefully. Where quicksand is met at subgrade, tight shee is driven to extra depth and it may be necessary also to excavate for and p the floor quickly in short sections. On the other hand, where the groun dry and hard enough to stand with but little bracing and where decking is required, steam shovels have been successfully used. Intercepted se may be depressed or under-siphoned.

Adjacent foundations are underpinned, either temporarily or permane where required to prevent settlement. Finally, subsurface structures restored or rebuilt and the street is backfilled and repaved.

Types of Sections are shown in Fig. 97. Earlier sections usually of the single arch type if headroom permitted; where close to the surfac roof was of beams with jack-arches between them. Later, beams cam be used also in sidewalls, forming bents, saving in width and facilitating struction. More recent American design has tended toward reinforced crete, requiring somewhat less and cheaper steel and permitting the u large forms, but bents continue in favor because better adapted to requirem of bracing and piecemeal construction. The single arch of concrete, pla reinforced, is still used where conditions of headroom and lateral suppor favorable. In soft or wet ground the floor may be formed as an inve may be reinforced with beams or rods. Waterproofing is commonly fe fabric saturated and laid with tar or asphalt, and in dry situations ma omitted from floor and sides. Stations are painted, plastered or tiled in or light colors.

The New York Subway System, the largest, has 69 miles undergr structure built or nearing completion, mostly 2- or 4-track subway, of nearly all is of type (1) Fig. 97 in the portion first (1900–3) built and mu type (3) in portions now (1918) or recently under construction. Both are bent type, though certain portions built since 1902 are of reinforced con mostly of type (2). The recent type (3), provides a partition betwee middle tracks to promote ventilation by train movement. The roof and necessary the sides and floor are waterproofed generally with felt or b and pitch. The inside tracks are for express, and the outside for local t At express stations the platforms are between local and express tracks, se both, and at local stations at the sides. Excavation was partly in Groundwater and very fine quicksand were frequently met. Methods widely. The system includes several miles of arch tunnels in rock, cast lined tubes and steel viaduct extensions.

The Boston Subway System, the first in America, with 9 miles underg structure, mostly 2-track subway, is principally of bent type (4) and arch ty

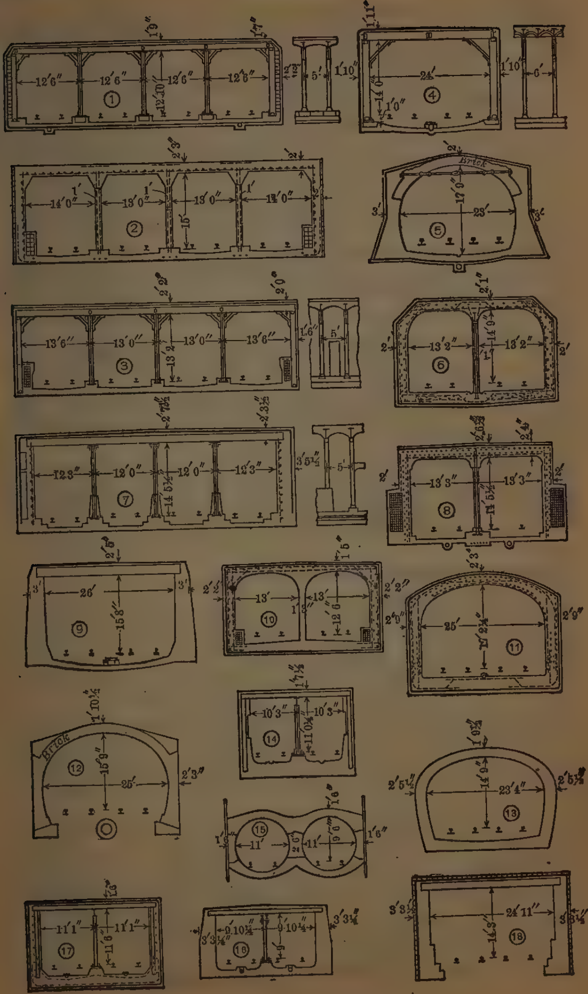

Fig. 97. Subway Sections

in earlier (1895–1908) portions and of reinforced concrete type, (6) in recent (1912–17) portions. Where traffic was dense a short portion somewhat like (5) was tunneled with roof shield. Excavation was nearly all in sand, clay and gravel. The system is for both surface cars and trains. It includes two shield-driven subaqueous tunnels and steel viaduct extensions or connections.

The Philadelphia Subway, in Market Street, built 1903–07, 2¼ miles long, is in about equal parts a 4-track (7) and a 2-track (8) structure. The walls of (7) and the roof and walls of (8) are rod-reinforced. The roof is waterproofed with asphaltic mastic and the sides with asphalted burlap. The outer tracks of (7) are for street cars and the inner tracks, continuous with those of (8), for trains. The columns of (7) are protected against derailment by low reinforced concrete bulkheads. Excavation was largely in gravelly soil and the structure is underdrained.

The Atlantic Avenue Subway, Brooklyn, (9), built 1901–7, 2 miles long, is for electric trains of the Long Island R.R. While not a city subway in a strict sense, it is structurally such. The sides are retaining walls and with the roof are waterproofed with tarred felt. Excavation was mostly in sand and gravel.

The Sixth Avenue Subway, N. Y., (10), built 1906–11, 1 mile long, is for Hudson and Manhattan R.R. trains entering the city by tunnel under the Hudson. Roof and sides and, where in earth, the floor are reinforced. Waterproofing was mostly of asphalted burlap but in a short portion a waterproofing compound was mixed with the concrete. Excavation was partly in rock. Some quicksand was met.

The Cambridge Subway (11), built 1909–12, 2¼ miles long, connects by bridge with the Boston Subway. Roof, sides and floor are reinforced and waterproofed with tarred felt. Where cover is shallow the roof is flat. A portion of similar section, but with less reinforcement and not waterproofed, was tunneled with roof shield. Excavation was mostly in sand and gravel with some clay.

Foreign subways generally are of smaller cross-section.

The London Metropolitan and District Subway, (12), an irregular oval line termed the Inner Circle, was the first city subway for rapid transit. It was built 1860–84 and later extended from its original length of 13 miles, part of which is open cut. The arch and walls are of brickwork. The extrados is waterproofed with asphalt. Where cover is shallow, cast- or wrought-iron roof girders were used. With soft or wet foundation, an invert was added. Excavation was mostly in gravel, sand and clay. Later extensive underground lines are in deep-level tubes, shield driven in London clay.

The Paris underground railway, (13), a network of belt and intersecting lines, begun 1898 and opened 1900, had in 1914 a length of 56 miles, mostly subway and the rest viaduct, tunnel and open cut, in addition to extensions in progress or planned. Short portions first built were tunneled with roof shield or by the Belgian method. Watertightness was secured by grouting. Excavation was mostly in sandy soil and in some parts in soft rock.

The Berlin underground railway, (14), an original east-west trunk, begun 1896 and opened 1902, with later extensions or connections to suburbs, had in 1916 a length of 23 miles, mostly subway and the rest viaduct, tunnel and open cut, in addition to 18 miles of extension, or new lines in progress or planned. The section shown is that of the Schöneberg branch, opened 1910, of the bent type. The longitudinal girders are discontinuous, each supporting 5 roof beams, and rest on two columns over which they cantilever. A feature was the use of small I-beams, driven as piles at each side every few feet, to the inner flanges of which were clipped breast boards, retaining the earth and serving as back forms for the concrete of the sidewalls, in such manner as to permit the final withdrawal of the beams. The beam-piles were braced apart only at the top, leaving a free working cut. An earlier type has thicker walls without beams. A late

type has no columns. Waterproofing is asphalted paper. Excavation was mostly sandy and much of it waterbearing.

The Glasgow District Subway, (15), an irregular oval line, built 1902-6, is 6½ miles long, comprising subway, tunnel and open cut. For the subway, a heavily sheeted trench was excavated deep enough to build the roof which was next waterproofed with layers of asphalt and covered with the restored pavement. The roof, supported by the sheeting, was then undermined with drifts in which were built the walls and floor, completing the structure. A short section in soft ground was built under air pressure. Excavation was in sand, clay, mud and rock. Traction is by cable.

The Budapest Subway, (16), for surface cars, a line 2 miles long, built 1894-6, was the first underground electric railway. The I-beams of the roof, which is close under the pavement, are supported at the middle on a continuous girder of two I-beams resting on columns spaced about 13 feet apart. Waterproofing consists of sheets laid in pitch.

The Hamburg Subway, (17), begun 1907, forms 5 miles of a ring with external branches opened in part in 1912 and since being extended. Excavation was in varied soil, in parts waterbearing. In dry ground, openings are left in the floor under the tracks and only the roof and sides were waterproofed. Beam piles were used at the sides, as in Berlin. Where depth permitted, a single arch section with invert was used.

The Buenos Aires Subway, (18), for surface cars, was begun 1911 and opened 1913 for a length of two miles, with extensions in progress or planned. It is of the earlier German type without steel in side walls. Waterproofing is tar paper and asphalt. Excavation was in hard clay. Electric shovels were used.

The cost of subway work varies widely. The kind and depth of excavation, proportion of temporary decking required for traffic, size and number of sewers, pipes etc., to be supported or changed and the extent of underpinning to protect adjacent buildings, greatly limit methods and thereby influence cost. The following is a table of costs, per lineal foot of equivalent single track, of several New York subway sections built between 1912 and 1919, all of a type resembling (3) of Fig. 97. The figures are based on contract prices which may be unbalanced, and preliminary estimates which may be large. They are affected in some cases by war increases. They include nothing for station finish, track, equipment, engineering or inspection, and are not safe for use in estimates without fuller presentation of conditions than is possible here.

*Section No. 11-1. 4th Av., Brooklyn; 40th to 61st St.—Firm dry soil; steam shovel much open.

4-3. Varick St.; Beach to Commerce St.—Dry; one side decked; steam shovel.

29-2. Nostrand Av. Brooklyn; Erasmus to Flatbush Av.—Dry sandy soil; part decked.

*Section No. 5–4. Broadway, Bleecker St. to Union Sq.—Dry; decked except in square.

4–1. Broadway; Union Sq. to 26th St.—Mostly dry; decked except in square.

4–5. 7th Av.; 17th to 30th St.—Dry; all decked; large sewer rebuilt.

8–5. Metropolitan-Bushwick Ave., Brooklyn; Manhattan Av. to Meserole St.—Dry; mostly decked.

4–2. Broadway; 27th to 38th St.—Much rock; some sliding; one deep cut; all decked.

5–3. Broadway; Howard to Houston St.—Wet fine sand, dried by pumping; all decked.

8–4. N. 7th-Metropolitan Av., Brooklyn; Bedford to Manhattan Av.—Wet fine sand; mostly decked.

8–2. 14th St.; Irving Pl. to Av. B.;—Wet sand one end; all decked.

48–2. William St.; Beekman to Pearl St.—Quicksand; all decked; heavy underpinning.

SECTION 12

MATHEMATICS AND MECHANICS

BY

EDWARD R. MAURER

PROFESSOR OF MECHANICS IN UNIVERSITY OF WISCONSIN

ELEMENTARY MATHEMATICS

ELEMENTARY MATHEMATICS

1. Algebra

Notation. Known or constant quantities are usually represented by the first letters of the English alphabet and unknown or variable quantities by the last letters. The Greek letter π is universally used for 3.14159 . . . In this book ϵ is used for 2.71828 . . ., and other Greek letters are rarely used except for angles. Names of Greek letters are

α Alpha	η Eta	ν Nu	τ Tau
β Beta	θ Theta	ξ Xi	υ Upsilon
γ Gamma	ι Iota	o Omicron	ϕ Phi
Δ, δ Delta	κ Kappa	π Pi	χ Chi
ϵ Epsilon	λ Lambda	ρ Rho	ψ Psi
ζ Zeta	μ Mu	Σ, σ Sigma	ω Omega

In this volume the sign / is often used to indicate division; thus, 3/8 is the same as $\frac{3}{8}$ and a/b is the same as $a \div b$. For the product of the first n natural numbers $n!$ is used.

Powers and Roots. The notation a^n denotes the nth power of a, even when n is negativ or fractional. Rules for powers are: $(+a)^n = +a^n$; $(-a)^n = +a^n$ if n is an even integer and $-a^n$ if n is odd; also $(a^m)^n = a^{mn}$; $a^{-n} = 1/a^n$, $a^0 = 1$. For multiplication and division of powers, $a^m \times a^n = a^{m+n}$ and $a^m/a^n = a^{m-n}$.

The notation $a^{1/n}$ or $\sqrt[n]{a}$ denotes the nth root of a. Replacing m and n in the last paragraph by $1/m$ and $1/n$, the rules there given for powers apply also to roots. An even root of a positiv number is positiv or negativ and an odd root is positiv; an odd root of a negativ number is negativ and an even root is impossible or imaginary.

The symbol i denotes $\sqrt{-1}$ which is the simplest imaginary quantity. If a is positiv and n even, then $(-a)^{1/n} = a^{1/n} i$. Powers of i are $i^2 = -1$, $i^3 = -\sqrt{-1}$, $i^4 = +1$. A complex quantity is one partly real and partly imaginary, as $a + bi$. The complex numbers $-\frac{1}{2}(1 + 3^{\frac{1}{2}} i)$ and $-\frac{1}{2}(1 - 3^{\frac{1}{2}} i)$ are two of the cube roots of unity.

Factors of some algebraic expressions are

$$a^2 - b^2 = (a - b)(a + b) \qquad a^2 + b^2 = (a - bi)(a + bi)$$
$$a^3 + b^3 = (a + b)(a^2 - ab + b^2) \qquad a^3 - b^3 = (a - b)(a^2 + ab + b^2)$$
$$a^n - b^n = (a - b)(a^{n-1} + a^{n-2}b + a^{n-3}b^2 + \dots + b^{n-1})$$
$$a^n - b^n = (a + b)(a^{n-1} - a^{n-2}b + a^{n-3}b^2 - \dots - b^{n-1}) \text{ if } n \text{ is even}$$
$$a^n + b^n = (a + b)(a^{n-1} - a^{n-2}b + a^{n-3}b^2 - \dots + b^{n-1}) \text{ if } n \text{ is odd}$$

When a and b are small compared to 1, then approximately,

$$(1 + a)(1 + b) = 1 + a + b \qquad (1 + a)^m(1 + b)^n = 1 + ma + nb$$
$$1/(1 + a) = 1 - a \qquad 1/(1 - a) = 1 + a \qquad \sqrt{ab} = \tfrac{1}{2}(a + b)$$

Logarithms. When $y = b^x$ and b is a fixt number, x is the logarithm of y to the base b, or $\log_b y = x$. When $b = 10$ the logarithms are in the common system; thus since $100 = 10^2$, and $0.1 = 10^{-1}$, the common logs of 100 and 0.1 are +2 and −1. When $x = 0$, $y = 1$, and hence for all systems the log of 1 is 0. Numbers greater than 1 have positiv logs and those less than 1 negativ logs. When $b = 2.71828$ . . . the logs are in the Naperian system.

Proportion. All rules are included in this, where m, n, p, and q have any values:

$$\text{if} \quad \frac{a}{b} = \frac{c}{d}, \quad \text{then} \quad \frac{ma + nb}{pa + qb} = \frac{mc + nd}{pc + qd}.$$

A Permutation is any arrangement that can be made of several things; thus, for three letters there are six arrangements, abc, acb, bac, bca, cab, cba. The number of permutations of n things taken r at a time is $n(n -$

. . . $(n-r+1)$. For example the number of permutations of seven things taken three at a time is $7 \times 6 \times 5 = 210$. A COMBINATION is a group made by taking things without reference to their order; thus for three letters there is only one combination *abc*. The number of combinations of n things taken in groups of r is $[n(n-1)\ldots(n-r+1)]/r!$. For example, when seven lines radiate from a point the number of combinations of these taken two at a time is $7 \times 6/2 = 21$, and hence there are 42 angles that can be measured.

The Binomial Theorem or formula is a means for writing out the power of a binomial in a series It is

$$(a \pm b)^n = a^n \pm na^{n-1}b + \frac{n(n-1)}{1 \cdot 2}a^{n-2}b^2 \pm \frac{n(n-1)(n-2)}{1 \cdot 2 \cdot 3}a^{n-3}b^3 + \cdots$$

When n is a positiv integer it holds in all cases; when n is a fraction or negativ it holds only if a is greater than b. In the first case the expansion (right-hand member) has $n+1$ terms; in the second the number of terms is infinite. The coefficients of the powers of a and b in the expansion are called binomial coefficients; the general formula for the rth coefficient is $Cr = [n(n-1)(n-2)\ldots(n-r+1)] \div [1 \times 2 \times 3 \times \ldots r]$. Thus when $n = 5$, the coefficients are 1, 5, 10, 10, 5, 1.

If x stands for b/a, then $(a \pm b)^n = a^n(1 \pm x)^n$, and the expansion of a binomial of the type $(a \pm b)$ can be exprest by that of one of the type $(1 \pm x)$. When n is a positiv integer the following hold in all cases, but when n is a fraction or negativ they hold only if x is between 0 and 1.

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{1 \cdot 2}x^2 \pm \frac{n(n-1)(n-2)}{1 \cdot 2 \cdot 3}x^3 + \cdots$$

$$\frac{1}{1 \pm x} = (1 \pm x)^{-1} = 1 \mp x + x^2 \mp x^3 + x^4 \mp x^5 + \cdots$$

$$\sqrt{1 \pm x} = (1 \pm x)^{1/2} = 1 \pm \frac{1}{2}x - \frac{1 \cdot 1}{2 \cdot 4}x^2 \pm \frac{1 \cdot 1 \cdot 3}{2 \cdot 4 \cdot 6}x^3 - \cdots$$

$$\frac{1}{\sqrt{1 \pm x}} = (1 \pm x)^{-1/2} = 1 \mp \frac{1}{2}x + \frac{1 \cdot 3}{2 \cdot 4}x^2 \mp \frac{1 \cdot 3 \cdot 5}{2 \cdot 4 \cdot 6}x^3 + \cdots$$

When x is small compared to 1, the first two or three terms in the four preceding expansions give generally a sufficient approximation in ordinary computations.

A Series is a succession of numbers which proceed according to some fixt law. A converging series is one whose sum, as the number of its terms is indefinitely increased, approaches some finite value as a limit; a diverging series is one whose sum, so taken, increases indefinitely. An ARITHMETIC SERIES, or arithmetic progression, is one in which the differences between successive terms are equal, as in $a, a+d, a+2d, a+3d, \ldots$; the nth term is $a+(n-1)d$, and the sum of the n terms is $\frac{1}{2}n[2a+(n-1)d]$. A GEOMETRIC SERIES, or geometric progression, is one in which the ratios of successive terms are equal, as in $a, ar, ar^2, ar^3, \ldots$; the nth term is ar^{n-1}, and the sum of the n terms is $a(r^n-1)/(r-1)$.

Some special series (see also preceding paragraph for Binomial series):

$$1+2+3+4+\cdots+(n-1)+n = \tfrac{1}{2}n(n+1)$$
$$2+4+6+8+\cdots+(2n-2)+2n = n(n+1)$$
$$1+3+5+7+\cdots+(2n-3)+(2n-1) = n^2$$
$$1+2^2+3^2+4^2+\cdots+(n-1)^2+n^2 = \tfrac{1}{6}n(n+1)(2n+1)$$
$$1+2^3+3^3+4^3+\cdots+(n-1)^3+n^3 = \tfrac{1}{4}n^2(n+1)^2$$

$$a^x = 1 + \frac{x}{1}\log_\varepsilon a + \frac{x^2}{2!}\log_\varepsilon^2 a + \frac{x^3}{3!}\log_\varepsilon^3 a + \cdots \quad (1)$$

$$\varepsilon^x = 1 + \frac{x}{1} + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots \quad \text{where } \varepsilon = 2.71828\ldots \quad (2)$$

$$\tfrac{1}{2}\log_\varepsilon x = \frac{x-1}{x+1} + \tfrac{1}{3}\frac{(x-1)^3}{(x+1)^3} + \tfrac{1}{5}\frac{(x-1)^5}{(x+1)^5} + \cdots$$

If $x^2 < 1$, $\log_\varepsilon(1 \pm x) = \pm x - \tfrac{1}{2}x^2 \pm \tfrac{1}{3}x^3 - \tfrac{1}{4}x^4 \pm \ldots$ (3)

$$\tfrac{1}{2}\log_\varepsilon\frac{1+x}{1-x} = x + \frac{x^3}{3} + \frac{x^5}{5} + \frac{x^7}{7} + \cdots \quad (4)$$

In right-hand members of the following, x is the angle in radians:

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!}\cdots \quad (5) \qquad \cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!}\cdots \quad (6)$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{3\cdot 5} + \frac{17x^7}{3^2\cdot 5\cdot 7}\cdots \quad (7)$$

Approximations when x is Small. In series (1) the first two terms, or at most three are generally sufficient when x is small compared to a, and in (2), (3), (4) when x is small compared to 1. In (5), (6), (7), two terms, or even one, may be sufficient when x is less than the arc of 10°; thus, for 8° the value of x is $(8/180)\pi = 0.13963$, and $\sin x = x - \tfrac{1}{6}x^3 = 0.13918$, which is one unit in error in the fifth decimal place. When the angle is less than 5°, the values of x and $\sin x$ do not differ more than one unit in the fourth decimal place. (See Sect. 1, Art. 5.)

2. Solution of Equations.

Algebraic Equations, rational and integral, and of the first, second, third or fourth degrees have been solved algebraically; that is, formulas have been found for the values of the unknown, the roots of the equation.

A Linear Equation, one of the first degree, as $ax + b = 0$, has only one root, namely $x = -b/a$.

A Quadratic Equation, one of the second degree, as $x^2 + 2ax + b = 0$, has two roots, namely $-a \pm (a^2 - b)^{\frac{1}{2}}$. If $a = 0$, the roots are equal and opposite in sign; if $b > a^2$ both roots are imaginary.

A Cubic Equation, or one of the third degree, can be written in the form $x^3 + 3ax^2 + 3bx + 2c = 0$; it has three roots, here called x_1, x_2, and x_3. To determine these compute B and C from $B = -a^2 + b$ and $C = a^3 - \tfrac{3}{2}ab + c$, and s_1 and s_2 from $s_1 = \left(-C + \sqrt{B^3 + C^2}\right)^{\frac{1}{3}}$ and $s_2 = \left(-C - \sqrt{B^3 + C^2}\right)^{\frac{1}{3}}$;

then
$$x_1 = -a + (s_1 + s_2)$$
$$x_2 = -a - \tfrac{1}{2}(s_1 + s_2) + \tfrac{1}{2}\sqrt{-3}\,(s_1 - s_2)$$
$$x_3 = -a - \tfrac{1}{2}(s_1 + s_2) - \tfrac{1}{2}\sqrt{-3}\,(s_1 - s_2)$$

When $B^3 + C^2$ is negativ the numerical solution leads to irreducible imaginary forms tho the three roots are real.

Equations of Degree Higher than the Second can generally be solved best by factoring, by trial, or graphically. In the following $f(x)$ is used to denote any expression containing x, and is read "a function of x," and $f(x) = 0$ may denote any equation containing x; the value of $f(x)$ when $x = a$ is denoted by $f(a)$.

(1) Factoring Method: Factor $f(x)$ and equate each factor to zero; solve each of the new equations for x; these roots are also roots of $f(x) = 0$. Thus, to find the roots of $x^3 - 19x - 30 = 0$, note that $x^3 - 19x - 30 = (x + 3)(x^2 - 3x - 10)$; from

$3 = 0$, $x = -3$ and from $x^2 - 3x - 10 = 0$, $x = +5$ and -2; hence -3, $+5$, and -2 are the roots sought.

(2) Trial Method: Make guesses at the roots until a value is found which nearly satisfies the equation; such a value is an approximate root. In finding it, note that if $f(x) = 0$ designates the equation, and if x_1 and x_2 are numbers such that $f(x_1)$ and $f(x_2)$ are of opposite sign, then there is an odd number of roots of $f(x) = 0$ between x_1 and x_2. Thus, to find a root of $f(x) = x^3 + 4x^2 - 5x - 15 = 0$: trying $x = 1$ and $x = 3$ one gets $f(1) = -15$ and $f(3) = +33$; 1 and 3 are not close values of the root but there is a root between them; trying 2 one gets $f(2) = -1$, a closer value. Trying 2.1, one gets $f(2.1) = +1.4$; the root is between 2 and 2.1.

(3) Plotting Method: The equation to be solved being $f(x) = 0$, plot the graph of $y = f(x)$ (see Art. 3); the abscissas of the intersections of the graph with the x axis are roots of $f(x) = 0$. Or, break up $f(x)$ into the difference of two functions of x as $f_1(x)$ and $f_2(x)$ and plot the graphs of $y = f_1(x)$ and $y = f_2(x)$; then the abscissas of the intersections of the two graphs are roots of $f(x) = 0$. Thus, to solve $x^3 + 4x^2 - 5x - 15 = 0$: the graph of $y = x^3 + 4x^2 - 5x - 15$ is shown by the solid curve of Fig. 1, and the abscissas of its intersections with the x axis are about 2.1, -1.6, and -4.3, which are also the roots sought. Or, again, $x^3 + 4x^2 - 5x - 15$ can be broken up into $(x^3 + 4x^2) - (5x + 15)$; the dashed curve is the graph of $y = x^3 + 4x^2$ and the straight line is the graph of $y = 5x + 15$; the abscissas of the intersections of these two graphs are about 2.1, -1.6 and -4.3, and they are the roots sought.

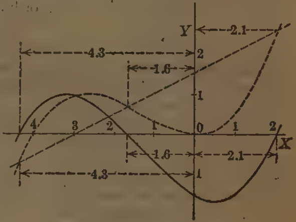

Fig. 1

Transcendental Equations are those involving trigonometry or logarithms; such equations with one unknown can be solved by one of the foregoing methods. For example, to find the roots of $\tan x - 2x = 0$ (x being in radians): plot the graphs of $y = \tan x$ and $y = 2x$, and determine the abscissas of the intersections of the graphs; the abscissas are the roots, one being $x = 1.16$.

To find the horizontal tension t in a catenary cable whose length is 22 ft, span 20 ft, and weight 10 lb per lin ft. The equation to be solved is $e^{10/t} - e^{-10/t} - 22 = 0$. By trial t is found to lie between 12 and 14; trying $t = 13$. the equation reduces to $+0.0298 = 0$; trying $t = 13.1$ it reduces to $-0.0012 = 0$, hence the root is a little less than $t = 13.1$.

An equation which arises in the theory of a column round at one end and fixt at the other is $x - \tan x = 0$, where x is to be in radians. This equation has many roots, the smallest one being $x = 4.49341$.

3. Graphic Representations

Rectangular Coordinates. XX' and YY' (Fig. 2) are two rectangular coordinate axes or x and y axes; and XOY, YOX', $X'OY'$, and $Y'OX$ are the first, second, third, and fourth quadrants respectively; O is the origin of coordinates. The position of any point in the drawing, as P, relative to the axes may be specified by two coordinates, the x coordinate, or abscissa of P, and the y coordinate, or ordinate of P. The abscissa, denoted by x, is the distance of P from the y axis, and the ordinate, denoted by y, is the distance of P from the x axis; the coordinates have signs as follows:

x is positiv when P is to the right of the y axis,
x is negativ when P is to the left of the y axis,
y is positiv when P is above the x axis,
y is negativ when P is below the x axis.

When P is actually plotted by means of its coordinates, the coordinates are also said to have been plotted. If the coordinates of P are x and y, say, P is referred to as the point (x, y).

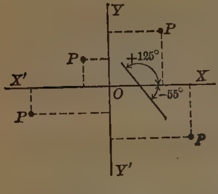

Fig. 2

Graphs. An equation between any two variables as x and y is sometimes written $y = f(x)$, for brevity; it is read "y equals a function of x." The graph of any equation as $y = f(x)$ is a graphical representation of the relation between y and x; to determine the graph compute values of y corresponding to assumed values of x, plot points whose coordinates are the corresponding values of x and y computed, and then draw a smooth curve thru the points.

Logarithmic Plotting. The equation $y = f(x)$ may be represented by a graph obtained by plotting corresponding values of log x and log y, instead of x and y, values of y having been obtained from $y = f(x)$ for assumed values of x; such an one is a logarithmic graph. If values of x and log y, or y and log x be plotted, the graphs are semi-logarithmic. These graphs are more advantageous than the ordinary one in some cases, and can be got as readily by using logarithmic or semi-logarithmic rulings as in Figs. 4 and 6 in which the unequal divisions are like those on an ordinary slide rule, based on the logarithms of numbers, and the figures on the rulings are not logarithms but the corresponding numbers, also as on a slide rule. If $y = f(x)$ be graphed on such ruling by plotting corresponding values of x and y, the graphs are logarithmic or semi-logarithmic, exactly like those first described.

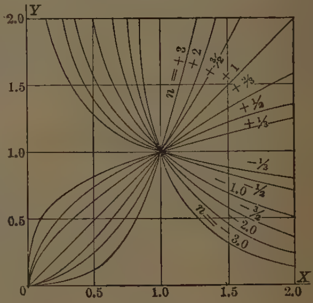

Fig. 3

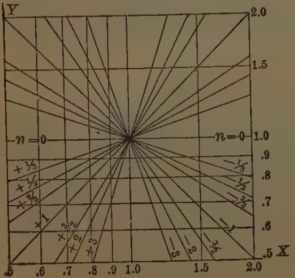

Fig. 4

The Intercept of a graph on the x (or y) axis is the x (or y) coordinate of the intersection of the graph with x (or y) axis. The SLOPE ANGLE of a straight line is the angle between the line and the positiv x axis; the slope angles of all lines may be exprest by angles between 0 and 180°, or $-90°$ and $+90°$ (see Fig. 2). The slope, or gradient, of a graph at any point is the tangent of the slope angle of its tangent line at that point.

The graph of $y = mx + c$, into the form of which any equation between two variables of the first degree can be put, is straight; m = the slope of the graph and c = its intercept

on the y axis. Thus $y = -2x + 3$ has a graph sloping upwards to the left at an angle of 63½° and cutting the y axis 3 units above the origin.

The graph of $y - b = m(x - a)^n + c$ is curved, its shape depending upon the numerical values of m and n; a, b, and c affect only the position of the graph with respect to the coordinate axis. Fig. 3 represents graphs of $y = x^n$ for the different values of n noted. The corresponding graphs of $y = mx^n$ are enlargements in the y direction if $m > 1$ and reductions if $1 > m > 0$ of those shown; if m is negativ, the effect is enlargement or reduction as explained and a rotation of the graphs through 180° about the x axis. The logarithmic graph of $y = x^n$ is straight; Fig. 4 shows these graphs corresponding to those of Fig. 3. The logarithmic graphs of $y = mx^n$ are also straight, but they do not pass thru the point (1, 1).

The graph of $(y - a) = me^{nx-b} + c$, a "logarithmic or compound interest" equation, is curved; its shape depends on the numerical values of m and n; a, b and c affect only the position of the curve relative to the coordinate axes. Fig. 5 represents graphs of $y = \epsilon^{nx}$ for the several values of n noted. In $y = m\epsilon^{nx}$, m affects the graphs shown as explained in the preceding paragraph. The semi-logarithmic graph of $y = \epsilon^{nx}$ is straight; Fig. 6 shows these graphs corresponding to those of Fig. 5. The semi-logarithmic graph of $y = m\epsilon^{nx}$ is also straight, but it does not pass through the point (0, 1).

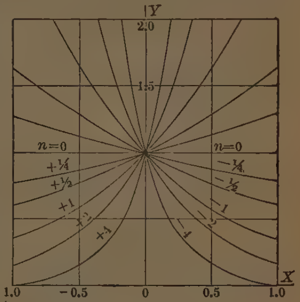

Fig. 5

To Find an Equation for a Given Graph. If the graph, plotted on axes x and y, is straight, the equation is of the first degree; let (x_1, y_1) and (x_2, y_2) be the coordinates of any two points of the graph; the equation is $(y - y_1)(x_2 - x_1) = (x - x_1)(y_2 - y_1)$. If the intersection of the graph with either axis is available, that intersection may well be taken as one of the points; if it passes thru the origin, that may be advantageously chosen. If the graph is curved, there may be no corresponding equation but an equation can usually be found which will approximately fit at least a limited portion of the graph.

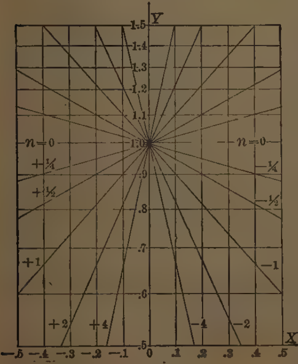

Fig. 6

(1) If the graph resembles a portion of one of the family represented in Fig. 3, plot its logarithmic graph; if this is practically straight, the original graph can be closely represented by $y = mx^n$. To determine m and n: $m = y$ when $x = 1$, and this value of y can be got from either graph, probably more accurately from the logarithmic; then in $\log(y/m) = n \log x$ substitute the coordinates x and y of any point and solve for n.

(2) If the graph resembles a portion of one of the family represented in Fig. 5, plot semi-logarithmically (Fig. 6); if the resulting graph is practically straight, then the original graph can be closely represented by $y = m\epsilon^{nx}$. To determine m and n: the value of

m is found from $m = y$ when $x = 0$, and this value of y can be got from either graph, probably most accurately from the semi-logarithmic graph; then in $\log_e y = \log_e m + nx$ substitute the x and y coordinates of any point on either graph and solve for n.

4. Trigonometry

Functions of Acute Angles. If from a point in either line bounding an angle (Fig. 7) a perpendicular is drawn to the other line, then in the right triangle thus formed the leg adjacent to α is the base, and the leg opposite, the perpendicular; they are denoted by b and p respectively and the hypothenuse by h. The sine, cosine, tangent, cotangent, secant, and cosecant of the angle are defined (and abbreviated) thus:

$$\sin\alpha = p/h \qquad \cos\alpha = b/h \qquad \tan\alpha = p/b$$
$$\csc\alpha = h/p \qquad \sec\alpha = h/b \qquad \cot\alpha = b/p$$

The versed sine, abbreviated vers, is unity minus the cosine; thus vers $\alpha = 1 - \cos\alpha$. The exsecant, abbreviated exsec, is secant minus unity, thus exsec $\alpha = \sec\alpha - 1$. From the foregoing it follows that

$$\sin\alpha/\cos\alpha = \tan\alpha \qquad \cos\alpha/\sin\alpha = \cot\alpha$$
$$\sin\alpha\csc\alpha = \cos\alpha\sec\alpha = \tan\alpha\cot\alpha = 1$$
$$\sin^2\alpha + \cos^2\alpha = \sec^2\alpha - \tan^2\alpha = \csc^2\alpha - \cot^2\alpha = 1$$

If $\alpha + \beta = 90°$, $\sin\alpha = \cos\beta$, $\tan\alpha = \cot\beta$, $\sec\alpha = \csc\beta$. If the arc $A''B'$ (Fig. 7) be struck from O with a radius unity, then in the triangle $OA'B'$ h is unity and in the triangle $OA''B''$ b is unity. Then also

$$\sin\alpha = A'B' \qquad \cos\alpha = OA' \qquad \tan\alpha = A''B''$$
$$\sec\alpha = OB'' \qquad \text{vers}\,\alpha = A'A'' \qquad \text{exsec}\,\alpha = B'B''$$

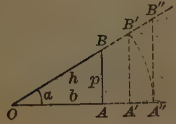

Fig. 7

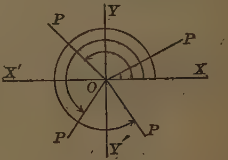

Fig. 8

Functions of any Angle. Let $\alpha = XOP$ (Fig. 8), x and y = the coordinates of P, and $h = OP$. Then whether α is in the first, second, third, or fourth quadrant, the functions of α are defined as follows:

$$\sin\alpha = y/h \qquad \cos\alpha = x/h \qquad \tan\alpha = y/x$$
$$\csc\alpha = h/y \qquad \sec\alpha = h/x \qquad \cot\alpha = x/y$$

Since x and y may be positiv or negativ, the functions may also be; the sign of a function depends on the quadrant of α, thus:

quad	sin	cos	tan	cot	sec	csc
1	+	+	+	+	+	+
2	+	−	−	−	−	+
3	−	−	+	+	−	−
4	−	+	−	−	+	−

The values of the functions for the four cardinal angles are,

angle	sin	cos	tan	cot	sec	csc
0°	0	+1	0	∞	+1	∞
90	+1	0	∞	0	∞	+1
180	0	−1	0	∞	−1	∞
270	−1	0	∞	0	∞	−1
360	0	+1	0	∞	+1	∞

Functions of angles greater than 90° are not given in trigonometric tables generally. These can be obtained from the functions of acute angles by means of the following in which α_2, α_3, and α_4 denote angles in the second, third, and fourth quadrants respectively.

α_2	$180° - \alpha_2$	$\alpha_2 - 90°$
sin =	+ sin =	+ cos
cos =	− cos =	− sin
tan =	− tan =	− cot

α_3	$\alpha_3 - 180°$	$270° - \alpha_3$
sin =	− sin =	− cos
cos =	− cos =	− sin
tan =	+ tan =	+ cot

α_4	$360° - \alpha_4$	$\alpha_4 - 270°$
sin =	− sin =	− cos
cos =	+ cos =	+ sin
tan =	− tan =	− cot

Negativ Angles. Angles in the preceding figures and those referred to in the foregoing were regarded as measured from OX in the counterclockwise direction and considered positiv; an angle regarded as measured clockwise is considered negativ. OP (Fig. 8) may be specified by a positiv or a negativ angle, the arithmetic sum of the two being 360°. If α denotes merely the numerical value of any angle, then

$$\sin(-\alpha) = -\sin\alpha \qquad \cos(-\alpha) = \cos\alpha \qquad \tan(-\alpha) = -\tan\alpha$$
$$\csc(-\alpha) = -\csc\alpha \qquad \sec(-\alpha) = \sec\alpha \qquad \cot(-\alpha) = -\cot\alpha$$

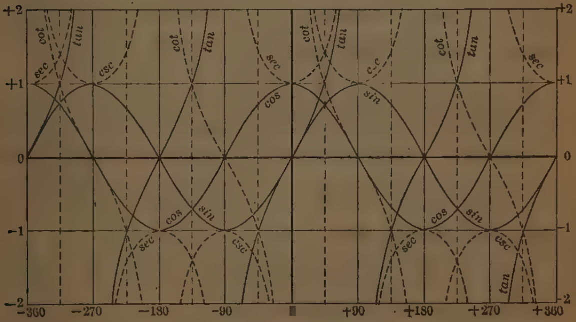

Fig. 9. Graphs of Trigonometric Functions

Graphs of sin α, cos α, tan α, cot α, sec α, and csc α are seen in Fig. 9 for values of α between −360° and +360°; the graphs of the last four functions have infinite branches which are asymptotic to the solid vertical lines adjacent at the upper and lower margins. The figure shows the sign and periodicity of any function of any angle between the limits named and roughly the relative values of the functions of any particular angle.

Inverse, or Anti-Functions. The symbol $\sin^{-1} x$ means the angle whose sine is x, and is read inverse sine of x and anti-sine of x (also arc sine x). Similarly $\cos^{-1} x$, $\tan^{-1} x$, $\cot^{-1} x$, $\sec^{-1} x$, $\csc^{-1} x$, $\text{vers}^{-1} x$, the last meaning an angle α such that $(1 - \cos\alpha) = x$. While the direct functions (sine, etc.) are single valued, the indirect are many valued; thus $\sin 30° = 0.5$, but $\sin^{-1} 0.5 = 30°$ or $150°$ . . . .

Trigonometric Relations. Functions of an angle exprest in terms of each of the others; the following abbreviations are used:

$$A = \pm\sqrt{1 - \sin^2\alpha} \qquad B = \pm\sqrt{1 - \cos^2\alpha} \qquad C = \pm\sqrt{1 + \tan^2\alpha}$$

$$F = \pm\sqrt{\csc^2\alpha - 1} \qquad E = \pm\sqrt{\sec^2\alpha - 1} \qquad D = \pm\sqrt{1 + \cot^2\alpha}$$

$$\sin\alpha = B = \tan\alpha/C = 1/D = E/\sec\alpha = 1/\csc\alpha$$

$$\cos\alpha = A = 1/C = \cot\alpha/D = 1/\sec\alpha = F/\csc\alpha$$

$$\tan\alpha = \sin\alpha/A = B/\cos\alpha = 1/\cot\alpha = E = 1/F$$

$$\cot\alpha = A/\sin\alpha = \cos\alpha/B = 1/\tan\alpha = 1/E = F$$

$$\sec\alpha = 1/A = 1/\cos\alpha = C = D/\cot\alpha = \csc\alpha/F$$

$$\csc\alpha = 1/\sin\alpha = 1/B = C/\tan\alpha = D = \sec\alpha/E$$

Functions of the sum and difference of two angles:

$$\sin(\alpha \pm \beta) = \sin\alpha\cos\beta \pm \cos\alpha\sin\beta$$

$$\cos(\alpha \pm \beta) = \cos\alpha\cos\beta \mp \sin\alpha\sin\beta$$

$$\tan(\alpha \pm \beta) = (\tan\alpha \pm \tan\beta)/(1 \mp \tan\alpha\tan\beta)$$

$$\cot(\alpha \pm \beta) = (\cot\beta\cot\alpha \mp 1)/(\cot\beta \pm \cot\alpha).$$

If x is small, say 3 or 4°, then the following are close approximations, in which the coefficients x must be exprest in radians ($1° = 0.01745$ radians).

$$\sin(\alpha \pm x) = \sin\alpha \pm x\cos\alpha, \qquad \cos(\alpha \pm x) = \cos\alpha \mp x\sin\alpha.$$

Functions of half and double angles:

$$\sin \tfrac{1}{2}\alpha = \sqrt{\tfrac{1}{2}(1 - \cos\alpha)} = \tfrac{1}{2}\sqrt{1 + \sin\alpha} - \tfrac{1}{2}\sqrt{1 - \sin\alpha}$$

$$\cos \tfrac{1}{2}\alpha = \sqrt{\tfrac{1}{2}(1 + \cos\alpha)} = \tfrac{1}{2}\sqrt{1 + \sin\alpha} + \tfrac{1}{2}\sqrt{1 - \sin\alpha}$$

$$\tan \tfrac{1}{2}\alpha = \sqrt{(1 - \cos\alpha)/(1 + \cos\alpha)} = (1 - \cos\alpha)/\sin\alpha = \sin\alpha/(1 + \cos\alpha)$$

$$\cot \tfrac{1}{2}\alpha = \sqrt{(1 + \cos\alpha)/(1 - \cos\alpha)} = (1 + \cos\alpha)/\sin\alpha = \sin\alpha/(1 - \cos\alpha)$$

$$\sin 2\alpha = 2\sin\alpha\cos\alpha, \qquad \cos 2\alpha = 2\cos^2\alpha - 1 = 1 - 2\sin^2\alpha,$$

$$\tan 2\alpha = 2\tan\alpha/(1 - \tan^2\alpha), \qquad \cot 2\alpha = (\cot^2\alpha - 1)/2\cot\alpha.$$

Sums and products of functions:

$$\sin\alpha\cos\beta = \tfrac{1}{2}\sin(\alpha + \beta) + \tfrac{1}{2}\sin(\alpha - \beta)$$

$$\cos\alpha\sin\beta = \tfrac{1}{2}\sin(\alpha + \beta) - \tfrac{1}{2}\sin(\alpha - \beta)$$

$$\sin\alpha\sin\beta = \tfrac{1}{2}\cos(\alpha - \beta) - \tfrac{1}{2}\cos(\alpha + \beta)$$

$$\cos\alpha\cos\beta = \tfrac{1}{2}\cos(\alpha - \beta) + \tfrac{1}{2}\cos(\alpha + \beta)$$

$$\sin(\alpha + \beta)\sin(\alpha - \beta) = \sin^2\alpha - \sin^2\beta = \cos^2\beta - \cos^2\alpha$$

$$\sin\alpha + \sin\beta = 2\sin\tfrac{1}{2}(\alpha + \beta)\cos\tfrac{1}{2}(\alpha - \beta)$$

$$\sin\alpha - \sin\beta = 2\cos\tfrac{1}{2}(\alpha + \beta)\sin\tfrac{1}{2}(\alpha - \beta)$$

$$\cos\alpha + \cos\beta = 2\cos\tfrac{1}{2}(\alpha + \beta)\cos\tfrac{1}{2}(\alpha - \beta)$$

$$\cos\alpha - \cos\beta = -2\sin\tfrac{1}{2}(\alpha + \beta)\sin\tfrac{1}{2}(\alpha - \beta)$$

5. Plane and Spherical Triangles

Plane Triangles. The three angles are denoted by α, β, and γ, and the respective opposite sides by a, b, and c; also s denotes $\frac{1}{2}(a+b+c)$, r radius of inscribed circle, R radius of circumscribed circle, and A area of the triangle. Then, $\alpha+\beta+\gamma=180°$,

$$a/\sin\alpha = b/\sin\beta = c/\sin\gamma \text{ ("law of sines")}$$
$$c^2 = a^2+b^2-2ab\cos\gamma, \quad r=\sqrt{(s-a)(s-b)(s-c)/s}$$
$$A = sr = \tfrac{1}{2}ab\sin\gamma, \qquad R=\tfrac{1}{2}a\csc\alpha.$$

Solution of Right Triangles. If an acute angle and one side or if two sides of a right triangle are given the other elements can be determined. Let h = hypothenuse, α and β acute angles, and a and b the legs opposite them, respectively. The acute angles are complementary, that is, $\alpha+\beta=90°$; the area is $\frac{1}{2}ab$ always. Five cases may be distinguished:

Given h and α; $a = h\sin\alpha$, $b = h\cos\alpha$
Given a and α; $b = a\cot\alpha$, $h = a\csc\alpha$
Given b and α; $a = b\tan\alpha$, $h = b\sec\alpha$
Given a and h; $\alpha = \sin^{-1}a/h$, $b=\sqrt{(h+a)(h-a)}$
Given a and b; $\alpha=\tan^{-1}a/b$, $h=\sqrt{a^2+b^2}$

Solution of Oblique Triangles. If any three of the six elements (three angles and three sides) of a triangle are known, the remaining three can be determined provided one of the given three is a side. Any problem will fall under one of four cases.

Case 1. Given one side and two angles. Then the third angle equals 180° minus the sum of the two given. If the given side be a, then

$$b = a\sin\beta/\sin\alpha \quad \text{and} \quad c = a\sin\gamma/\sin\alpha.$$

Case 2. Given two sides and the included angle (a, b and γ). Then

$$\tfrac{1}{2}(\alpha+\beta) = 90° - \tfrac{1}{2}\gamma,\ \tfrac{1}{2}(\alpha-\beta) = \tan^{-1}[\tan\tfrac{1}{2}(\alpha+\beta)\cdot(a-b)/(a+b)]$$
$$\alpha = \tfrac{1}{2}(\alpha+\beta)+\tfrac{1}{2}(\alpha-\beta) \qquad \beta=\tfrac{1}{2}(\alpha+\beta)-\tfrac{1}{2}(\alpha-\beta)$$
$$c = a\sin\gamma/\sin\alpha.$$

Case 3. Given two sides a and b and the angle α opposite one of them. Then $\sin\beta=(b/a)\sin\alpha$, giving two values of β, one acute and one obtuse unless $\sin\beta>1$, in which case the data are impossible. Calling these two angles β_1 and β_2 respectively, then

corresponding to β_1, $\gamma_1 = 180-(\alpha+\beta_1)$ and $c_1 = a\sin\gamma_1/\sin\alpha$
corresponding to β_2, $\gamma_2 = 180-(\alpha+\beta_2)$ and $c_2 = a\sin\gamma_2/\sin\alpha$.

That is, there are two solutions unless $\gamma_2<0$, when only the first holds. (The meanings of these exceptions, $\sin\beta>1$ and $\gamma_2<0$, will become evident if a geometrical construction of the triangle is attempted.)

Case 4. Given the three sides. Let s denote $\frac{1}{2}(a+b+c)$. Then

$$\cos\tfrac{1}{2}\alpha=\sqrt{s(s-a)/bc} \quad \cos\tfrac{1}{2}\beta=\sqrt{s(s-b)/ca} \quad \cos\tfrac{1}{2}\gamma=\sqrt{s(s-c)/ab}$$

Spherical Triangles. The intersection of the surface of a sphere with a plane thru its center is a great circle of the sphere; an arc of the circle is measured by the angle between the radiuses of the sphere drawn to the ends of the arc. A spherical angle is the angle between two intersecting arcs of great circles; it is measured by the angle between their tangents at the intersection. A spherical triangle is a portion of the surface of a sphere bounded

by arcs of three great circles. Spherical triangles are classified in the sam way as plane ones; thus, isosceles, equilateral, right, etc. The spherica excess of a triangle is the excess of the sum of its angles over 180°. An spherical triangle can be solved if any three of its six elements (three side and three angles) are given; from the following formulas a solution may b made in any given case. The notation is as follows: α, β, and γ represen the three angles, while a, b, and c designate the opposite sides respectivel and e = the spherical excess.

$$\sin a / \sin \alpha = \sin b / \sin \beta = \sin c / \sin \gamma$$

$$\cos c = \cos a \cos b + \sin a \sin b \cos \gamma$$

$$\cos \gamma = -\cos \alpha \cos \beta + \sin \alpha \sin \beta \cos c$$

$$\cot \tfrac{1}{2} e = (\cot \tfrac{1}{2} a \cot \tfrac{1}{2} b + \cos \gamma) / \sin \gamma$$

A spherical right triangle can be solved if any two of its elements, not including th right angle, are given. In the following h is the hypothenuse, a and b the other tw sides, and α and β the angles opposite a and b respectively.

$$\sin a = \sin h \sin \alpha = \tan b \cot \beta \cdot \quad \cos \alpha = \cos a \sin \beta = \cot h \tan b$$

$$\cos h = \cos a \cos b = \cot \alpha \cot \beta$$

6. Geometry and Mensuration

Angles. The common unit of angle is the degree (one-ninetieth of a rig angle); the degree is divided into 60 minutes and the minute into 60 second Another unit is the *radian*, called also the unit in circular measure of angle it is an angle equal to that between two radiuses of a circle which embra an arc equal to the radius. Then

$$1 \text{ radian} = 180 \div \pi \text{ degrees} = 57.296°, \ 1 \text{ degree} = 0.0175 \text{ radian}$$

If an angle α subtends a circular arc whose length and radius are s and respectively, then $\alpha = s/r$ or $s = r\alpha$ provided that s and r are exprest the same unit and α in radians.

Triangles. Let a, b, and c = lengths of sides; α, β, and γ the opposite angl h the altitude to the side b, s denote $\frac{1}{2}(a + b + c)$, and A = area.

$$A = \tfrac{1}{2} bh = \tfrac{1}{2} ba \sin \gamma = \tfrac{1}{2} b^2 \sin \gamma \sin \alpha / \sin \beta = \sqrt{s(s-a)(s-b)(s-c)}$$

Quadrilaterals. Let D_1 and D_2 = lengths of the two diagonals and α the an between them, then $A = \frac{1}{2} D_1 D_2 \sin \alpha$. Parallelogram: let a = one side, b = ba α = angle between a and b, h = altitude; then $A = bh = ab \sin \alpha$. Trapezoid: let b a B = parallel sides, and h = altitude; then $A = \frac{1}{2}(b + B)h$.

Polygons. The area A equals the sum of the areas of the constitue triangles. For a regular polygon (equal sides and equal angles) let R radius of circumscribed circle, r = radius of inscribed circle, a = length o side, n = number of sides, 2α = central angle subtended by one side; the

$$A = \tfrac{1}{4} na^2 \cot \alpha = \tfrac{1}{2} nR^2 \sin 2\alpha = nr^2 \tan \alpha \qquad a = 2R \sin \alpha = 2r \tan \alpha$$

Circle (Fig. 11). Circumference $L = 2\pi r = \pi d$. Area $A = \pi r^2 = \frac{1}{4}\pi$ Chord $C = 2r \sin \frac{1}{2}\theta$. Rise of arc $h = r(1 - \cos \frac{1}{2}\theta)$. Arc subtended b $a = \pi d \times (\theta \text{ in degrees})/360 = r\,(\theta \text{ in radians})$; when h is small compared C, $a = \frac{1}{3}(8c - C)$; this is approximate, but even when $h = r$, the error less than $1\frac{1}{4}$%. Sector $OMPN$: area = area of circle (θ in degrees)/3 Segment $MPNM$: area = area sector $- \frac{1}{2} r^2 \sin \theta$; when h is small compa to C, area = $\frac{2}{3} Ch$, also $h(8c + 6C)/15$, both approximate; when $h = \frac{1}{}$ the first errs about $3\frac{1}{2}$% and the second less than 1%.

To Find the Center of a Given Circle, draw a chord and then a perpendicular to the chord at its middle point; this line extended in both directions to the circumference is a diameter, etc. To draw a circle thru three points: join one of the points with the others, thus getting two chords; at the middle points of the chords erect perpendiculars; the intersection of these is the center of the circle. If, in the preceding problem, the center is inaccessible or the radius is too long for drawing instruments, proceed as follows, the three points being A, O, A', Fig. 10: draw arcs Aa' and $A'a$ with centers at A' and A respectively; extend AO to determine a and $A'O$ to determine a'; divide aA' into equal parts ab, bc, etc; lay off $a'b'$, $b'c'$, etc., equal to ab; join A with any point as b and A' with the corresponding point b'; the intersection P of these joining lines is a point in the circle. If in the preceding problem it is desired to determine points in the circle by ordinates as NP, let r = radius of the circle, h = rise or center ordinate OQ, C = chord AA', y = any ordinate as NP, and $x = QN$ (distance of that ordinate from the center one), then $r = (4\,h^2 + C^2)/8\,h$, and

$$y = \sqrt{r^2 - x^2} - (r - h) = \sqrt{r^2 - x^2} - \sqrt{r^2 - C^2/4}$$

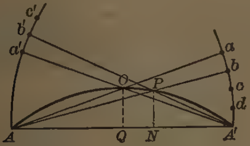

Fig. 10

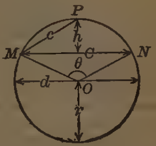

Fig. 11

Ellipse (see also Art. 11). The circumference of an ellipse whose semi-axes are a and b is $\pi(a + b)\,k$ where k is an abbreviation for $(1 + c^2/4 + c^4/64 + c^6/256 + \cdots)$ and $c = (a - b)/(a + b)$. The following table gives k for several values of c:

c	k	c	k	c	k	c	k	c	k
0.05	1.0006	0.25	1.0158	0.45	1.0516	0.65	1.1083	0.85	1.1903
.10	1.0025	.30	1.0215	.50	1.0635	.70	1.1267	.90	1.2154
.15	1.0054	.35	1.0311	.55	1.0768	.75	1.1466	.95	1.2430
.20	1.0100	.40	1.0404	.60	1.0922	.80	1.1677	1.00	1.2732

The area of an ellipse is given by πab; the area of any part as $ABQP$ (Fig. 12) is $xy + ab \sin^{-1} x/a$, in which x and y are the distances of P or Q from the axes.

Hyperbola (see also Art. 11). The area of any symmetrical segment like $PAQP$ (Fig. 13) is $xy - ab \log_e (x/a + y/b)$, where $2\,a$ and $2\,b$ are the lengths of the axes of the hyperbola and x and y the distances of P or Q from the axes.

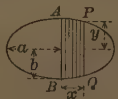

Fig. 12

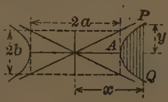

Fig. 13

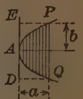

Fig. 14

Parabola (see also Art. 11). The length of any arc beginning at the vertex as AP (Fig. 14) is $(b^2/4\,a)\left[\sqrt{c\,(1 + c)} + \log_e\left(\sqrt{c} + \sqrt{1 + c}\right)\right]$, in which c is an abbreviation for $4\,a^2/b^2$, a and b being distances as marked. The area of a symmetrical segment like $PAQP$ is two-thirds that of the rectangle $PEDQ$.

Irregular Figure (Fig. 15). To find the area divide the figure into an even number of strips of equal width; the more numerous these strips the more

Fig. 15

accurate is the result given by the following formulas. The first of the ordinates bounding the strips is called y_0, the second y_1, etc., n the numbe of strips, w their common width and A the area. The following formulas give A approximately:

$A = w(\frac{1}{2}y_0 + y_1 + y_2 + \cdots + y_{n-1} + \frac{1}{2}y_n)$, Trapezoidal.

$A = \frac{1}{3}w(y_0 + 4y_1 + 2y_2 + 4y_3 + \cdots + 2y_{n-2} + 4y_{n-1} + y_n)$, Simpson's

$A = w(0.4y_0 + 1.1y_1 + y_2 + y_3 + \cdots + y_{n-2} + 1.1y_{n-1} + 0.4y_n)$, Durand's

Simpson's rule applies only when n is odd; when n is even the area of $n-3$ strip may be computed and then the area of the remaining 3 strips may be found b

$$A = \tfrac{3}{8}w(y_0 + 3y_1 + 3y_2 + y_3), \text{ Cotes's.}$$

Prism. Let V = volume, h = altitude, A = base area; $V = Ah$. Trun cated prism: V = the product of the length of line joining the centers of gravit of the bases and the area of section perpendicular to the line. Truncate triangular prism: V = product of one-third the sum of the parallel edge and the area of section perpendicular to edges.

Cylinder. Let V = volume, A = base area, h = altitude; $V = Ah$. Rigl circular cylinder: Let r = base radius, S = area cylindrical surface; V $\pi r^2 h$, $S = 2\pi rh$, $A = \pi r^2$. Frustum right circular cylinder: H = greatest height, h = least height; $V = \pi r^2 (H + h)/2$, $S = \pi r(H + h)$. Wedge of right circular cylinder (Fig. 16); Let $2C$ = straight edge of base, p = altitude of the base (segment of circle), 2ϕ = central angle of the arc of base in degrees, r = radius of base; $V = [C(3r^2 - C^2) + 3r^2(p - r)\phi\pi/180]\,h/3p$, $S = [C + (p - r)\phi\pi/180]\,2rh/p$. Hollow right circular cylinder: R = outer radius of base, r = inner radius, t = thickness $= R - r$; $V = \pi(R^2 - r^2)h = \pi(2R - t)th = \pi(2r + t)th$.

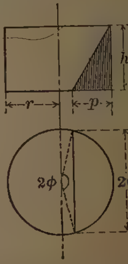

Fig. 16

Pyramid. Let V = volume, A = area base, h = altitude; $V = Ah/3$. Frustum of a pyramid: let A and a = areas of bases; $V = (A + a + \sqrt{Aa})\,h/3$.

Cone. Let V = volume, A = area of base, h = altitude; then $V = Ah/3$. Circular Cone: let r = radius of base; $V = \pi r^2 h/3$. Right circular cone: area of conical surface, $S = \pi r\sqrt{r^2 + h^2}$. Frustum of right circular cone: let R = rad larger and r = radius smaller base; $V = \pi(R^2 + Rr + r^2)\,h/3$; $S = \pi(R +$ $\sqrt{(R - r)^2 + h^2}$.

Sphere. Let V = volume, A = area, r = radius, and d = diameter. Th $V = \frac{4}{3}\pi r^3 = \frac{1}{6}\pi d^3$; $A = 4\pi r^2 = \pi d^2$. Zone: let h = a tude, a = radius larger base, b = radius smaller base; $V = \frac{1}{2}$ $(a^2 + b^2 + h^2/3)$; convex $A = 2\pi rh$; $r^2 = a^2 + [(a^2 - b^2 - h^2)/2$ Segment (zone with one base): make $b = 0$ in formulas zone. Sector with one conical surface (Fig. 17): $V = \frac{2}{3}\pi$ total $A = \pi r(2h + a)$.

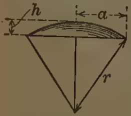

Fig. 17

Ellipsoid. Every section is a circle or an ellipse. a, b, and c = the semi-axes; then the volume = $\frac{4}{3}\pi abc$.

Paraboloid of Revolution generated by revolving a parabola about own axis (Fig. 18). Let r = radius of base and a = altitude of parabol

then volume = $\frac{1}{2}\pi r^2 a$. Volume of a frustum, R and r being radii of bases and h = height (see Fig. 18), is $\frac{1}{2}\pi(R^2 + r^2)\,h$ (approx.)

Surface and Solid of Revolution. The first may be generated by revolving a plane curve about a line in its plane, or else by a straight line about an intersecting line; and the second by revolving a plane area about a line in its plane. The AXIS of the surface or solid is the line about which the revolution takes place. The area and volume can be determined by the principles of Pappus and Guldinus which are:

Fig. 18

(a) For area A: let l = length of generating curve (must not cut the axis of revolution) and x_1 = distance of its center of gravity from the axis; then $A = 2\pi x_1 l$.

(b) For volume V: let a = area of the generating figure (must not be intersected by the axis) and x_2 = distance of its center of gravity from the axis; then $V = 2\pi x_2 a$.

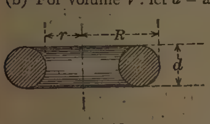

Fig. 19

The revolution of a circle about a line in its plane but not cutting the circle generates a 'tore,' or 'torus' or anchor ring (Fig. 19). The preceding formulas give its area and volume thus: $A = 2\pi \frac{1}{2}(R+r)\,\pi d = \pi^2(R+r)\,d$, and $V = 2\pi\frac{1}{2}(R+r)\frac{1}{4}\pi d^2 = \frac{1}{4}\pi^2(R+r)d^2$.

A Prismoid is a solid with plane faces two being parallel (and called ends) and each of the others containing a part of the perimeter of one end and at least a point in that of the other end. Let V = volume of the prismoid, A_1 and A_2 = areas of the ends, A_m = area of the cross section of the prismoid midway between the ends, and l = length of prismoid (distance between ends); then $V = \frac{1}{6}(A_1 + A_2 + 4A_m)l$.

7. Interest and Sinking Fund

Interest. The notation in the formulas is: p = principal, the sum loaned; i = rate of interest, exprest thus, 0.06 or 6/100 for 6%; n = time, term, or period of the loan in years; a = amount due after n years, that is, the sum of the principal and interest. When interest is paid only on the principal and not also on interest which may be due, the interest is simple; then

$$a = p(1 + in) \qquad i = (a - p)/pn \qquad p = a/(1 + in) \qquad n = (a - p)/pi$$

The adjoining table gives the simple interest on $100 at various rates for one year, one month (1/12 year), and one day (1/30 month, bank practise).

	2%	3%	4%	5%	6%	8%
1 year.....	$2.00	$3.00	$4.00	$5.00	$6.00	$8.00
1 month ...	0.16⅔	0.25	0.33⅓	0.41⅔	0.50	0.66⅔
1 day......	0.0055⅚	0.0083⅓	0.0111⅑	0.0138⅞	0.0166⅔	0.0222⅖

When interest is not paid periodically but regarded as additions to the principal, also to draw interest during the remainder of the time, then the interest is compound. If additions of interest to principal are made annually, then

$$a = p(1 + i)^n, \quad i = \sqrt[n]{(a/p)} - 1, \quad p = a/(1 + i)^n, \quad n = (\log a - \log p)/\log(1 + i)$$

For semiannual compound interest, $a = p(1 + i/2)^{2n}$. The adjoining table gives the amount of one dollar at interest compounded annually at various rates for various periods. Thus, $2000 at 3% in 20 years amounts to 2000 × $1.80611 = $3612.22; the interest earning is $3612.22 − $2000, or $1612.22.

Amount (Principal plus Interest) of $1 at Compound Interest

No. of Years	Rates of compound interest

An Annuity is a succession of equal sums paid regularly, generally annuall each payment is also called annuity, but more properly, installment. Th amount of an annuity for a term of years is the sum of the installments pl their interest earnings, interest being generally considered as compoun Let A = amount; i = interest rate express decimally (as 0.05 for 5%); n number of years in the period of the annuity; and I = (annual) insta ment, one at the end of each year. Then $A = I\,[(1 + i)^n - 1]/i$. The fo lowing table gives the amount of an annual annuity of $1 for various perio and various rates of interest. Thus, $200 invested at the end of each ye of a 20-year period at 4% amounts to 200 × $29.77808, or $5955.62, at the e of that period; the interest earned is $5955.62 − (20 × $200) = $1955.62.

Amount (Installments plus Interest Earned) of an Annual Annuity of $

A Sinking or Amortization Fund is one created to provide a def sum (for canceling a debt for example) at a certain time; it is usually cre by equal and regular contributions or installments and their interest earn compounded, that is, by an annuity and its interest earnings. Let S = amount of a sinking fund; n = number of years for its creation; i = int rate expressed decimally (as 0.05 when the rate is 5%); and I = an

installment required, paid at the end of each year of the period. Then $I = Si/[(1+i)^n - 1]$. The following table gives annual installments required to create a fund of one dollar (equal to I/S) in various periods at various interest rates. Thus the annual installment necessary to accumulate $22 000 in 25 years, at 4 %, is 22 000 × $0.02401, or $528.22; the interest earning is 22 000 − (25 × 528.22), or $8794.50.

Annual Annuity Required to Accumulate $1 (Installments plus Interest Earnings)

The Present Worth of a given sum due at a future time is such a sum which if now placed at interest, would amount to the given sum at that time. Let p = present worth, a = given sum due in n years from now, and i = interest rate; then on simple interest basis, $p = a/(1 + in)$, and on annual compound $p = a/(1+i)^n$. The following table gives present worths, computed at various rates of compound interest, of $1 due in various periods. For example, an addition to plant necessary 5 years hence will then entail a cost of $8000; how much can one afford to pay for such addition now, it being without use or expense for 5 years? As much as the present worth of $8000 due in 5 years at the current rate of interest, that is, if the rate is 5 %, 8000 × $0.78353, or $6268.24.

Present Worth of $1 Due at a Future Date

No. of Years	Rates of compound interest						
	2%	2½%	3%	3½%	4%	4½%	5%

The Present Worth of an Annuity is the sum which now placed at compound interest will reach the same amount as will be reached by the annuity. Let V = the present value of an annuity I; then $V = I[1 - (1+i)^{-n}]/i$. The following table gives values of an annuity of \$1 for various periods and various rates. Thus, the present worth of an annuity of \$1 for 20 years at 4% is \$13.59.

Present Value of an Annuity of \$1

Annual Depreciation of a property is the necessary annual installment of the annu which will amount to the first cost of that property at the expiration of its useful l annual depreciation is also exprest in percentage of first cost. Thus, if the first c of a part of a plant is \$10 000 and its life is estimated at 40 years, then if money is wo 3%, the annual depreciation is 10 000 × \$0.01326, or \$132.60, and the rate of depre tion is 1.326%. CAPITALIZATION of a plant is the sum of the first cost C and the cap necessary to earn annually (a) the annual cost of operation O and (b) the annual de ciation D; that is, if i is the interest rate, capitalization equals $C + (O + D)/i$. Th if in the preceding illustration O = \$500, the capitalization equals \$10 000 + (\$50 \$132.06)/0.03 = \$31 068.

Annual Annuity for Various Periods which \$1 will Purchase

The formula for this table is $i/[1 - (1 + i)^{-n}]$.

ADVANCED MATHEMATICS

8. Differential Calculus

Definitions and Symbols. In a discussion of quantities, a constant is one regarded as having the same value thruout, and a variable is one supposed to take different values. When several variables are related, their values being interdependent, each is a function of the others; thus the area and the base of a triangle of constant altitude being definitely related, these quantities are functions of each other. Also any expression containing the symbol of a quantity is a function of that quantity; thus $ax^2 + bx - c$ is a function of x, and $ay^2 + bx$ is a function of x and y. The following abbreviations are used: $f(x)$, $F(x)$, $\phi(x)$, etc., for functions of x; $f(x, y)$, $F(x, y)$, $\phi(xy)$, etc., for functions of x and y, etc. The letters f, F, ϕ, etc., are functional symbols; and $f(x)$ and $f(y)$, or $F(x)$ and $F(y)$, denote the same functions of x and of y; thus if $f(x)$ denotes $x^3 + 6x - 7$, then $f(y)$ denotes $y^3 + 6y - 7$. When $y = f(x)$ as $y = x^3 + 4x$, the equation being solved for y, then y is an explicit function of x; but in $F(x, y) = 0$, as $xy + 4x^2 - y^2 = 0$, the equation not being solved for y, then y is an implicit function of x. If $y = f(x)$, and for each value of x there is only one value of y, then y is a single-valued function of x; if for each value of x there is more than one value of y, then y is a multiple-valued function.

If two variables x and y are related and x is regarded as taking on any values and then y its corresponding values, x is the independent and y the dependent variable. When any variable x changes from a value x_1 to a value x_2, the difference $x_2 - x_1$ is an increment of x; any increment of x is denoted by Δx, also δx. An increment of x may be positiv or negativ; when negativ, the numerical value of the increment is called decrement. A variable regarded as taking on equal increments is an equicrescent variable. If in $y = f(x)$ all equal changes in x produce equal changes in y, then y is a uniform variable with respect to x, and the graph of $y = f(x)$ is straight. The rate of y with respect to x, or the x-rate of y, is the change in y per unit change in x. If $x_2 - x_1$, or Δx (Fig. 20), is any change in x, and $y_2 - y_1$, or Δy, is the corresponding change in y, then the x-rate of y is $(y_2 - y_1)/(x_2 - x_1) = \Delta y/\Delta x$. If in $y = f(x)$ all equal changes in x do not produce equal changes in y, then y varies non-uniformly with respect to x, or at a variable rate; the graph of $y = f(x)$ is a curve. The average rate of y with respect to x, or average x-rate of y, for any change in x, is that constant rate which would give the actual change in y due to the change in x. For the change $x_2 - x_1$ in x (Fig. 21) this constant rate is $(y_2 - y_1)/(x_2 - x_1)$, or $\Delta y/\Delta x$, and is represented by the slope of the chord AB. The actual x-rate of y when $x = x_1$, say, is the value which the average rate $\Delta y/(x_2 - x_1)$ approaches as x_2 is taken closer and closer to x_1; this limiting average rate, or actual rate, is represented by the slope of the tangent at A. As $y = f(x)$, the x-rate of y is also the x-rate of $f(x)$.

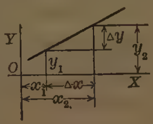

Fig. 20

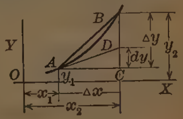

Fig. 21

The Derivative, the differential coefficient, and the derived function of y or $f(x)$, y being equal to $f(x)$, with respect to x are expressions which denote the x-rate of y or of $f(x)$; the first is the most common. There are several standard notations for this quantity: thus, D_xy or $D_xf(x)$, y_x' or $f_x'(x)$ (the subscript is generally omitted), and dy/dx or $d/dx f(x)$. The last two are the most common symbols and have the advantage of suggesting how the rate is obtained in the first instance. If the curve in Fig. 21 is the graph of $y = f(x)$, $dy/dx = \tan\alpha$ (when $x = x_1$), α being the slope angle at A. The derivative dy/dx is essentially one quantity, but may be regarded as a fraction provided that dy and dx

be regarded so that their ratio equals $\tan\alpha$; thus if dx is regarded as a fin increment of x, equal to Δx, then dy must be taken as CD, not equal to Δ So taken, dy is the DIFFERENTIAL of y with respect to x; it is an hypotheti increment of y, equal to the increment which occurs in y for a change in from x_1 to $x_1 + dx$ on the supposition that the x-rate of y remains consta during the change in x and is equal to its actual value when $x = x_1$. Th $dy/dx = \phi(x)$ may also be written $dy = \phi(x) \cdot dx$.

The fluxion of a variable function is its time rate. This term was used by Newton, is now uncommon; a fluxion of a variable as y was denoted by him thus, $\dot{y}$.

Differentiation is the process of finding the differential or derivative o function. The following formulas give differentials (and derivatives division) of some simple functions. Differentials of many other functi can be obtained by combining formulas; thus according to the formula $d(uv)$, $d(\sin x \cdot \cos x) = \sin x \cdot d(\cos x) + \cos x \cdot d(\sin x)$, and as gi $d(\cos x) = -\sin x\, dx$ and $d(\sin x) = \cos x\, dx$; hence $d(\sin x \cdot \cos x) = -$ si $dx + \cos^2 x\, dx$. In the formulas, a and n are constants, e is the base of Naperian system of logarithms, and in each case the differential of the fu tion is given with respect to x.

$$d(a + x) = dx \qquad d(ax) = a\,dx \qquad dx^n = nx^{n-1}\,dx$$
$$de^x = e^x dx \qquad da^x = a^x \log_e a\, dx \qquad d\log_e x = dx/x$$
$$d\sin x = \cos x\, dx \qquad d\csc x = -\csc x \cot x\, dx$$
$$d\cos x = -\sin x\, dx \qquad d\sec x = \sec x \tan x\, dx$$
$$d\tan x = \sec^2 x\, dx \qquad d\cot x = -\csc^2 x\, dx$$
$$d\operatorname{vers} x = \sin x\, dx \qquad d\operatorname{covers} x = -\cos x\, dx$$
$$d\sin^{-1} x = dx/\sqrt{1 - x^2} = -d\cos^{-1} x$$
$$d\tan^{-1} x = dx/(1 + x^2) = -d\cot^{-1} x$$
$$d\sec^{-1} x = dx/x\sqrt{x^2 - 1} = -d\csc^{-1} x$$
$$d\operatorname{vers}^{-1} x = dx/\sqrt{2x - x^2} = -d\operatorname{covers}^{-1} x$$
$$d\sinh x = \cosh x\, dx \qquad d\operatorname{csch} x = -\operatorname{csch} x \coth x\, dx$$
$$d\cosh x = \sinh x\, dx \qquad d\operatorname{sech} x = -\operatorname{sech} x \tanh x\, dx$$
$$d\tanh x = \operatorname{sech}^2 x\, dx \qquad d\coth x = -\operatorname{csch}^2 x\, dx$$
$$d\sinh^{-1} x = dx/\sqrt{x^2 + 1} \qquad d\operatorname{csch}^{-1} x = -dx/x\sqrt{1 + x^2}$$
$$d\cosh^{-1} x = dx/\sqrt{x^2 - 1} \qquad d\operatorname{sech}^{-1} x = -dx/x\sqrt{1 - x^2}$$
$$d\tanh^{-1} x = dx/(1 - x^2) \qquad d\coth^{-1} x = -dx/(x^2 - 1)$$

In the four following, u, v, w, etc., are functions of x and all differentia with respect to x:

$$d(u + v + w + \ldots) = du + dv + dw + \ldots \qquad d(uv) = u\,dv + v\,d$$
$$d(uvw \ldots) = [du/u + dv/v + dw/w + \ldots]\, uvw \ldots$$
$$d(u/v) = (v\,du - u\,dv)/v^2$$

Partial Derivatives and Differentials. The partial derivative of a func two or more independent variables with respect to one of them is the derivation function obtained on the supposition that the others are for the time being con the partial x-derivation of a function u is written $\partial u/\partial x$, also (du/dx); for ex if $u = y^3 + 4xy + x^2 + 2$, $\partial u/\partial x = 4y + 2x$ and $\partial u/\partial y = 3y^2 + 4x$. If u (or function of two independent variables, the partial derivatives have geometrical cance. The equation $z = f(x, y)$ represents a surface; suppose that APa, Fig. 2 intersection with a plane parallel to ZOX, and BPb its intersection with a plane to ZOY: on these curves y and x respectively are constant. PT' and PT'' are tan the curves at P as shown, and the slopes of these tangents represent $\partial z/\partial x$ and

espectively. The partial differential of a function of two or more independent variables vith respect to any one of them is the differential of the function obtained on the upposition that the other variables are, for he time being, constants. Thus if $z = y^3 + 4xy + x^2 + 2$, the x-partial differential of z s $4\,ydx + 2\,xdx$ and the y-partial differenial is $3\,y^2dy + 4\,xdy$. If z is a function of nly two independent variables the partial lifferentials have geometrical significance. f Pm and Pn are taken to represent the lifferentials dx and dy respectively, then mT' nd nT'' represents the x- and the y-partial lifferentials of z. Also these partial differenials are equal to $[\partial z/\partial x]\,dx$ and $[\partial z/\partial y]\,dy$.

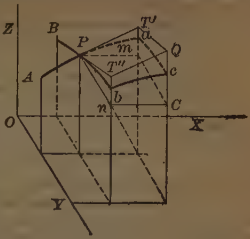

Fig. 22

Total Derivatives and Differentials. The total differential of a function of two or nore variables is the differential obtained n the supposition that all change. It equals he sum of the partial differentials of the unction with respect to the several variables; thus if $u = f(xyz)$,

$$du = \frac{\partial u}{\partial x}dx + \frac{\partial u}{\partial y}dy + \frac{\partial u}{\partial z}dz$$

f u is a function of only two variables, du has a geometrical significance. Thus if $z = (x, y)$ and Pm and Pn (Fig. 22) are taken as dx and dy respectively, then CQ represents z. The differential dz then is a hypothetical and not the actual increment, Cc in z ue to changes dx and dy in x and y. The total derivative of a function of two or nore variables all dependent on a single variable is the rate at which the function changes er unit change of that variable; thus if $u = f(x, y, z)$ and x, y, and z are all functions of t,

$$\frac{du}{dt} = \frac{\partial u}{\partial x}\frac{dx}{dt} + \frac{\partial u}{\partial y}\frac{dy}{dt} + \frac{\partial u}{\partial z}\frac{dz}{dt}$$

nd similarly for any number of variables. If the independent variable is x say, then

$$\frac{du}{dx} = \frac{\partial u}{\partial x} + \frac{\partial u}{\partial y}\frac{dy}{dx} + \frac{\partial u}{\partial z}\frac{dz}{dx}$$

Successive Differentiation is the process of finding derivatives or differentials f derivatives or differentials. The successive derivatives and differentials re called first, second, third, etc., derivatives and differentials, and of the first, econd, third, etc., order; those of the second, third, etc., order are "higher erivatives" and higher differentials. For the successive x-derivatives of $y = f(x)$ the following symbols are used:

first,	$Dy, y', f'(x)$, and dy/dx
second,	$D\,(Dy)$ or $D^2y, y'', f''(x)$, and $d/dx\;dy/dx$ or d^2y/dx^2
third,	$D^3y, y''', f'''(x)$, and d^3y/dx^3

he first x-differential of y is dy, the second d^2y, the third d^3y, etc.

For the successive partial derivatives of $u = f(xy)$ the following symbols are used:

first partial x-derivative $\partial u/\partial x$, first partial y-derivative $\partial u/\partial y$
second partial x-derivative $\partial^2u/\partial x^2$, second partial y-derivative $\partial^2u/\partial y^2$

The first partial x-derivative may be taken with respect to x and the second with respect y; this second is written $\partial^2u/\partial y\partial x$. Similarly $\partial^2u/\partial x\partial y$ means the x-partial derivative the y-partial derivative of u. But the order of differentiation is immaterial, that is, $\partial^2u/\partial y\partial x = \partial^2u/\partial x\partial y$, and this independence is true for any number of successive differntiations with respect to any number of variables.

Maxima and Minima. A maximum value of a function is one which is lgebraically greater than, and a minimum value is one algebraically less

than its adjacent values. Thus, if the curve in Fig. 23 is the graph of $y = f$ y_1, y_2, and y_3 are maximum values of y or $f(x)$ and y_4, y_5, and y_6 are minir values; again, imagine $u = f(x, y)$ graphed, x and y independent vari plotted on horizontal axes and u vertically, thus defining in general an u lating surface; then the valu u corresponding to high and points of the surface are maxi or minimum values of u or $f($ Maximum and minimum v are also known as turning va the values of the independent able or variables correspondi

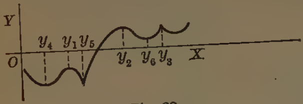

Fig. 23

turning values are critical values. The following formulas refer to ma and minima, like y_1 and y_4, where the tangent line is horizontal and not t like y_3 and y_5 (rare), where the tangent line is not horizontal. At maxim minima of the first kind the gradient dy/dx changes sign gradually, a the peaks the change of sign is sudden. From this property peak val a function can be obtained "by trial" with dy/dx.

(1) Turning value of $y = f(x)$: Solve $f'(x) = 0$; any root obtained, as x_1, is a value if the lowest x-derivative of y which does not vanish for $x = x_1$ is of an even the turning value, $f(x_1)$, is a maximum or minimum according as that lowest x-de is negativ or positiv for $x = x_1$.

(2) Turning value of y in $f(x, y) = 0$: Solve $\partial f(x, y)/\partial x = 0$ and $f(x, y) = 0$ taneously for x and y; the values obtained, x_1 and y_1, are critical and turning respectively if $\partial f(x, y)/\partial y$ does not vanish for $x = x_1$ and $y = y_1$; y_1 is maxir minimum according as $[-\partial^2 f(x, y)/\partial x^2] \div [\partial f(x, y)/\partial y]$ is negativ or positiv for and $y = y_1$.

(3) Turning values of $u = f(x, y)$: Solve $\partial f(x, y)/\partial x = 0$ and $\partial f(x, y)/\partial y =$ taneously for x and y; the values obtained, x_1 and y_1, are critical values if $[\partial^2 f(x,$ $[\partial^2 f(x, y)/\partial y^2] - [\partial^2 f(x, y)/\partial x \partial y]^2$ is positiv for $x = x_1$ and $y = y_1$;

$$\left.\begin{array}{l} u \text{ is a maximum} \\ u \text{ is a minimum} \end{array}\right\} \text{ if } \frac{\partial^2 f(x, y)}{\partial x^2} \text{ and } \frac{\partial^2 f(x, y)}{\partial y^2} \text{ are both } \left\{\begin{array}{l} \text{negativ} \\ \text{positiv} \end{array}\right.$$

Indeterminate Forms. In general a function of a variable has a value for any particular value of the variable; yet the values of som tions for special values of the variable lead to expressions like $0/0$, $0\cdot$ the like, which are so-called indeterminate forms. For example, the f $(1 - \cos x)/x$ for $x = 0$ becomes $0/0$ and $(\frac{1}{2}\pi - x)\tan x$ for $x = \pi/2$ is

(1) The quotient $f(x) \div F(x)$ becomes $0/0$ for a particular value of x as a: terminate form equals the value of $f'(x) \div F'(x)$ when $x = a$; if this ratio i indeterminate form, the original one equals $f''(x) \div F''(x)$ when $x = a$.

(2) The quotient $f(x) \div F(x)$ becomes ∞/∞ when $x = a$: the true value obtained as in case (1).

(3) The product $f(x) \times F(x)$ becomes $0 \cdot \infty$ when $x = a$: the product equal $[1/F(x)]$ which takes the form $0/0$ when $x = a$ and may be evaluated as in (1

(4) The difference $f(x) - F(x)$ becomes $\infty - \infty$ when $x = a$: the differen $\phi(x) \div \psi(x)$, case (1), where $\phi(x) = [1/F(x)] - [1/f(x)]$ and $\psi(x) = 1/[f($

(5) The function $[F(x)]^{f(x)}$ becomes 1^∞, 0^0, or ∞^0 when $x = a$: the functi $e^{f(x)\log F(x)}$ (the logarithm being Naperian), and the value of this form can $f(x) \log F(x)$ can be evaluated; but $f(x) \log F(x)$ falls under case (3).

Maclaurin's Theorem expresses the law for the expansion of a of a variable in a series of ascending powers of the variable, thus.

$$f(x) = f(0) + \frac{x}{1}f'(0) + \frac{x^2}{2!}f''(0) + \frac{x^3}{3!}f'''(0) + \cdots$$

wherein $f(0)$ means the value of $f(x)$ when $x = 0$ and $f'(0)$ is the $f'(x)$ when $x = 0$, etc.

As illustration, $\cos x$ is here expanded by Maclaurin's theorem: $f(x) = \cos x$, $f'(x) = -\sin x$, $f''(x) = -\cos x$, $f'''(x) = \sin x$, $f''''(x) = \cos x$, etc.; $f(0) = 1$, $f'(0) = 0$, $f''(0) = -1$, $f'''(0) = 0$, $f''''(0) = 1$. Hence $\cos x = 1 - x^2/2! + x^4/4! - \ldots$

Taylor's Theorem expresses the law for the expansion of a function of a ariable plus an increment in a series of ascending powers of the increment; hus h, denoting an increment of x,

$$f(x+h) = f(x) + \frac{h}{1} f'(x) + \frac{h^2}{2!} f''(x) + \frac{h^3}{3!} f'''(x) + \ldots$$

To expand $\cos(x+h)$ by Taylor's theorem: $f(x) = \cos x$ $f'(x) = -\sin x$, $f''(x) = -\cos x$, $f'''(x) = \sin x$, $f''''(x) = \cos x$, etc., and $\cos(x+h) = \cos x\,(1 - h^2/2! + h^4/4! - \ldots) - \sin x\,(h - h^3/3! + h^5/5! - \ldots)$.

9. Integral Calculus

Definitions and Notation. Integration is the process of determining function from its derivative or differential; it is the inverse of differentiation. The function is called the integral of the derivative or differential; also anti-derivative and anti-differential. The symbol of integration is $\int$. Thus he x-derivative of $f(x)$ being written $f'(x)$, $\int f'(x) = f(x)$, but integration of he differential instead is generally indicated, as $\int f'(x)\,dx = f(x)$; dx indicates the 'variable of integration,' $f'(x)$ is called integrand, and the result of the integration, that is, the function determined $f(x)$, is the integral of the derivative or differential from which it is found. Strictly $\int f'(x)$ or $\int f'(x)\,dx = f(x) + C$, C being a constant, called constant of integration; $f(x)$ is called the indefinite integral and $f(x) + C$ the general integral. In a general integral the constant of integration is an arbitrary constant, but in a particular problem of integration it has a special value determinable from data of the problem. Thus, suppose in a given case it is known that when $x = a$, $\int f'(x) = A$, then $A = f(a) + C$ or $C = A - f(a)$; and $f(x) + A - f(a)$ is a particular ntegral.

Integral Forms. In the following formulas K is the constant of integration; a, b, c, A, B, m, and n are constants; logarithms indicated are Naperian, and ε is the base of that system (Art. 2); Y is an abbreviation for $a + bx$, Z for $a + bx + cx^2$; and u and v are any functions of x.

$$\int a\,du = a\int du \qquad \int (u+v)\,dx = \int u\,dx + \int v\,dx$$

$$\int u\,dv = uv - \int v\,du \qquad \int Y^n dx = \frac{Y^{n+1}}{(n+1)b} + K$$

$$\int \frac{dx}{Y} = \frac{1}{b}\log Y + K \qquad \int \frac{x\,dx}{Y} = \frac{1}{b^2}(Y - a\log Y) + K$$

$$\int \frac{x\,dx}{Y^2} = \frac{1}{b^2}\left(\log Y + \frac{a}{Y}\right) + K$$

$$\int \frac{x^2\,dx}{Y} = \frac{1}{b^3}\left(\tfrac{1}{2}Y^2 - 2aY + a^2\log Y\right) + K$$

$$\int \frac{x^2\,dx}{Y^2} = \frac{1}{b^3}\left(Y - 2a\log Y - \frac{a^2}{Y}\right) + K$$

$$\int \frac{dx}{xY} = -\frac{1}{a}\log\frac{Y}{x} + K \qquad \int \frac{dx}{xY^2} = \frac{1}{aY} - \frac{1}{a^2}\log\frac{Y}{x} + K$$

$$\int \frac{dx}{x^2Y} = -\frac{1}{ax} + \frac{b}{a^2}\log\frac{Y}{x} + K \qquad \int \sqrt{Y}\,dx = \frac{2}{3b}Y^{3/2} + K$$

$$\int x\sqrt{Y}\,dx = -\frac{2(2a-3bx)Y^{3/2}}{15b^2} + K$$

$$\int x^2\sqrt{Y}\,dx = \frac{2(8a^2-12abx+15b^2x^2)Y^{3/2}}{105b^3} + K$$

$$\int \frac{dx}{\sqrt{Y}} = \frac{2\sqrt{Y}}{b} + K \qquad \int \frac{x\,dx}{\sqrt{Y}} = -\frac{2(2a-bx)\sqrt{Y}}{3b^2} + K$$

$$\int \frac{x^2\,dx}{\sqrt{Y}} = \frac{2(8a^2-4abx+3b^2x^2)\sqrt{Y}}{15b^3} + K$$

$$\int \frac{dx}{x\sqrt{Y}} = \frac{1}{\sqrt{a}}\log\frac{\sqrt{Y}-\sqrt{a}}{\sqrt{Y}+\sqrt{a}} + K, \text{ if } a > 0$$

$$= \frac{2}{\sqrt{-a}}\tan^{-1}\frac{\sqrt{Y}}{\sqrt{-a}} + K, \text{ if } a < 0$$

$$\int \frac{\sqrt{Y}\,dx}{x} = 2\sqrt{Y} + a\int \frac{dx}{x\sqrt{Y}}$$

$$\int \frac{dx}{x^2\sqrt{Y}} = -\frac{\sqrt{Y}}{ax} - \frac{b}{2a}\int \frac{dx}{x\sqrt{Y}}$$

$$\int \frac{dx}{a+bx^2} = \frac{1}{\sqrt{ab}}\tan^{-1}\sqrt{\frac{b}{a}}\,x + K, \text{ if } a > 0 \text{ and } b > 0$$

$$\int \frac{dx}{a-bx^2} = \frac{1}{2\sqrt{ab}}\log\frac{\sqrt{ab}+bx}{\sqrt{ab}-bx} + K, \text{ if } a > 0 \text{ and } b > 0$$

$$\int \frac{\varepsilon^{ax}}{x^n}\,dx = -\frac{\varepsilon^{ax}}{(n-1)x^{n-1}} + \frac{a}{n-1}\int \frac{\varepsilon^{ax}}{x^{n-1}}\,dx$$

$$\int \varepsilon^{ax}\log x\,dx = \frac{\varepsilon^{ax}\log x}{a} - \frac{1}{a}\int \frac{\varepsilon^{ax}}{x}\,dx$$

$$\int \varepsilon^x \sin x\,dx = \frac{\varepsilon^x(\sin x - \cos x)}{2} + K$$

$$\int \varepsilon^x \cos x\,dx = \frac{\varepsilon^x(\sin x + \cos x)}{2} + K$$

Definite integrals result from integration between "limits"; thus $\int_a^b f'(x)\,dx = [f(x)]_a^b = f(b) - f(a)$; a and b are "lower" and "upper limits" respectively and $(b - a)$ is the "range" of integration. Interchanging the limits in a definite integral changes the sign of the result, and a definite integral can be exprest as the sum of several other integrals; thus

$$\int_a^b f(x)\,dx = -\int_b^a f(x)\,dx \quad \text{and} \quad \int_a^c f(x)\,dx = \int_a^b f(x)\,dx + \int_b^c f(x)\,dx$$

Approximate Integration. An approximate value of $\int f(x)\,dx$ between any limits as x_0 and x_n can be obtained as follows: divide the range $x_n - x_0$ into an even number (n) of equal parts (w) and compute the values of $f(x)$ when $x = x_0, x_0 + w, x_0 + 2w, \ldots, x_n$, and call these values $y_0, y_1, y_2, \ldots, y_n$. Then substitute in an approximate formula for the area of an irregular figure (Art. 6), as Simpson's for example; the value obtained for A is an approximate value of the integral. If the values of x and y be plotted and a smooth curve be drawn thru the points obtained, then the area between the curve, the x axis, and the end ordinates y_0 and y_n represents the integral; and the area according to the proper scale in a given case equals the integral. If the area is cut by the x axis, the parts above and below should be regarded as positiv and negativ respectively.

10. Plane Analytic Geometry

Plane Coordinate Systems. For rectangular coordinate systems, se Art. 3. An oblique coordinate system is like the rectangular except that th coordinate axes are not at right angles, and in the oblique the x and y coord nates of a point are measured parallel to the x and y axes respectively. Re tangular and oblique systems are called Cartesian. Th POLAR COORDINATES of a point P (Fig. 24) are its di tance from some point or pole O and the angle betwe a reference line as OX and the line joining P and the line OP is the radius vector of P. Change or tra formation of coordinates from one system to anoth can be made from $x = r \cos \phi$, $y = r \sin \phi$, or $\sin \phi = y$ $\cos \phi = x/r$, $r = \sqrt{x^2 + y^2}$; the reference line and p of the polar system and the axes of the rectangular system must be related shown in the figure. For example, the equation of the circle (Fig. 25) w respect to axes OX and OY is $x^2 + y^2 = 2\,ay$, a being the radius; its po equation with OX as reference line and O as pole is $r^2 \cos^2 \phi + r^2 \sin^2 \phi$ $2\,ar \sin \phi$, or $r = 2\,a \sin \phi$.

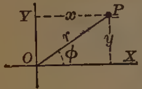

Fig. 24

Transformation from a set of rectangular axes to a parallel set: XOY (Fig. 26) is original set, UQV the new, and (x_1, y_1) the coordinates of the new origin Q with resp to the original set; then P being any point whose coordinates with respect to the two of axes are (x, y) and (u, v) respectively, $x = u + x_1$ and $y = v + y_1$.

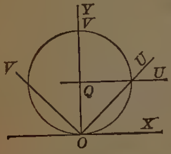

Fig. 25

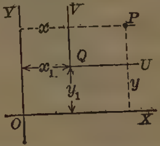

Fig. 26

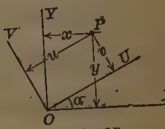

Fig. 27

For example, the equation of the circle (Fig. 25) with respect to the axes XOY b $x^2 + y^2 = 2\,ay$, its equation with respect to UQV is

$$(u + o)^2 + (v + a)^2 = 2\,a\,(v + a), \text{ or } u^2 + v^2 = a^2$$

Transformation from a set of rectangular axes to another set, they having a com origin but different directions: XOY (Fig. 27) is the original set, UOV the new, a denotes the angle through which OX must be turned to bring it into OU, a being p for counter-clockwise turning; then P being any point whose coordinates are as sh $x = u \cos a - v \sin a$ and $y = u \sin a + v \cos a$. For example, the equation o circle (Fig. 25) with respect to XOY being $x^2 + y^2 = 2\,ay$ its equation with resp UOV is $(u \cos 45° - v \sin 45°)^2 + (u \sin 45° + v \cos 45°)^2 = 2\,a\,(u \sin 45° + v \cos$ or $u^2 + v^2 = a\sqrt{2}\,(u + v)$.

Straight Line. When a straight line lies in a coordinate plane (Fig. by its slope-angle is meant the angle thru which XM must be turne bring it into the line, the angle being regarded as positiv or negativ accor as the turning is counter-clockwise or not, and by the slope or gradient o line is meant the tangent of its slope-angle. OM and ON are the "interce cut off by the line on the coordinate axes, and the intercepts are rega as positiv or negativ according as they lie on the positiv or negativ of the coordinate axes. The equation of a straight line is of the first de its general form being $Ax + By + C = o$; written in the form $y = mx$

m is the slope or gradient of the line, and b the intercept on the y axis; written in the form $x/a + y/b = 1$, a and b are the intercepts on the x and y axes respectively. The equation of a line whose slope is m and containing the point (x_1, y_1) is $y - y_1 = m(x - x_1)$; the equation of a line containing the points (x_1, y_1) and (x_2, y_2) is $y - y_1 = (x - x_1)(y_2 - y_1)/(x_2 - x_1)$; the equation of a line whose angle with the x axis is α and distance from the origin is p, is $y \cos \alpha - x \sin \alpha = p$. (See also Art. 8.)

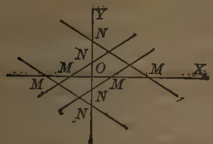

Fig. 28

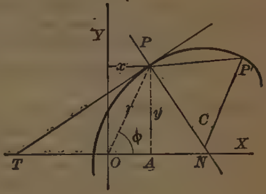

Fig. 29

Equation of a Curve. The equation of a curve referred to any coordinate reference frame is an equation between the coordinates of any and all points on the curve. When rectangular or oblique coordinates x and y are used, it is an equation between x and y; when polar coordinates r and ϕ are used, it is an equation between r and ϕ and is called the polar equation of the curve.

Tangents, Normals, Asymptotes. The TANGENT to a curve at P is the limiting position of a secant PP' (Fig. 29) as P' is taken nearer and nearer to P. The NORMAL at P is a perpendicular to the tangent there, and in the plane of the curve. Generally these are understood to be lines of indefinite length, but when they are referred to as of definite lengths, the parts between the points of tangency and the x axis are meant, PT and PN. The subtangent and the subnormal are the projections of the definite tangent and normal on the x axis, AT and AN respectively. If a curve extends to a point of which one (or both) of the coordinates is infinitely great, then the tangent at that point is an ASYMPTOTE of the curve. The equation of the tangent to a curve at a point P at (x_1, y_1) is $y - y_1 = (dy/dx)(x - x_1)$, and the equation of the normal at that point is $y - y_1 = -(dx/dy)(x - x_1)$. The definite tangent $PT = y_1 ds/dy$; the definite normal $PN = y_1 ds/dx$; the subtangent $AT = y_1 dx/dy$; and the subnormal $AN = y_1 dy/dx$.

Curvature. The total curvature of an arc PP' (Fig. 29) is the angle between the tangents to the curve at the points P and P'. The average curvature of the arc is the ratio of the curvature to the length of the arc; or $\Delta\alpha/\Delta s$, if $\Delta\alpha$ is the total curvature and Δs the length of arc. The curvature at a point P of the curve is the limiting value of the average curvature as P' approaches P, that is, $d\alpha/ds$; also curvature is given by

$$\frac{d\alpha}{ds} = \frac{d^2y}{dx^2} \Big/ \left[1 + \left(\frac{dy}{dx}\right)^2\right]^{3/2}$$

When for any arc the tangent lines are only slightly inclined to the x axis, then dy/dx is nearly zero for all points on the curve and the curvature is approximately equal to d^2y/dx^2.

PC and $P'C$ are normals to the curve at P and P'; as P' is taken nearer and nearer to P, the intersection of the normals moves along the normal

at P, approaching a definite point on that normal. This definite point is the center of curvature of the curve for the point P; the line joining the center and P is the radius of curvature of the curve at P, and a circle with that center and radius is the circle of curvature of the curve at P. If R denotes the radius of curvature, then

$$R = \frac{ds}{d\alpha} = \left[1 + \left(\frac{dy}{dx}\right)^2\right]^{3/2} \div \frac{d^2y}{dx^2}$$

and if x_1 and y_1 denote the coordinates of the center of curvature corresponding to any point (x, y) on a curve, then

$$x_1 = x - Rdy/ds \qquad \text{and} \qquad y_1 = y + Rdx/ds$$

and for R, dy/ds and dx/ds must be substituted, their values corresponding to the point (x, y).

Evolute and Involute. The line determined by the centers of curvature of a curve is the evolute of the curve, and the curve is an involute of the evolute. Thus C_1, C_2, and C_3 (Fig. 30) being centers of curvature for points on $P_1P_2P_3$, they lie on the evolute of $P_1P_2P_3$. The radii of curvature P_1C_1, P_2C_2 and P_3C_3 are tangent to the evolute; and the free end of a thread fastened at C_3, wound around the evolute and stretched into the position $C_3C_1P_1$, would, when unwound, describe $P_1P_2P_3$, an involute of $C_1C_2C_3$. The free end of a shorter cord, as $C_3C_1Q_1$, would, if unwound, describe $Q_1Q_2Q_3$, another involute of $C_1C_2C_3$. All points of the straight part of the thread describe parallel curves all of which are involutes of $C_1C_2C_3$, and $C_1C_2C_3$ is the evolute of all the parallel curves. The equation of the evolute of a given curve, $f(x, y) = 0$, can be obtained by eliminating x and y from $f(x, y) = 0$ and the equations for the coordinates of the center of curvature; then the final equation (free from x's and y's) is the equation sought, x_1 and y_1 being regarded as the variables in it.

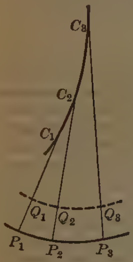

Fig. 30

Gradient, Convexity and Concavity. The slope-angle of a curve at any point of the curve is the angle which the tangent line to the curve makes with the positiv x axis; the gradient or slope of the curve there is the tangent of the slope-angle; it is given by the value of dy/dx for that point of the curve. This derivative is positiv or negativ according as the curve extends upward and to right or left (see Fig. 31 for all possible cases). The second derivative d^2y/dx^2 relates to the bending of the curve. It is positiv or negativ according as the curve is concave or convex upward (see Fig. 31 for all possible cases).

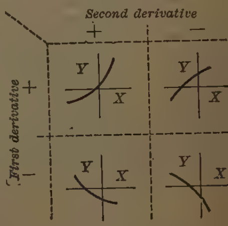

Fig. 31

Envelope. An equation of a curve contains one or more constants, called PARAMETERS; thus in $y = 4x + 2$, the equation of a straight line, 4 and 2 are parameters. The equation $y = mx + 2$ represents an infinitude of straight lines, one for each possible numerical value of m; a literal parameter, as m, regarded as capable of taking on different values is a variable parameter. The diagram representing an equation with a variable parameter is called a FAMILY OF CURVES, and the parameter is the parameter of the family. In general

members of the family intersect; the successive intersections of members lie on some line, and the line containing the successive intersections of all members of a family is the envelope of the family. In general, the envelope of a family touches each member. If $f(x, y, a) = 0$ is the equation of a family of curves, the equation of the envelope may be obtained by eliminating a between $f(x, y, a) = 0$ and $\partial f(x, y, a)/\partial a = 0$.

Singular Points. An inflection point of a curve is one where the curve crosses the tangent line at the point and bends away from the tangent in opposite directions on opposite sides of the point (Fig. 32). (The tangent is an inflectional tangent.) At an inflection point $d^2y/dx^2 = 0$, and to locate an inflection point on a curve (having one) whose equation is $y = f(x)$, get

Fig. 32

Fig. 33

Fig. 34

Fig. 35

$f''(x)$, that is, dy^2/dx^2; equate to zero and solve for x; from that value of x and the equation of the curve get y; in general (x, y) is an inflection point. To make sure that it is, determine whether $f''(x)$ changes sign at the point; if so, it is an inflection point. When two or more branches of a curve intersect, or cross one another (Fig. 33), the point of intersection is a multiple point; if two branches cross, the intersection is a node. At a multiple point, dy/dx has two or more real unequal values and y at least two equal values. A cusp is a point of a curve where two branches have a common tangent; if the two branches stop at the point the cusp is single (Fig. 34); if not it is double (Fig. 35).

11. Conic Sections

A Conic is a curve traced by a point moving in a plane so that the distance of the point from a fixt point is in a constant ratio to its distance from a fixt line, the point and line lying in the plane. The fixt point is the focus, the fixt line the directrix, and the constant ratio the eccentricity of the conic. If the directrix is taken as a y axis, a line perpendicular to it and passing thru the focus as the x axis, d to denote the distance between focus and directrix, and e the eccentricity, then the equation of the conic is $(x - d)^2 + y^2 = e^2x^2$. If

$e > 1$, the equation represents a hyperbola
$e = 1$, the equation represents a parabola
$e < 1$, the equation represents an ellipse
$e = 0$, the equation represents a circle

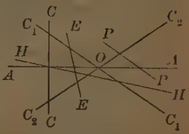

Fig. 36

Hence the circle is a special case of the ellipse, and the parabola is a limiting case for both hyperbola and ellipse.

The general second-degree equation between two coordinates x and y, $Ax^2 + 2Hxy + By^2 + 2Gx + 2Fy + C = 0$, represents a conic. It is an ellipse (or circle), parabola, or hyperbola according as $AB - H^2$ is positiv, zero or negativ; but if $ABC + 2FGH - AF^2 - BG^2 - CH^2 = 0$, the conic is a "degenerate," it being a point, two intersecting straight lines, or two parallel straight lines in the three cases respectively.

A conic may be defined with reference to a double right cone with a circular base, whence the name conic. Let AA (Fig. 36) be the axis of such a cone, C_1C_1 and C_2C_2 elements of the surface in the plane of the paper, and let HH, PP, EE, and CC represent planes perpendicular to the paper; then HH, which cuts the elements on opposite sides of the vertex O, cuts a hyperbola from the surface; PP, which is parallel to an element

cuts off a parabola, EE which cuts the elements on the same side of O and is not perpendicular to the axis, cuts off an ellipse, and CC, perpendicular to the axis, cuts off a circle.
For mensuration of the conic sections, see Art. 6.

Circle. The equation of a circle of radius r is, if the center is at the origin of rectangular coordinates, $x^2 + y^2 = r^2$; if the center is at a point (a, b) the equation is $(x - a)^2 + (y - b)^2 = r^2$. Any equation of the form $Ax^2 + Ay^2 + 2Gx + 2Fy + C = 0$, A not being zero, is the equation of a circle.

An Ellipse is a curve such that the sum of the distances of any and every point on it from two fixt points is always the same (Fig. 37). The two fixt points are foci of the ellipse, and the distances of a point on the curve to the foci are focal distances, or focal radii, of the point. An ellipse has two lines of symmetry, called the axes of the ellipse; the longer is the major axis and the shorter the minor axis. The equation of an ellipse with respect to x and y axes coincident with the major and minor axes respectively, is $x^2/a^2 + y^2/b^2 = 1$, a and b denoting semi-major and semi-minor axis respectively. Any line thru the center, terminating in the ellipse, is a diameter. Two diameters are conjugate to each other when either is parallel to tangents to the ellipse at the extremities of the other. The acute angles α and β which two conjugate diameters make with the major axis are related thus: tan α tan $\beta = b^2/a^2$, and if A and B are semi-conjugate diameters, $A^2 + B^2 = a^2 + b^2$.

The definition of ellipse here given is in accordance with the one given in the present article under conic, but the focus and directrix there named are in case of the ellipse double; that is, there are two of each. As there, let e = eccentricity of the ellipse, d = distance from either focus to corresponding directrix, also c = distance from center to either focus; then $a = de/(1 - e^2)$, $b = de/\sqrt{1 - e^2}$, $c = de^2/(1 - e^2)$, $e = 1 - b^2/\ldots$, $c = ae$, $c^2 = a^2 - b^2$. The latus rectum is the length of the focal chord perpendicular to the major axis; denoting it by p, then $p = 2de = 2a(1 - e^2) = 2b^2/a$. The polar equation of the ellipse with F as pole and FA as polar axis (Fig. 37) is $r = p/2(1 - e\cos\phi) = a(1 - e^2)/(1 + e\cos\phi)$.

Geometric Constructions of Ellipse. (1) To determine the foci of any ellipse, axes given: from either end of the minor axis draw an arc whose radius equals the semi-major axis; the intersections of arc and major axis are the foci. (2) To draw a tangent and a normal to the ellipse at any point on it: from the point draw focal radii;

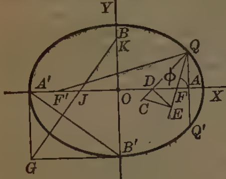

Fig. 37

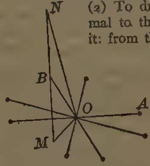

Fig. 38

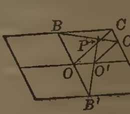

Fig. 39

the bisector of one of the angles between them is the tangent and that of the other angle is the normal. (3) To draw a tangent from a point P without the ellipse: join the point with either focus; on the joining line as diameter construct a circle; on the major axis as diameter construct a circle; the lines connecting the intersections of the two circles with P are tangents. (4) To find the center and the radius of curvature for any point of the ellipse: let Q (Fig. 37) be the point; at Q draw the normal and at its intersection with the major axis erect a perpendicular to the normal; at intersection of this perpendicular with either focal radius from Q erect a perpendicular to that radius; the intersection C of this last line with the normal is the center of curvature and QC is the radius of curvature. This construction fails for a point at either end of the major axis. For such points determine G, and thru G draw a perpendicular to $A'B'$; the intersection J is the center of curvature for A' and K for the point B'. (5) To determine the axes of an ellipse fr

pair of semi-diameters: from one end B (Fig. 38) of the shorter diameter draw a perpendicular to the longer and make BM and $BN = OA$; then the bisectors of the angles between the lines OM and ON are the directions of the axes; their lengths are $ON + OM$ and $ON - OM$. (6) Construction of an ellipse on its axes: draw auxiliary circles on the axes as diameters (Fig. 40); draw any diameter of these circles; thru its intersections b with the small circle draw lines parallel to the major axis; thru the intersections a with the other draw lines parallel to the minor axis; the intersections c of these lines are points on the ellipse. (7) Construction of an ellipse on a pair of coordinate diameters: construct a parallelogram on the diameters as medians (Fig. 39); divide OA and CA into proportional parts, beginning at O and at C, readily done by parallels to OC; join any point of division C' on AC with B and determine the intersection of BC' with the line joining B' and the corresponding division point O' on OA; this intersection P is on the ellipse.

Mechanical Constructions of an ellipse from its axes: (a) First locate the foci; then take an inelastic string and fasten it at the foci so that the length of the loop between the fast points equals that of the major axis; then if the string is pulled out taut into any position, as FPF' (Fig. 40), P is a point on the ellipse, and a moving pencil, or other scribe, pressing against the string at P will describe the ellipse. (b) On a strip of stiff paper or other suitable material, from a point Q (Fig. 40) lay off QM = the semi-major axis and QN = the semi-minor; a pencil, or other scribe, at Q will trace the ellipse when the strip is moved so that M moves along the minor axis and N along the major.

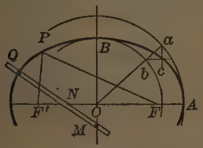

Fig. 40

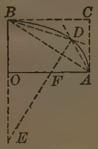

Fig. 41

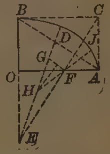

Fig. 42

Approximate Ellipse, consisting of arcs of circles; it is supposed that the axes of the ellipse are given. (1) Semi-ellipse with three centers: OA and OB (Fig. 41) are the given semi-axes; join A and B and bisect the angles CAB and CBA, thus determining D; thru D draw a perpendicular to AB, thus determining F and E; from F with radius FA and from E with radius EB draw arcs; they meet tangentially at D. (2) Semi-ellipse with five centers: OA and OB (Fig. 42) are the given semi-axes; join A and B, and thru C draw a perpendicular to AB, determining F and E, two of the centers; from E with EB as radius draw an arc BD as long as thought suitable, and join D with E; make $DG = AF$; join F and G; at the center of FG draw a perpendicular to FG and note its intersection H (the third center) with DE; from H with radius HD draw an arc to HF extended, and from F with FA as radius complete the curve.

The Hyperbola is a curve such that the difference between the distances of any and every point on the curve from two fixt points is always the same. The two fixt points are foci, the distances are focal distances, focal radiuses, or radius vectors. A hyperbola has two axes of symmetry (Fig. 43), one cut by the curve; the length AA' cut off by the curve is the transverse or real axis of the hyperbola, and the length BB' on the other line equal to $\sqrt{(FF')^2 - (AA')^2}$ is the conjugate or imaginary axis. The intersection of the axes is the center of the hyperbola, and any line thru the center terminating on the hyperbola is a diameter. The equation of the hyperbola referred to the transverse and conjugate axes as x and y coordinate axes is $x^2/a^2 - y^2/b^2 = 1$.

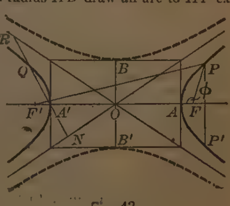

Fig. 43

a and b denoting semi-transverse and conjugate axes respectively. Two diameters are conjugate when each bisects all chords parallel to the other; either of two such diameters is parallel to the tangents at the extremities of the other. The acute angles α and β which two such diameters make with the transverse axis are related thus; $\tan\alpha \tan\beta = b^2/a^2$; if A and B denote semi-conjugate diameters, $A^2 - B^2 = a^2 - b^2$. The two hyperbolas $x^2/a^2 - y^2/b^2 = 1$ and $-x^2/a^2 + y^2/b^2 = 1$ are conjugate hyperbolas; the latter is shown by dotted lines in Fig. 43. They have the same asymptotes.

The definition of hyperbola given above is in agreement with the one given earlier in this article. As there, let e = eccentricity and d = distance between either focus and corresponding directrix; also let c = distance from center to either focus; then

$$a = de/(e^2 - 1) \qquad b = de/\sqrt{e^2 - 1} \qquad c = de^2/(e^2 - 1)$$
$$e^2 = 1 + b^2/a^2 \qquad c = ae \qquad c^2 = a^2 + b^2$$

The latus rectum of a hyperbola is the length of either focal chord perpendicular to the transverse axis; denoting it by p, then $p = 2\,de = 2\,a\,(e^2 - 1) = 2\,b^2/a$. The polar equation of the hyperbola with F as pole and FA as polar axis is

$$r = p/2\,(1 + e\cos\phi) = a\,(e^2 - 1)/(1 + e\cos\phi)$$

A hyperbola whose axes are equal is an equilateral or rectangular hyperbola; the asymptotes are at right angles. The equation of such a hyperbola referred to the axes is $x^2 - y^2 = a^2$, or $-x^2 + y^2 = a^2$; referred to the asymptotes, the equation is $xy = \frac{1}{2}a^2$. The eccentricity is $\sqrt{2}$.

Geometric Constructions of Hyperbola. (1) To determine the foci when the axes are given: make OF and OF' (Fig. 43) equal to AB; then F and F' are the foci. (2) To draw a tangent and a normal at any point of a hyperbola: from the point draw the focal radii; the bisector of one of the angles between the radii is the tangent and that of the other is the normal. (3) To construct the asymptotes to a hyperbola, the axes being given: construct a rectangle on the axes as medians; diagonals of the rectangle extended are the asymptotes. (4) Construction of a hyperbola, its axes AA' and BB' (Fig. 43) being given: (a) Locate the foci F and F', mark any point M on the transverse axis extended but not between the foci; with MA and MA' as radii, strike arcs from F and F' respectively; their intersections are points on the hyperbola. Repeat for other points like M. (b) Draw the asymptotes; through A' draw any oblique line and note its intersections N and R with the nearer and remoter asymptote; lay off from R toward A' a length $RQ = A'N$; then Q is on the hyperbola. Repeat with other oblique lines through A', A, or through any other known point of the curve, as Q.

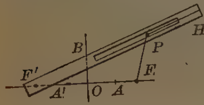

Fig. 44

Mechanical construction of a hyperbola from its axes AA' and BB': Determine the foci F and F' (Fig. 44); pivot one end of a strip of stiff paper or suitable material at F'; fasten an inextensible string HPF at H and F and so that the length HPF is less than HF' by AA'; place a pencil or other scribing point under the string and thru the slot; keep the string taut with the pencil and then rotate the strip about F'; the pencil describes an arc of a hyperbola.

Parabola. This is a curve such that any and every point of it is equidistant from a fixt point and a fixt line. The point is the focus, the line the directrix of the parabola, and the distance of any point of the curve to the focus is a focal radius, or focal distance. A parabola has a line of symmetry called the axis of the parabola (Fig. 45); it contains the focus F and is perpendicular to the directrix. The vertex is the intersection of the axis with the curve; the latus rectum is the length of the focal chord perpendicular to the axis.

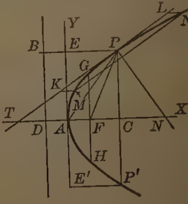

Fig. 45

The equations of the parabola referred to the axis as x axis and the vertex tangent as a y axis is $y^2 = px$ where p = latus rectum; the polar equation referred to F as pole and FA as polar axis is $r = p/2\,(1 + \cos\phi)$.

Geometric Properties and Constructions. The vertex is midway between the focus and the directrix. The length of the latus rectum equals four times the distance between focus and vertex. Any line parallel to the axis of a parabola bisects a system of parallel chords and is therefore a diameter of the parabola; the chords are parallel to the tangent at the end of the diameter terminating in the parabola. The extension of a diameter at P to the directrix equals the focal radius at P ($PB = PF$), and the distances from the focus to the ends of a definite tangent are equal ($FT = FP$). The tangent and the normal at any point bisect the angles between the focal radius and the diameter at that point; a subtangent is bisected by the vertex ($AC = AT$), and all subnormals equal one-half the latus rectum ($CN = ½ GH$). The projection of the radius of curvature R at any point on the axis of the parabola equals twice the focal distance of the point, and the extension of R to the directrix also equals twice the focal distance; R at the vertex equals the latus rectum. To construct a parabola: (a) Given the vertex A (Fig. 46), the axis AX, and a point P. Join A and P, and thru P draw a line parallel to the axis; draw any line as AQ; then perpendicular to the axis a line QR to AP; then parallel to the axis a line RS to AQ; S is a point on the parabola. Repeat for other points Q. Or, divide AB into equal parts and BP into the same number of equal parts; number the points of division, beginning at A on AB and at B on BP; draw lines as shown and note intersections of corresponding lines; they are on the parabola. (b) The vertex A and focus F (Fig. 47) are given. Join A and F and draw a perpendicular to AF at A; draw any line as FB and then BC perpendicular to FB; BC is a tangent to the parabola. Repeat with other lines like FB and BC and thus determine the parabola by means of tangents.

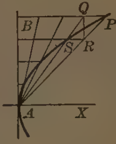

Fig. 46

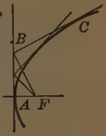

Fig. 47

12. Higher Curves

A Cycloid is the curve generated or traced by any point on the circumference of a circle which rolls on a straight line. Fig. 48 shows one half of one branch of a cycloid OA generated by the point P on the circle PQ rolled on OX; the other half of the branch is symmetrical with respect to AX. Let θ be the angle described by any line of the circle while it rolls from its original position OaY to any other as the one shown, r the radius of the circle, and x and y the coordinates of P relative to the axis shown; then $x = r(\theta - \sin\theta)$, $y = r(1 - \cos\theta)$, and the equation of the cycloid is $x = r\cos^{-1}(1 - y/r) \pm\sqrt{(2r - y)\,y}$. A cycloid may be constructed as follows: Draw the circle OaY of the chosen radius r, and make $OX = \pi r$; divide the arc OaY and OX into the same number of equal parts; at two corresponding points of division, as a and b, draw a horizontal and a vertical respectively to their intersection c and make $cd = ae$; then d is a point on the cycloid. Repeat for other points of division. To find the position of the generating circle corresponding to any point of the cycloid as P: make $Pf = gh$, and from f drop a perpendicular to OX; its foot Q is the lowest point of the circle desired. The normal at any point of the cycloid, as P, passes thru the lowest point of the corresponding position of the generating circle; $PQ = 2r\sin ½\theta = \sqrt{2ry}$. The radius of curvature is twice PQ; at the highest point it equals $4r$ and at the lowest 0. The length of any arc as OP beginning at the lowest point is $4r\,(1 - \cos ½\theta)$ =

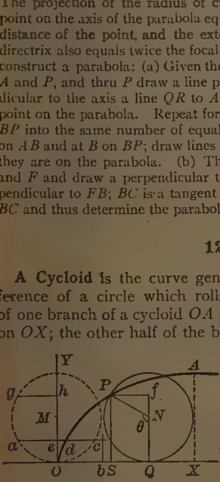

Fig. 48

$4r - 2\sqrt{2r(2r-y)}$, y being the ordinate of P; the length of one complete cycloid or 2 OPA is $8r$. The area of any part as $OPSO$ is $r^2(\frac{3}{2}\theta - 2\sin\theta + \frac{1}{4}\sin 2\theta) = \frac{3}{2}rx - \frac{1}{2}y\sqrt{(2r-y)y}$, x and y being the coordinates of P; the entire area between one cycloid and the track, that is 2 $OAXO$, is $3\pi r^2$.

When a circle rolls upon the outside of a fixt circle, each point of the circumference of the rolling circle describes or traces an epicycloid; and when it rolls upon the inside the curve described is a hypocycloid. A point without or within the rolling circle and fixt to it describes a trochoid, an epitrochoid, or a hypotrochoid according as the circle rolls on a straight line, on the outside of a fixt circle, or on the inside of a fixt circle.

The Spiral of Archimedes is a curve generated by a point moving at a constant speed in a given straight line which rotates at constant speed about a fixt point of the line. Fig. 49 shows such a spiral; O is the fixt point and OA the position of the line when the moving point is at the fixt point. The polar equation of the spiral is $r = (r'/2\pi)\phi$, in which r is the distance of the moving point P from O, ϕ the corresponding angle described by the moving line exprest in radians, and r' is the distance traveled by the moving point along the line while the line turns thru 360°. To construct the spiral having selected r': draw lines OA, OB, OC, etc., so that the successive angles between them is $360/n$, n being a convenient number; make $OB = r'/n$; $OC = 2r'/n$;

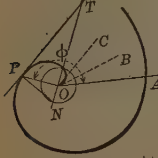

Fig. 49

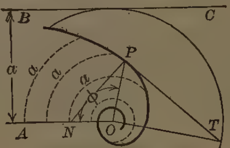

Fig. 50

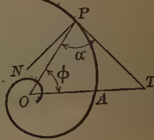

Fig. 51

$OD = 3r'/n$, etc.; B, C, D, etc., are on the spiral. To draw a normal and tangent at any point P: draw a circle with center at O and radius $r'/2\pi$; joi P and O, and draw a perpendicular to OP at O, and note the intersection N as shown; then PN is the normal and PT (perpendicular to PN) the tangen The length of any arc OP is $(r'/4\pi)[\phi\sqrt{1+\phi^2} + \sinh^{-1}\phi]$; for many turns equals approximately $r'\phi^2/4\pi$.

The Hyperbolic Spiral may be constructed as follows: draw a numb of concentric circles and then a radius of the largest circle; from this radiu measure off on the circles equal arcs all on the same side of the radius; th other ends of the arcs lie on the spiral (Fig. 50). The polar equation the spiral is $r\phi = a$, a being the constant length of arc referred to, r the distan of any point of the curve as P from O and ϕ the angle between the radius O and OP. The curve has an asymptote BC distant a from the referen radius. To draw a tangent and a normal at any point P: draw a circ with center at O and radius a, and join P and O; to OP at O draw a perpe dicular, and note its intersection T with the circle on the side shown; th TP is the tangent and PN (perpendicular to PT) is the normal.

The Logarithmic or Equiangular Spiral is a curve such that the ang between its tangents and the corresponding radii drawn to the center of t curve are equal. Its polar equation is $r = a\varepsilon^{m\phi}$; a is the value of r wh $\phi = 0$ and $m = \cot\alpha$, α being the constant angle referred to (Fig. 51). construct a curve for given values of a and α: compute m and then $m\phi$ a number of values of ϕ in radians, as 20° = 0.349 radian, 40° = 0.6

60° = 1.047, etc.; from a table of Naperian logarithms (page 35) find the values of $\epsilon^{m\phi}$ (these are the numbers corresponding to the logarithms $m\phi$); compute values of $a\epsilon^{m\phi}$ or r; then lay off these values of r from a fixt point on radii making the different angles ϕ (20°, 40°, 60°, etc.) with a reference line thru the fixt point. The length of any arc as $PO = r/\cos\alpha$.

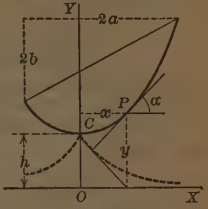

Fig. 52

The Catenary is the curve assumed by a chain suspended from two points. Its equation is $y = \frac{1}{2}h\ (\epsilon^{x/h} + \epsilon^{-x/h}) = h \cosh x/h$, or $x = h \log_\epsilon (y/h \pm \sqrt{(y/h)^2 - 1}) = h \cosh^{-1} y/h$; h is the distance from the lowest point of the curve to the origin (Fig. 52). The gradient at any point P whose coordinates are x and y is given by $\tan\alpha = \sinh x/h$ or $\cos\alpha = h/y$, from which the direction of the tangent line at any point can be computed. The radius of curvature R at any point P is $R = y^2/h = h/\cos^2\alpha$; it also equals the length cut off by the x axis from the normal thru P. The length of any arc, as CP, is given by $s = h \sinh x/h = h \tan\alpha = \sqrt{y^2 - h^2}$, and the abscissa of P is

$$x = h \log_e [s/h + \sqrt{1 + (s/h)^2}] = h \sinh^{-1} s/h$$

To locate the origin of coordinates for a chain of length $2l$, supported from two points whose horizontal distance is $2a$ and vertical distance is $2b$: Let A and B denote the distances from the middle of the line joining the points of suspension to the y and x axis respectively; $A = \psi h$ and $B = l \cot\phi$, in which $h = a/\phi$ and $\psi = \tanh^{-1} b/l$, ϕ to be obtained by trial from $a \sinh\phi = \phi\sqrt{l^2 - b^2}$. The catenary is the evolute of the other curve shown in Fig. 52; its tangents are all equal to h. It is also called "anti-friction" curve, it being the axial section of the surface of a vertical pivot of uniform wear.

13. Hyperbolic Functions

The Hyperbolic Functions are related to an equilateral or rectangular hyperbola much as the circular functions are related to a circle. Let P (Fig. 53) be any point (x, y) on the hyperbola $x^2 - y^2 = a^2$; r = the radius OP always positiv, l = arc AP positiv or negativ according as the arc is above or below the axis OX, and $u = l/r$; then

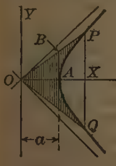

Fig. 53

hyperbolic sine of u, or $\sinh u = y/a$
hyperbolic cosine of u, or $\cosh u = x/a$
hyperbolic tangent of u, or $\tanh u = \sinh u \div \cosh u = y/x$
hyperbolic cotangent of u, or $\coth u = 1/\tanh u = x/y$
hyperbolic secant of u, or $\operatorname{sech} u = 1/\cosh u = a/x$
hyperbolic cosecant of u, or $\operatorname{csch} u = 1/\sinh u = a/y$

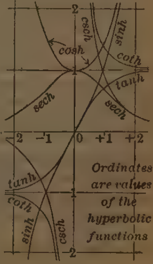

Fig. 54

If a is made 1, then the numerical values of double the area of the hyperbolic sector $OPAO$ equals l/r or u; also $\sinh u = XP$, $\cosh u = OX$; $\tanh u = AB$. See Sect. 1, Art. 22, for tables of hyperbolic functions. Fig. 54, plotted to scale, shows the relations between the functions for values of u from -2 to $+2$; it also indicates the sign of any function of u as dependent on the sign of u. Inverse hyperbolic

sine of n means the l/r or u whose hyperbolic sine equals n; it is written $\sinh^{-1} n$; similarly, inverse hyperbolic cosine, tangent, etc.

The hyperbolic functions of u are closely related to the exponential function ε^u and ε^{-u}, ε being the Naperian base, thus

$$\sinh u = \tfrac{1}{2}(\varepsilon^u - \varepsilon^{-u}), \quad \cosh u = \tfrac{1}{2}(\varepsilon^u + \varepsilon^{-u})$$
$$\tanh u = (\varepsilon^u - \varepsilon^{-u})/(\varepsilon^u + \varepsilon^{-u})$$
$$\sinh u + \cosh u = \varepsilon^u, \quad \cosh u - \sinh u = \varepsilon^{-u}$$

Inverse hyperbolic functions as functions of Naperian logarithms:

$$\sinh^{-1} u = \log_\varepsilon \left(u + \sqrt{u^2 + 1}\right), \quad \cosh^{-1} u = \log_\varepsilon \left(u + \sqrt{u^2 - 1}\right)$$
$$\tanh^{-1} u = \tfrac{1}{2}\log_\varepsilon [(1 + u)/(1 - u)]$$

The hyperbolic functions are related to circular functions, thus $\left(i = \sqrt{-1}\right)$:

$$i \sinh u = \sin iu, \quad \sin u = -i \sinh iu$$
$$\cosh u = \cos iu, \quad \cos u = \cosh iu$$
$$i \tanh u = \tan iu, \quad \tan u = -i \tanh iu$$

The following are some of the relations between hyperbolic functions:

$$\cosh^2 u - \sinh^2 u = 1 \qquad 1 - \tanh^2 u = \operatorname{sech}^2 u$$
$$\coth^2 u - 1 = \operatorname{csch}^2 u$$
$$\sinh(u \pm v) = \sinh u \cosh v \pm \cosh u \sinh v$$
$$\cosh(u \pm v) = \cosh u \cosh v \pm \sinh u \sinh v$$
$$\tanh(u \pm v) = (\tanh u \pm \tanh v)/(1 \pm \tanh u \tanh v)$$
$$\sinh 2u = 2 \sinh u \cosh u$$
$$\cosh 2u = 1 + 2\sinh^2 u = 2\cosh^2 u - 1$$
$$\tanh 2u = 2 \tanh u/(1 + \tanh^2 u)$$
$$\sinh \tfrac{1}{2} u = \sqrt{\tfrac{1}{2}(\cosh u - 1)}$$
$$\cosh \tfrac{1}{2} u = \sqrt{\tfrac{1}{2}(\cosh u + 1)}$$
$$\tanh \tfrac{1}{2} u = \sinh u/(1 + \cosh u) = (\cosh u - 1)/\sinh u$$

14. Probability of Errors

The Probability of an event is the ratio of the number of favorable chances of its occurrence to the total number of chances, favorable and unfavorable. Thus, if there are a white and b black balls in a jar, the probability of drawing a white ball at a single trial is $a/(a + b)$. If the probabilities of two independent events are p_1 and p_2, the probability of their concurrence in any single instance is p_1p_2. Thus, suppose that there are two jars, J_1 and J_2, J_1 containing a_1 white and b_1 black balls, and J_2 containing a_2 white and b_2 black balls; the probability of drawing a white ball from J_1 is $a_1/(a_1 + b_1)$, the probability of drawing a white one from J_2 is $a_2/(a_2 + b_2)$, and that of drawing a pair of white balls, one from each jar, in a single trial is $a_1a_2/(a_1 + b_1)(a_2 + b_2)$.

An Error of an Observation is the true value of a quantity minus the observed value. Errors are accidental or systematic; accidental errors are those which in the long run are as often negativ as positiv, and they affect the mean result but little; systematic errors due to the same cause affect the mean in the same sense, and do not tend to balance each other in the mean. Only accidental errors are referred to in the following. From the theory of probabilities, it has been shown that in a series comprising a great number of observations the relative frequency (proportionate number) of the errors whose values lie between x and $x + \Delta x$ is approximately $(h/\sqrt{\pi})\varepsilon^{-h^2x^2}\Delta x$ and the relative frequency of the errors whose values lie between a and b is $(h/\sqrt{\pi})\int_a^b \varepsilon^{-h^2x^2}dx$; here ε is the Naperian base (Art. 1) and h a constant for any particular series of observations. The graph of $y = (h/\sqrt{\pi})\varepsilon^{-h^2x^2}$ (Fig. 55) is a probability or "error curve"; the shaded area represents the relative frequency of the errors between a and b, and the whole area between

the curve and the x axis is unity, according to the scale used, and represents the frequency of the whole number of errors that is 1 or 100 %. The dotted curve is also an error curve but the constant h for that curve is greater than for the first; also in the second the relative frequency of small errors is greater and that of large errors is smaller than in the first. Thus the constants h serve as a means for comparing the accuracies of several series of observations, and the value of h for any given series is called the measure of precision for that series. Another index of accuracy is the so-called probable error of the series, an error of such value that the number of errors in the series less and greater than it are equal, the signs of the errors being disregarded in the count. It is the error r (Fig. 55) corresponding to the symmetrical ordinates which include one-half the whole area below the error curve. This middle error is more often called the PROBABLE ERROR of a single observation to convey the idea that the error of any subsequent observation in such a series is just as apt to be less as greater than the middle error. The probable error and the measure of precision are always related thus, $rh = 0.4769$. The expression for relative frequency of the errors falling between $-a$ and $+a$ is

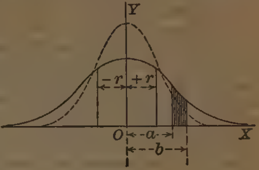

Fig. 55

$$\frac{h}{\sqrt{\pi}}\int_{-a}^{+a} \epsilon^{-h^2x^2}\,dx = \frac{2}{\sqrt{\pi}}\int_{0}^{0.4769\,a/r} \epsilon^{-h^2x^2}\,d\,(hx)$$

The table below gives the values of the expressions for the various values of the arguments a/r given therein. Thus, in a large series of observations, the relative frequency of the errors falling between $a = -r$ and $a = +r$ is .500, or 50 %; between $a = -2r$ and $a = +2r$, 0.823, or 82.3 %; the relative frequency of the errors arithmetically greater than $4r$ is 0.007, or 0.7 %; etc.

Values of the Probability Integral

a/r	frqncy	a/r	frqncy	a/r	frqncy	a/r	frqncy	a/r	frqncy

The probable error r for n observations of equal precision on the same quantity is computed as follows: (1) find the arithmetic mean by adding the observations and dividing by n, (2) subtract each observation from that mean thus obtaining n residuals v_1, v_2, v_3, etc., (3) square each residual and find their sum Σv^2. Then

$$r = 0.6745\sqrt{\frac{\Sigma v^2}{n-1}} \quad \text{and} \quad r_0 = \frac{r}{\sqrt{n}}$$

the first formula giving the probable error of a single observation, while the sec-

ond gives the probable error of the arithmetic mean. For a numerical example, see below.

14½. Method of Least Squares

An Observation is the result of a measurement, thus when 635.74 ft is stated as the measured length of a line, the quantity 635.74 ft is called an observation, it being understood that all constant errors have been removed therefrom; this quantity, however, is still affected by the result of accidental errors. The true value of a quantity cannot be found by measurement, but the best that can be done is to deduce from the observations the most probable value of the quantity. The Method of Least Squares teaches how to obtain the most probable values of observed quantities.

Direct Observations are those which result from measurements made directly upon a single quantity. When only one observation is at hand, it is the most probable value of the quantity. When two or more observations are made with equal precision on the same quantity, their arithmetic mean is the most probable value, and the probable error of this arithmetic mean can be computed by the formulas at the end of Art. 14.

Example: Let a line be measured eight times with equal care by a tape graduated in centimeters and the following results be found, M indicating an observation, v a residual found by subtracting M from the arithmetic mean, and v^2 the square of a residual:

M	789.7	788.1	789.1	789.9	788.3	788.0	788.1	788.8
v	0.95	0.65	0.35	1.15	0.45	0.75	0.65	0.051
v^2	0.902	0.423	0.122	1.323	0.203	0.562	0.423	0.002

Here, the arithmetic mean, found by adding the observations and dividing by 8, is 788.75, which is the most probable length of the line in centimeters. The eight residuals are some positive, some negative, their sum being zero. The sum of the squares of the residuals is $\Sigma v^2 = 3.96$. Then by the formula at foot of last page $r = 0.51$ cm, which is the probable error of a single observation; also $r_0 = 0.18$ cm, which is the probable error of the arithmetic mean. The final result of this series of observations may then be written 788.75 ± 0.18, that is, the true length of the line is just as likely to be between 788.57 cm and 788.93 cm as it is to be outside of those limits.

Weighted Observations. Weights of Observations are numbers proportional to their degrees of precision, so that one observation of weight p is worth as much as p observations of weight unity. When there are n weighted observations, M, with weight p_1, M_2 with weight p_2, and so on, these being made directly upon the same quantity, then the most probable value of the quantity is the weighted mean z, or

$$z = \frac{p_1 M_1 + p_2 M_2 + \ldots + p_n M_u}{p_1 + p_2 + \ldots + p_n} = \frac{\Sigma p M}{\Sigma p}$$

To find the probable errors, let each observation be subtracted from this mean z, the difference being a residual v, square each residual, multiply each square by its weight, and find the sum $\Sigma p v^2$, then

$$r = 0.6745 \sqrt{\frac{\Sigma p v^2}{n-1}} \quad \text{and} \quad r_0 = \frac{r}{\sqrt{\Sigma p}}$$

the first being the probable error of an observation of the weight unity and the second being the probable error of the weighted mean Z.

Example: Let six observations on the same quantity be made, with weights as in the first line, the sum of these weights being 21. Multiplying each observation M by its weight p, gives the quantities in the third line the sum of which is 3741.36. Then the most probable value of the observed quantity is $z = 3741.36/21 = 178.16$. Subtracting each

M from this gives the residuals in the fourth line. The weighted squares of the residuals are in the last line, their sum being $\Sigma pv^2 = 62.95$. Then the above formulas give the

p	5	4	1	4	3	4
M	178.26	176.30	181.06	177.95	176.20	180.85
pM	891.30	705.20	181.06	711.80	528.60	723.40
v	0.10	1.86	2.90	0.21	1.96	2.69
v^2	0.010	3.460	8.410	0.441	3.842	7.236
pv^2	0.05	13.84	8.41	0.18	11.53	28.94

probable error of an observation of the weight unity as $r = 2.39$ and the probable error of the weighted mean as $r_0 = 0.52$. The final result then is $z = 178.16 \pm 0.52$.

Observation Equations arise when measurements are made to find the values of several quantities. For example, let O be a given bench and Z_1, Z_2, Z_3 three points whose elevations above O are to be determined. Let z_1, z_2, z_3 be the most probable elevations of Z_1, Z_2, Z_3; let five lines of levels be run giving

$$
\begin{array}{llll}
Z_1 \text{ above } O = 10 \text{ feet} & \text{or} & z_1 & = 10 \\
Z_1 \text{ above } Z_3 = 2 \text{ feet} & \text{or} & z_1 - z_3 & = 2 \\
Z_2 \text{ above } O = 18 \text{ feet} & \text{or} & z_2 & = 18 \\
Z_2 \text{ above } Z_3 = 9 \text{ feet} & \text{or} & z_2 - z_3 & = 9 \\
Z_1 \text{ above } Z_3 = 2 \text{ feet} & \text{or} & -z_1 + z_2 & = 7
\end{array}
$$

The problem is to determine the most probable values of z_1, z_2, z_3.

Normal Equations are derived from observation equations, when these are of equal weight, by the following rule: To find a normal equation for z_1, multiply each observation equation by the coefficient of z_1 in that equation and add the results; similarly a normal equation for each of the other unknown quantities is found; thus, for the above level observations the normal equation for z_1 is found by multiplying the first equation by $+1$, the second by $+1$, the third by 0, the fourth by 0, and the fifth by -1; the addition of these gives $3z_1 - z_2 - z_3 = 5$ as the normal equation for z_1. Similarly the normal equation for z_2 is $-z_1 + 3z_2 - z_3 = 34$, and that for z_3 is $-z_1 - z_2 + 2z_3 = -11$. These three normal equations contain three unknown quantities, and their solution gives $z_1 = 10\frac{3}{8}$, $z_2 = 17\frac{5}{8}$, $z_3 = 8\frac{1}{2}$, which are the most probable elevations of the points Z_1, Z_2, Z_3 above the bench mark O.

General Method. Let the n observation equations be:

$$
\begin{array}{ll}
a_1 z_1 + b_1 z_2 + c_1 z_3 + \ldots = M_1 & \text{with weight } p_1 \\
a_2 z_1 + b_2 z_2 + c_2 z_3 + \ldots = M_2 & \text{with weight } p_2 \\
\cdots\cdots\cdots\cdots & \\
a_n z_1 + b_n z_2 + c_n z_3 + \ldots = M_n & \text{with weight } p_n
\end{array}
$$

in which M_1, M_2 . . . M_n are the observed quantities, z_1, z_2, z_3 are quantities required to be found, and a, b, c, are known coefficients. For each unknown quantity form a normal equation by multiplying each observation equation by the coefficient of that unknown quantity in that equation and also by its weight, and adding the results. If the number of unknown quantities is q the number of normal equations will also be q, thus:

$$
\begin{array}{l}
\Sigma pa^2.z_1 + \Sigma pab.z_2 + \Sigma pac.z_3 + \ldots = \Sigma paM \\
\Sigma pab.z_1 + \Sigma pb_2.z_2 + \Sigma pbc.z_3 + \ldots = \Sigma pbM \\
\Sigma pac.z_1 + \Sigma pbc.z_2 + \Sigma pc_2.z_3 + \ldots = \Sigma pcM
\end{array}
$$

in which $\Sigma pa^2 = p_1a_1^2 + p_2a_2^2 + \ldots p_na^2_n$ and similarly $\Sigma pab = p_1a_1b_1 + p_2a_2b_2 + \ldots p_na_nb_n$. The solution of these normal equations gives the most probable values of the unknown quantities z_1, z_2, z_3, . . . z_q.

After these probable values are found, let them be inserted in the observation

equations and the second members be subtracted from the first, thus giving small residuals $v_1, v_2, \ldots v_n$. Then

$$r = 0.6745\sqrt{\frac{\Sigma pv^2}{n-q}} \quad \text{and} \quad r' = \frac{r}{\sqrt{p'}}$$

the first being the probable error of an observation of weight unity, while the second is the probable error of an observation of weight p'.

For an example in which the weights are unequal, see the adjustment of angles at a station in Art. 49 of Sect. 2. When the weights are equal p is to be taken as unity.

Probable Error of a Line. When a line is measured the probable error of an observation increases as the square root of the length of the line. Thus $R = r\sqrt{l}$, where r is the probable error of a line one unit long, and R is the probable error of a line l units long.

The same rule holds good for discrepancies or apparent errors which are found in duplicate measurements of a line. The discrepancy r for a line one unit long may be found as follows: Let a line of length l_1 be measured twice. R_1 being the difference of the observed lengths; let a second length, l_2, be measured twice, R_2 being the difference of the observed lengths. Then $r = (R_1 - R_2)/(\sqrt{l_1} - \sqrt{l_2})$.

The same rule holds for duplicate lines of levels. Thus, if r is the difference in the results for a line one unit long, then the difference R for a line of length l ought to be $R = r\sqrt{l}$. The practical rules stated at foot of page 83 are derived from this principle.

STATICS

15. Forces and Moments

Force. An action of one body upon another which changes or tends to change the state of rest or motion of the body acted upon, is called force. A force has magnitude, direction, and place of application. When the extent of the place of application is negligible, and the force is regarded as applied or concentrated at a point, this is the point of application; and a line thru the point parallel to the direction of the force is the line of action. The word "sense" as applied to forces refers to one of the two directions along the line of action of the force. The unit of force commonly used in America is the "pound," which is a force equal to the earth's attraction on the standard of weight, also called pound; this unit of force varies slightly from place to place on the earth, but the variation is negligible in most engineering calculations. Any number of forces considered collectively is a system of forces; a system is CONCURRENT, or nonconcurrent, according as the lines of action of the forces do or do not intersect in a point, and it is COPLANAR, or noncoplanar, according as they do or do not lie in a plane. The resultant of a system of forces is the single force which is equivalent to that system, but if a system has no single force equivalent, then the simplest equivalent system may be called the resultant; a resultant never includes more than two forces. The process of determining the resultant is called composition (Art. 16).

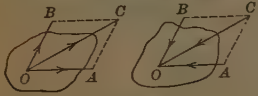

Fig. 56

Parallelogram Law. If magnitudes, lines of action, and senses of two concurrent forces acting on a rigid body be represented by OA and OB (Fig. 56), then the magnitude, line of action, and sense of their resultant is represented by the diagonal OC of the parallelogram $OABC$. The points of application of the forces may be anywhere on the body in the lines OA, OB, and OC, or their extensions. The arrowheads on the lines on AO, OB, and OC all point toward or all away from the poin

of concurrence O. TRIANGLE LAW: If the magnitudes and directions of two concurrent forces are represented by AB and BC, (Fig. 57 or 58) then the magnitude and direction of the resultant is represented by the side AC of the triangle ABC. The arrowheads on the sides AB and BC are confluent (point

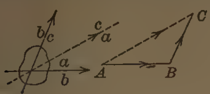

Fig. 57

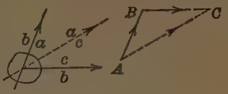

Fig. 58

the same way around), but the arrowhead on AC is not confluent with the others. The two forces and their resultant being concurrent, the line of action of the resultant is ac, parallel to AC.

The resultant of two concurrent forces may be determined algebraically, thus: let P and Q be the forces and α that angle between their lines of action in which the resultant lies, R the resultant and θ the angle between R and P; then $R = (P^2 + Q^2 + 2\,PQ \cos \alpha)^{1/2}$ and $\tan \theta = (Q \sin \alpha)/(P + Q \cos \alpha)$. If the angle between the given forces is 90°, then $R = \sqrt{P^2 + Q^2}$ and $\tan \theta = Q/P$.

Parallelopiped Law. If the magnitudes and lines of action of three noncoplanar concurrent forces be represented by OA, OB, and OC, then the magnitude and the line of action of the resultant is represented by the diagonal OD of the parallelopiped $OABC - D$ (Fig. 59). This is not a practical device to get numerical results; for a better, see Art. 16. When the three forces are mutually at right angles then the parallelopiped is right-angled, and the resultant can be conveniently determined algebraically thus: let P, Q, and S denote the three forces, R the resultant and α, β and γ the angles between R and the three forces respectively; then $R = (P^2 + Q^2 + S^2)^{1/2}$, $\cos \alpha = P/R$, $\cos \beta = Q/R$ and $\cos \gamma = S/R$.

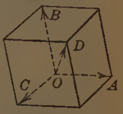

Fig. 59

Resolution of a Force. Two or more forces which together are equivalent to a given force are components of the force. The process of determining components of a force is called resolution; resolution of a force into two components at right angles to each is the common case; such components are "rectangular" and each is a "resolved part" of the given force. (1) Resolution into concurrent components. A force may be resolved into two concurrent components by applying the parallelogram law inversely; thus to resolve the 10 lbs (Fig. 60) into two components: lay off AB by scale to

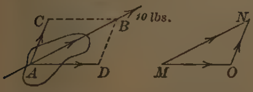

Fig. 60

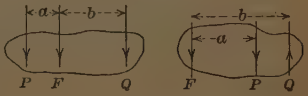

Fig. 61

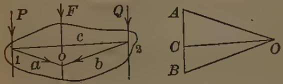
represent 10 lbs; construct a parallelogram on AB as diagonal; then AC and AD represent components of the given force. Or, by means of the triangle law, thus: lay off MN by scale to represent the magnitude and direction of the given force; construct a triangle on MN as one side; then MO and ON represent magnitudes and directions of two components of the given force, the action lines being concurrent with that of the 10-lb force. Two rectangular components of a force can readily be found algebraically; each equals

the product of the force and the cosine of the acute angle between the force and that component. Three rectangular components of a force can be readily computed if the angles between the force and the desired components are known; each component equals the product of the force and the cosine of the acute angle between the force and that component. (2) Resolution into two components parallel to the force, their lines of action being specified: Let F (Fig. 61) be the force to be resolved into two components P and Q (values and senses unknown), a and b the distances from F to P and Q respectively, and c the distance between P and Q; the principle that the moment of F about a point on either force equals the moment of the other about the same point determines the senses of the components as shown, also their values, $P = Fb/c$ and $Q = Fa/c$. Or, graphically, suppose F (Fig. 62) to be



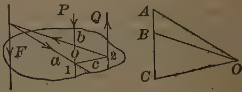


Fig. 62

the force and P and Q the components; resolve AB (representing magnitude and direction of F) into any two concurrent components AO and OB, action lines in ao and ob; at 1 resolve AO along P and the line 12, and at 2 resolve OB along Q and the line 12; the two components along 12 balance, and those along P and Q represented by AC and CB in value and direction are the desired components. (3) To resolve a force into three nonconcurrent nonparallel forces coplanar with the force: Let P (Fig. 63) be the force, the components to act in F_1, F_2 and F_3; join the intersection of P and F_1 with that of F_2 and F_3; draw AB to represent P and then resolve P into two

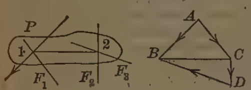

Fig. 63

components along F_1 and the line 12 (represented by AC and CB); then resolve CB into two components along F_2 and F_3 (represented by CD and DB); then AC, CD, and DB are the magnitudes and directions of the desired components.

The Moment of a Force with Respect to a Point is the product of the magnitude of the force and the perpendicular distance between the force and the point; this distance is the "arm" of the force with respect to the point and the point is the origin or center of moments. Moments are commonly given signs, those corresponding to forces which tend to turn the body acted upon in one direction (clockwise) being given the same sign and all others the opposite. The moment of a force with respect to a point may also be computed by taking the algebraic sum of the moments of its two rectangular components with respect to that point; and it will often be convenient to resolve the force so that one of the components will act thru the origin of moments, so that that component will have no moment.

The Moment of a Force with Respect to a Line is the product of its rectangular component perpendicular to the line (the other being parallel) and the distance between the line and the perpendicular component (or the force); the line is the "axis" of moments. If a force is parallel to the axis of moments or if it cuts the axis, then its moment with respect to that axis is zero. Moments of forces about the same axis are commonly given signs; those corresponding to the forces which tend to turn the body acted upon about the axis (regarded as a shaft) in the same direction (clockwise) being given the same sign and others the opposite. The moment of a force with respect to an axis may also be computed by resolving the force into three rectangular components, one being parallel

the axis, the other two perpendicular to it; then the moment of the given force equals the algebraic sum of the moments of the two perpendicular components. If the resolution is made so that one of the perpendicular components cuts the axis, then the moment of the given force equals the moment of the other perpendicular component.

The moment of the resultant of any coplanar forces about a point in their plane (or of any noncoplanar forces about a line) equals the algebraic sum of the moments of those forces about the point (or line). This is called the principle of moments for forces. The word TORQUE is frequently used as synonymous with moment of a force, especially when the force is distributed around a circumference.

Couples. Two equal, parallel, and opposite forces are called a couple; the perpendicular distance between the forces is the "arm" of the couple. The moment or torque of a couple with respect to any point or origin in their plane is the algebraic sum of the moments of the two forces with respect to that point; this sum or moment, the same for all origins in the plane, always equals the product of one of the forces and the arm of the couple. Moments of couples whose planes are parallel are sometimes given signs; those corresponding to couples which tend to turn the body in the same direction are given the same sign, and the others the opposite sign. A couple may be represented sufficiently for statical purposes by means of a single vector; the vector is drawn perpendicular to the plane of the couple, and the arrowhead is so placed that it points toward the place from which the rotation appears, say counter-clockwise. Two couples whose vectors are equal, same in length and direction, have equal moments (sign included) and their planes coincide or are parallel. Such are equivalent couples; that is, either may be substituted for the other without change of effect on the body acted upon if rigid. The resultant of a number of couples is a couple. If the planes of the given couples are parallel or coincident, the resultant couple is one whose plane is parallel to the others and whose moment (with sign) equals the algebraic sum of the moments of the given couples. If the planes of the given couples are not parallel or coincident, then the resultant can be determined from the vectors representing the different couples; thus, add the vectors, that is, find their resultant; this resultant vector represents the resultant couple. A couple can be resolved into component couples thus; resolve the vector of the given couple into component vectors (Art. 16) which are perpendicular to the planes of the desired components; these component vectors represent the several component couples.

16. Composition of Forces

The Force Polygon for a system of forces is the figure formed by drawing consecutively lines representing the magnitudes and directions of the forces of a system; the order in which the lines are drawn is immaterial, but the arrowheads on the lines (to indicate the senses of the forces) must be confluent, that is, pointing the same way around. A force polygon, unlike a geometrical one, need not be a closed figure. For a given system, as

Fig. 64

many different force polygons may be drawn as there are orders of taking the forces; if the number of forces is n, then the number of possible force polygons is $n!$ (see Art. 1). In Fig. 64 there are three different force polygons for the system acting upon the body shown at the left. If a system is not coplanar, then its force polygon is not plane, but is called "gauche."

Concurrent Systems. (1) Graphic Method: Draw a force polygon for the system; the magnitude of the resultant is represented by the length of the line joining the ends of the polygon; the sense of the resultant is represented by an arrowhead on that line not confluent with the other arrowheads, and the resultant is concurrent with the given forces. If the forces are noncoplanar, then this method is not practical but it can be used by drawing the force polygon in "plan and elevation." (2) Algebraic Method: If the forces F are coplanar, resolve each into components F_x and F_y along axes x and y at right angles to each other; get the algebraic sums of the x and y components, ΣF_x and ΣF_y; then the resultant being called R, and its angle with the x axis α, $R^2 = (\Sigma F_x)^2 + (\Sigma F_y)^2$ and $\tan \alpha = (\Sigma F_y)/(\Sigma F_x)$. The approximate direction of the resultant is apparent from the directions of its x and y components, which respectively equal ΣF_x and ΣF_y. If the forces F are noncoplanar, then each force should be resolved into components parallel to three rectangular axes x, y, and z. $R^2 = (\Sigma F_x)^2 + (\Sigma F_y)^2 + (\Sigma F_z)^2$, $\cos \alpha = (\Sigma F_x)/R$, $\cos \beta = (\Sigma F_y)/R$, $\cos \gamma = (\Sigma F_z)/R$, α, β, and γ being the angles between R and the x, y, and z axes respectively.

Nonconcurrent Coplanar Systems. (1) Graphic Method: If the forces are not parallel or not nearly parallel, find the resultant R_1 of any two forces (Triangle Law, Art. 15), then the resultant R_2 of R_1 and the third force, etc., until all the forces have been compounded. If the forces are parallel or nearly so, the method just explained fails because the lines of action of the several resultants cannot be determined readily on account of inaccessible intersections. In this case, each force may be replaced by two components in a certain way, and then the resultant of these components can be found. Thus, to find the resultant of the three forces ab, bc, and cd acting on the body in Fig. 65: draw a force polygon, as $ABCD$, for the given forces; resolve AB into AO and OB; BC into BO and OC, etc.; O having been taken anywhere; all components except the first and last occur in pairs and the forces of each pair are equal and opposite, thus OB and BO, OC and CO, etc.; choose the action lines of these components so that those of any one pair shall be colinear; thus, insert the components of AB at pleasure as at oa and ob, the components of BC so that the component BO shall act in ob, and hence the component OC is oc, etc.; thus the pairs of components consisting of equal, colinear, and opposite forces each balance, leaving only the first and last components AO and OD acting in ao and od; and their resultant (which is also the resultant of the given forces) is AD (magnitude and direction) ad (action line). The point O (Fig. 65) is called pole, lines OA, OB, OC, etc., are rays; oa, ob, oc, etc., are strings, and all the strings constitute the string polygon for the forces. This polygon is also called "funicular," "link" and "equilibrium polygon," the last being especially appropriate when the given forces are in equilibrium. The part of the drawing which represents the body and the lines of action of the

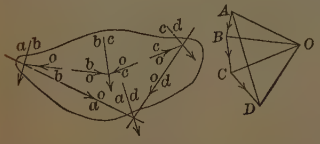

Fig. 65

forces is the space diagram; that representing force magnitudes, the vector diagram. If the force polygon closes, then the resultant is in general a couple, the forces of the couple acting in the first and last strings of the string polygon, the magnitude of the forces being represented by the corresponding rays. If it happens that the first and last strings coincide, then the string polygon is closed and the resultant vanishes.

(2) Algebraic Method. When the forces F are parallel, give to the forces in the one direction the same sign, and to the others the opposite; then the resultant R equals ΣF, the sense of R being indicated by the sign of ΣF. The position or line of action of R may be fixt by means of the arm of R, a, with respect to any origin O in the plane of the forces; thus if ΣM denotes the sum of the moments of the given forces with respect to O, then $a = (\Sigma M)/R$, a being measured in such direction from O that the sign of the moment of R will be the same as that of ΣM. If $\Sigma F = 0$, then the resultant of the system is a couple whose moment equals ΣM. When the parallel forces are two in number, P and Q (Fig. 66), then if P and Q act in the same direction, R cuts any line AB internally, and if P and Q are opposite, then externally on the side of the larger force; and in each case the segments of AB are inversely proportional to P and Q, that is, $AC/BC = Q/P$. When the forces are not parallel, compute the algebraic sums of the x and y components of the forces (ΣF_x and ΣF_y) and the algebraic sum of the moments of the forces with respect to any origin O in their plane (ΣM). Then the resultant $R^2 = (\Sigma F_x)^2 + (\Sigma F_y)^2$, its angle with the x axis $= \tan^{-1}(\Sigma F_y)/(\Sigma F_x)$ and its arm with respect to O is $a = \Sigma M/R$. The general direction of R is apparent from the directions of its components ΣF_x and ΣF_y; a must be measured in such a direction from O that the sign of the moment of R will be the same as that of ΣM. If $\Sigma F_x = \Sigma F_y = 0$, the resultant is in general a couple whose moment $= \Sigma M$.

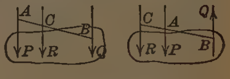

Fig. 66

Nonconcurrent Noncoplanar Systems. The graphic method is generally not advantageous; the algebraic is here given. (1) Forces Parallel. Give to the forces F acting in the same direction one sign and to the others the opposite sign; then the resultant $R = \Sigma F$, the sense of R being indicated by the sign of ΣF. Next compute the sums of the moments of the forces with respect to two axes (x and y, say) perpendicular to the forces; call these sums ΣM_x and ΣM_y and the arms of R with respect to those axes respectively a_x and a_y; then $a_x = (\Sigma M_x)/R$ and $a_y = (\Sigma M_y)/R$. The signs in these ratios may be disregarded; a_x and a_y have such positions that the moments of R with respect to the x and y axis have the same signs as those of ΣM_x and ΣM_y respectively. If $\Sigma F = 0$, the resultant in general is a couple which can be determined by finding the resultant of all the forces but one; the resultant and the omitted force constitute the resultant couple.

(2) Forces not Parallel. In general, the resultant is not a single force, but the system can be reduced to a force R acting thru any point of the body selected and a couple C; and if desired, R and C can in general be compounded into two nonparallel nonconcurrent forces. To determine R and C: select a set of coordinate axes (x, y, and z) in the body, the origin O being at the selected point referred to; determine the sums of the x, y, and z components of the given forces (ΣF_x, ΣF_y, and ΣF_z) and the algebraic sums of the moments of the forces with respect to the x, y, and z axes (ΣM_x, ΣM_y, and ΣM_z); ΣF_x, ΣF_y, and ΣF_z are the x, y, and z components of R, and ΣM_x, ΣM_y, and ΣM_z are the moments of the components of C perpendicular to the x, y, and z axes respectively.

$R^2 = (\Sigma F_x)^2 + (\Sigma F_y)^2 + (\Sigma F_z)^2$ and $C^2 = (\Sigma M_x)^2 + (\Sigma M_y)^2 + (\Sigma M_z)^2$; if α_1, α_2, and α_3 denote the angles between R and the x, y, and z axes, and θ_1, θ_2, and θ_3 the angles between the vector representing C (Art. 15) and the x, y, and z axes respectively, then

$$\cos\alpha_1 = (\Sigma F_x)/R \qquad \cos\alpha_2 = (\Sigma F_y)/R \qquad \cos\alpha_3 = (\Sigma F_z)/R$$
$$\cos\theta_1 = (\Sigma M_x)/C \qquad \cos\theta_2 = (\Sigma M_y)/C \qquad \cos\theta_3 = (\Sigma M_z)/C$$

The resultant force R and the resultant couple C can be compounded into two force as follows: take the plane of the couple so that one of the forces of the couple intersects R find the resultant of this force and R; this resultant and the other force of C are the tw forces sought. In general the final two forces are skewed. If the plane of C is parall to R, then C and R may be compounded into a single force as follows: take forces of th couple so that they are parallel to R; then find the resultant of those forces and R; this a single force.

17. Principles of Equilibrium

Conditions of Equilibrium. A force exerted on a body (definite portio of matter) by another body is an external force with reference to the fir body. A force exerted upon one part of a body by another part of the sam body is an internal force. All the external forces applied to a body at re constitute a system said to be in equilibrium. When a force system is i equilibrium, its resultant is zero; this is the general condition of equilibriur Detailed conditions for the various kinds of force systems follow, the notatio being: F denotes force, F_x, F_y, and F_z, x, y, and z components of F, M denot moment of F, M_a, M_b, and M_c moments of F with respect to points a, b, and M_x, M_y, and M_z moments of F with respect to x, y, and z axes respectivel (1) Colinear System: $\Sigma F = 0$ or $\Sigma M_a = 0$ (a is not to be taken on th forces). (2) Coplanar Concurrent System: $\Sigma F_x = 0$ and $\Sigma F_y = 0$; $\Sigma F_x = 0$ and $\Sigma M_a = 0$ (the x axis must not be perpendicular to the li joining a and the point of concurrence of the forces); or $\Sigma M_a = 0$ and $\Sigma M_b =$ (a, b, and the point of concurrence must not be colinear). For the ca of three forces: $F_1 : F_2 : F_3 :: \sin \alpha_1 : \sin \alpha_2 : \sin \alpha_3$; F_1, F_2, and F_3 deno the forces, α_1, α_2, and α_3 the acute angles between F_2 and F_3, F_3 and F_1, a F_1 and F_2 respectively. (3) Coplanar Parallel System: $\Sigma F = 0$ a $\Sigma M_a = 0$; or $\Sigma M_a = 0$ and $\Sigma M_b = 0$ (the line joining a and b must not parallel to the forces). (4) Coplanar Nonconcurrent Nonparall System: $\Sigma F_x = 0$, $\Sigma F_y = 0$, and $\Sigma M = 0$; or $\Sigma F_x = 0$, $\Sigma M_a = 0$, and $\Sigma M_b =$ (the x axis must not be perpendicular to the line joining a and b); or ΣM $= 0$, $\Sigma M_b = 0$, and $\Sigma M_c = 0$ (a, b, and c must not be colinear). (5) No coplanar Concurrent System: $\Sigma F_x = 0$, $\Sigma F_y = 0$, and $\Sigma F_z = 0$. (Noncoplanar Parallel System: $\Sigma F = 0$, $\Sigma M_x = 0$, and $\Sigma M_y = 0$ (x and y axes are not parallel to the forces or to each other). (7) Non planar Nonconcurrent Nonparallel System: $\Sigma F_x = 0$, $\Sigma F_y =$ $\Sigma F_z = 0$, $\Sigma M_x = 0$, $\Sigma M_y = 0$ and $\Sigma M_z = 0$.

Also, based on graphic methods, these conditions of equilibrium: For concurrent s tems, the force polygon closes; for coplanar nonconcurrent systems, the force and str polygons close. Special Principles, applicable in either algebraic or graphic analy (1) If three forces are in equilibrium, then they are coplanar, and concurrent or para (2) If four coplanar nonconcurrent nonparallel forces are in equilibrium, then the result of any two is concurrent with the other two.

Virtual Work. Any imaginary displacement of a body or system of bo is a virtual displacement. The work done by a force during a virtual placement of its point of application is called the virtual work of that fo Virtual works are computed according to the definitions and rules for c puting real works (see Art. 28). The quantity here called virtual worl also called "virtual moment." (1) If a rigid body is in equilibrium, then any infinitesimal virtual displacement the algebraic sum of the virtual w of the external forces equals zero. The work of a force for a displacen of its application point at right angles to the force is zero; and so in appl the principle of virtual work to determine a particular force of a system equilibrium, it is generally advantageous to take a virtual displacemen that the displacements of the application points of as many forces (particul unknowns but excepting the one in question) as possible shall be at r

angles to the corresponding forces. (2) If any system of particles (constituting a rigid body, a deformable body, or a collection of such bodies) is in equilibrium, then for any infinitesimal virtual displacement of the system the algebraic sum of the virtual works of all external and internal forces acting upon it equals zero. Internal forces occur in pairs, and the forces of any pair are equal, colinear, and opposite. Let S denote the magnitude of either force of a pair (regarded as positiv if they are pulls and negativ if pushes), and let ds denote the change in the distance between the application points of the forces for infinitesimal virtual displacement of the points (regarded as positiv or negativ according as the distance is increased or decreased); then in such a displacement the work of the pair is $-Sds$. For any infinitesimal displacement of a rigid body ds is zero for all pairs of internal forces, and the work of each pair (and of all pairs) is zero. In applying the principle to a collection of rigid bodies which press against one another or are connected as by hinges or strings, the equation of virtual work must in general include, besides the external forces, those internal forces which the bodies exert upon each other. But the virtual works of these forces may be zero; thus the virtual works of the pressures at a frictionless contact is zero for any virtual displacement which preserves the contact, and the virtual work of the binding forces of a string is zero for any virtual displacement which leaves the string taut and unchanged in length.

Stability. When a body (or collection of bodies) is in equilibrium and the state is such that if when displaced slightly in any way the body returns of itself to its original position, then the equilibrium is stable; if when displaced slightly the body moves farther from its original position, then the equilibrium is unstable; and if when displaced slightly it remains in that displaced position, the equilibrium is neutral, or indifferent. The body or collection is also said to be stable, unstable, or neutral (or indifferent) respectively. When a body or collection is stable, its potential energy is a minimum; when unstable, a maximum; and when neutral, constant (or stationary); the converse statements also are true. When the potential energy is gravitational, that is, due to weight, then when a body or collection is stable its center of gravity is in a lowest position; when unstable, in a highest position; and when neutral, at a uniform height, that is, it moves in a horizontal plane if the body or collection is slightly displaced. When a body rests on a number of points, the smallest polygon including all the points is called the supporting base or, simply, base. If the resultant of all forces acting on the body including its own weight but not the supporting forces, cuts the base, the equilibrium is stable, and the moment of the resultant about the side of the base nearest the resultant is a measure of the stability.

Properties of the Equilibrium or String Polygon. (See also Art. 16.) In the following the force-systems are not assumed to be in equilibrium except where so stated. (1) The line of action of the resultant of any number of coplanar forces which are represented consecutively in a force polygon passes thru the intersection of the two strings of the equilibrium polygon which are parallel to the two rays embracing those forces in the force polygon. Thus the resultant of AB, BC, and CD (Fig. 67), acting in ab, bc, and cd, acts thru the intersection of ao and od; the resultant of BC, CD, and DE acts thru the intersection of ob and oe; etc. (2) If a pole is taken

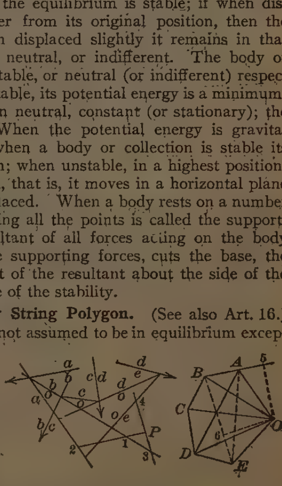

Fig. 67

at the beginning of a force polygon for a given force-system, then each strin of a corresponding equilibrium polygon is the action line of all the forces fron (and including) the first up to that string. Thus, the string od (Fig. 68) i the line of action of the forces AB, BC, and CD, actin in ab, bc, and cd; and ae is the line of action of AB, BC CD, and DE. (3) If two equilibrium polygons be draw for a given force-system from the same force polygon bu with different poles, then the intersections of correspond ing strings will lie on a straight line parallel to that joinin the poles. Thus in Fig. 69 there are represented force AB, BC, and CD, acting in ab, bc, and cd, and two equ librium polygons are shown corresponding to poles P an Q; corresponding strings intersect in points 1, 2, 3, and all being in a line parallel to PQ. (4) If an equilibriu polygon for a system of forces in equilibrium be regarded as a series of link jointed at the intersections of the segments of the polygon, by means of whic the forces react upon each other, the series would remain at rest under th action of the forces; each link would be under te sion or compression, and the ray corresponding any particular link represents the amount of th tension or compression. In Fig. 70 each link under compression.

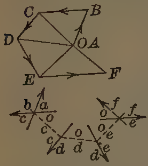

Fig. 68

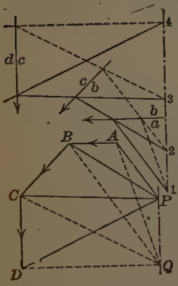

Fig. 69

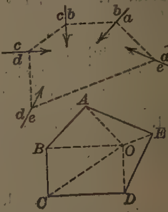

Fig. 70

An equilibrium polygon for a coplanar force-system furnishes a ready means of obtaining the moment of any one of the forces, and of the resultant of any of the forces consecutive in the force polygon. Thus the moment of any force with respect to any origin is the product of its "intersept" and "pole distance"; by intersept of a force is meant the distance (by the space scale) intercepted by the strings corresponding to the force from the line drawn parallel to the fo thru the origin of moments, and the pole distance of a force is the perpendicular dista (by the force scale) from the pole to the line representing the force in the force polyg Thus the moment of AB (Fig. 67) acting in ab, about P, is $\overline{12} \times \overline{O5}$, and the momen the resultant of BC, CD, and DE about P is $\overline{34} \times \overline{O6}$. Both moments are counterclockwise, determined from the lines of action and senses of forces as related to the origin of moments.

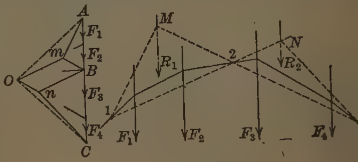

Fig. 71

An equilibrium polygon for a coplanar system of forces can be drawn so as to pass thru any three points of the plane of the forces. Thus, to draw one thru points 1, 2, and 3 for the forces F_1, F_2, F_3, F_4 (Fig. 71): find the resultants R_1 an of the forces whose lines of action are cut by the lines joining 1 and 2, and 2 and 3 first acts in R_1 and the second in R_2 (construction for position not shown), and values are represented by AB and BC respectively in the force polygon for the fo Extend lines R_1 and $\overline{32}$ to their intersection M, and lines R_2 and $\overline{12}$ to their intersectio

From A and B draw lines parallel to $\overline{M1}$ and $\overline{M2}$ to their intersection m, and from B and C draw lines parallel to $\overline{N2}$ and $\overline{N3}$ to their intersection n. Complete the parallelogram $BmnO$; then O is a pole and the corresponding equilibrium polygon, if started thru one of the three specified points, will pass thru the other two. (It is advisable to draw as first string the one thru point 2, parallel to OB.)

18. Typical Problems

In each of the problems following, some of the forces of the system in equilibrium are unknown in sense. In writing an equilibrium equation for the system, senses may be assumed when unknown; if the computed value of a force comes out positiv, the sense was guessed correctly; if negativ, then incorrectly. In the figure, incorrectly assumed senses are indicated by a short line thru the arrowhead.

A Coplanar Concurrent Force-System is in Equilibrium and the forces are all known except two whose action lines only are known; to determine these two completely. This is a common problem in the determination of the stresses of a roof or bridge truss, and the numerical illustration is from a truss, but the method of solution is as general as the statement of the problem.

(1) Algebraic Solution: Three sets of equilibrium equations are available (see Art. 17). No general rule covering all cases can be laid down as to which set is best in a particular case, but if a resolution equation ($\Sigma F_x = 0$ or $\Sigma F_y = 0$) is taken first, it is advantageous to take the resolution axis perpendicular to one of the unknown forces. If a moment equation ($\Sigma M = 0$) is taken first, it is advantageous to take the moment origin on the action line of one of the unknowns. Fig. 72 represents a joint of a truss under the action of a load of 1600 lb, a known pull of a member, 2000 lb, and two unknown forces F_1 and F_2; to find these two: Choosing $\Sigma F_x = 0$ and $\Sigma F_y = 0$, with the x axis horizontal, $\Sigma F_y = -1600 + F_1 \sin 30° = 0$, or $F_1 = +3200$ lb, the positiv sign indicating that F_1 acts as assumed in the figure. Next $\Sigma F_x = -2000 + 3200 \cos 30° + F_2 = 0$, or $F_2 = -771$ lb, the negativ sign indicating that F_2 acts toward the left. Or, beginning with $\Sigma M = 0$, the origin being on F_2, 10 feet to the right of O, say, then $\Sigma M = -1600 \times 10 + F_1 \times 10 \sin 30° = 0$, or $F_1 = 3200$; F_2 may now be determined as before or from another moment equation with origin anywhere except on F_2. When there are only three forces in the system, then a special condition of equilibrium (Art. 17) may be applied thus: suppose that the three forces are 1600 lb, F_1, and F_2 (Fig. 72); $F_1/\sin 90° = F_2/\sin 60° = 1600/\sin 30°$, which equations furnish values of F_1 and F_2.

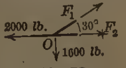

Fig. 72

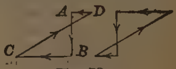

Fig. 73

(2) Graphic Solution: The condition of equilibrium is that the force polygon for the force system must close; constructing the polygon and making it close will determine the unknown forces. The order in which the forces are represented in the polygon is immaterial, but the knowns must be drawn first of course. To construct a force polygon for the forces: draw AB (Fig. 73) to represent the 1600-lb force, BC to represent the 2000-lb force; then from A and C lines parallel to the other two forces; the intersection of these two lines is D, and CD and DA represent the values and directions of the two unknowns. The unlettered polygon in Fig. 73 is another possible force polygon, giving the same results as the one explained.

A Coplanar Parallel Force-System is in Equilibrium and all the forces are known except two whose action lines only are known; to determine completely these two. The determination of the reactions on a beam or truss on horizontal supports and under vertical loads is a problem of this sort. Such a beam is used as an illustration, but the method of solution is as general as the statement of the problem.

(1) Algebraic Solution: Either one of two sets of equilibrium equations is available (Art. 17). It will be well to use the two moment equations with origins on the action lines of the two unknown forces. Then after the unknowns have been determined one might test, as a check, whether ΣF is zero. Fig. 74 represents a beam supported at R_1 and R_2, the beam bearing a concentrated load at the left end, a uniform load as shown, and its own weight, 1800 lb; to determine the reactions. With origin at R_2, the

moment equation is $-10\,000 \times 18 - 40\,000 \times 6 - 1800 \times 9 + R_1 \times 10 = 0$, or $R_1 =$ 43 620 lb; with origin at R_1, it is $-10\,000 \times 8 + 40.000 \times 4 + 1800 \times 1 - R_2 \times 10 = 0$ or $R_2 = 8180$ lb. As algebraic sum of loads and reactions is zero, the computation check

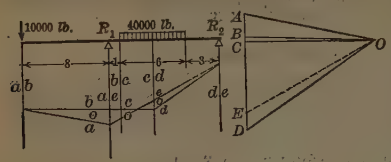

Fig. 74

(2) Graphic Solution. The conditions of equilibrium are that the force and string polygons close; if these be constructed and made to close, the problem will have been solved. Using the preceding illustration again, the 40 000-lb load is regarded as concentrated at its center and also the weight of the beam at the middle of the beam; first $ABCD$ the polygon for the known forces, is laid off; the right reaction will be taken next and called DE and the other EA, but E is as yet unknown; next a pole O chosen, rays are drawn and then the strings or oa, ob, oc, and od; od should be extended to de, and oa to ea. The line oe is the closing string, and a ray parallel to it fixes the point E. Then DE and EA represent the magnitudes of the reactions.

A Coplanar Nonconcurrent Nonparallel Force-System is in Equilibrium, and all the forces are known except two; the action line of one of these and a point in that of the other are known; required to determine the unknowns completely. This problem occurs in the determination of the reactions on a roof truss sustaining wind pressures, the truss being fixt at one end and resting on rollers at the other. This case is used in illustrations below but the solutions are as general as the statement of this problem.

(1) Algebraic Solution: Calling the first described unknown P and the second Q, imagine Q replaced by two rectangular components Q_x and Q_y acting at the given point of Q; then the unknowns of the system are the magnitudes and senses of P, Q_x, and Q_y. Any one of three sets of equilibrium equations may be used (Art. 17); generally it is advantageous to begin with a moment equation, the origin being at the known point of Q, as such an equation will furnish P directly. Q_x and Q_y can be determined from the other two equations of the set selected, and then Q itself from its components. Fig. 75 represents a roof truss whose span is 60 ft, rise 12 ft, resting on rollers at the left end and pinned to the support at the right; there are four loads as shown; required the reactions. The reaction at the roller end can be vertical only; that at the other end may have any direction. The first is P and the second Q, but Q is represented in the figure by its two unknown components Q_x and Q_y.

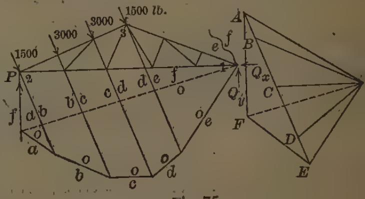

Fig. 75

The moment equation for the system with origin at 1 is $P \times 60 - 1500 \times 55.71 - 3000 \times 44.94 - 3000 \times 34.17 - 1500 \times 23.40 = 0$, or $P = 5933$. Then from $\Sigma M_2 = 0$, or $\Sigma F_y = 0$, Q_y may be found to be 2423, and from $\Sigma F_x = 0$, or $\Sigma M_3 = 0$, Q_x may be found to be 3342.

(2) Graphic Solution: The conditions of equilibrium are that the force and string polygons must close; constructing them and making them close will determine the unknowns. In order to make the construction possible, the first string drawn must be corresponding to the unknown force Q, one point of which is known, and it must be drawn thru that point. The following special graphic solution is simpler in principle. First determine the resultant R of the known forces, and imagine the knowns replaced by that resultant; then the system consists of three forces, namely that resultant and the two unknowns. If R and the unknown P whose action line is known are not parallel, t

the three forces R, P, and Q are concurrent and the action line of Q is determined. The solution of the three-force system can then be made as explained in the first paragraph. If R and P are parallel, then Q is also parallel to P and R; P and Q can be determined most readily algebraically, and graphically by constructing the force and funicular polygons for the three forces. (When R, P, and Q are parallel, this special graphical method is no simpler than the general method first described.) As illustration of the general method the reactions on the truss shown in Fig. 75 are determined thus: The force polygon for the known forces is $ABCDE$; calling the reaction at the fixt end ef and the other fa, the first string drawn is oe; then od, oc, ob, oa, and of the closing string. Next the ray parallel to of is drawn and its intersection with AF determines F; EF and FA represent the magnitudes and directions of the reaction at the fixt and roller ends respectively.

A coplanar noncurrent nonparallel force-system is in equilibrium and all the forces are known except three whose action lines only are known. Required to determine these three completely. (This problem is indeterminate if the three unknowns are concurrent or parallel.)

(1) Algebraic Solution: Any one of three sets of equilibrium equations may be used (Art. 15). In general it is advantageous to use a moment equation first, the origin being at the intersection of two of the unknowns; the choice of the other two equations will depend on the particular problem under consideration. For example, consider the overhanging truss (Fig. 76) which sustains three loads as shown and is supported at 1 so that the reaction there acts along the line marked R_1 and at 2 by two forces R_2 and R_3 which are horizontal and vertical respectively. Required R_1, R_2, and R_3. $\Sigma M_1 = -800 \times 20 - 1500 \times 10 + R_2 \times 10 = 0$, or $R_2 = 3100$ lb; $\Sigma M_3 = 1500 \times 10 + 1000 \times 20 - R_3 \times 20 = 0$, or $R_3 = 1750$ lb; and $\Sigma F_x = R_1 \cos a - 3100 = 0$, or $R_1 = 3466$ lb.

(2) Graphic Solution: The conditions of equilibrium are that the force and equilibrium polygons must close. In order to construct the equilibrium polygon, the first string must be drawn thru the intersection of two of the unknowns. Using the preceding illustration the force polygon for the three known forces is $ABCD$ (Fig. 76). The reaction at 1 is called de and the reactions at 2 are called ef and fa. The first string is oa

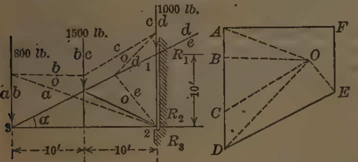

Fig. 76

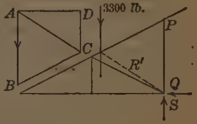

Fig. 77

and it is drawn thru the intersection of fa and ef; then ob, oc, and od are drawn, the latter to its intersection with de. The closing string is oe, and a ray parallel to oe determines E, in the line through D parallel to de. Then completing the force polygon by line through A and E parallel to R_2 and R_3 respectively determines F, and $FA = R_2$ and $EF = R_3$. The senses of R_1, R_2 and R_3, apparent in this example, are given by arrow heads on DE, EF and FA confluent with the senses of AB, BC and CD.

The following special method is simpler than the foregoing: Determine the resultant R of the known forces, and imagine them replaced by their resultant; then the system consists of R and the three unknowns P, Q, and S. Note that R, P, and the resultant R' of Q and S are concurrent, and by a force triangle determine P and R'; finally resolve R' into its components Q and S. For example, in the preceding illustration the resultant of the known forces is 3300 lb as shown in Fig. 77. The resultant R' of Q and S is concurrent with R and P, and acts in the dotted line. The force triangle for R, P, and R' is $ABCA$, AB representing 3300 lbs, BC representing P, and CA representing R'. Then resolving CA into Q and S, it is found that CD represents S and DA represents Q.

19. Shear and Moment in Beams

Beams and Trusses are usually subjected to vertical loads and reactions. In such cases, the VERTICAL SHEAR at any cross-section of the beam or truss is the algebraic sum of all the loads and reactions on either side of the section; if the shear is computed from the forces (loads and reactions) to the left of the section, then upward forces are given the positiv sign, but if from those on the right, then the upward forces are taken as negativ. The BENDING MOMENT at any cross-section of a beam or truss is the algebraic sum of the moments of all the loads and reactions on either side of the section, the origin of moments being taken in the section; if the bending moment is computed from the forces to the left of the section, clockwise moments are regarded as positiv, but if from those to the right, clockwise moments are taken as negativ. V and M are used to denote shear and moment respectively.

Fig. 78*a* represents a cantilever sustaining a concentrated load of 1000 lb at the free end and uniform load of 2000 lb on half its length as shown. Fig. 78*b* is a shear diagram for the cantilever as loaded, showing how the external shear varies from section to section; at a section just to the right of the concentrated load $V = -1000$, at the wall $V = -3000$ lb. Fig. 78*c* is a moment diagram for the cantilever as loaded, showing how the bending moment varies from section to section; at the middle $M = 5000$ and at the wall $M = 15\ 000$ ft lb. Fig. 79*a* represents a beam resting on two supports A and B and bearing a uniform load of 1000 lb per ft between the supports, and a concentrated load of 2500 lb at the right end; the reactions at A and B are respectively 4000 and 8500 lb. Fig. 79*b* is a shear diagram for the beam so loaded; just to the right of A, $V = +4000$ lb, just to the left of B, $V = -6000$ lb, and at any section to the right of B, $V = +2500$ lb. Fig. 79*c* is a moment diagram for the beam as loaded; at B, $M = -10\ 000$ ft-lb and the greatest positiv value of M is 8000 ft-lb, at the section 4 ft from the left end.

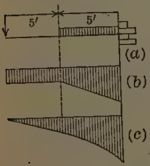

Fig. 78

The equilibrium polygon is a moment diagram for the beam as loaded, the vertical ordinates in it being proportional to the bending moments at the corresponding sections. The bending moment at any particular section is the product of the corresponding ordinate in the equilibrium polygon (according to the scale of the drawing of the beam) and the distance from the pole to the "load line" (according to the scale of the force polygon).

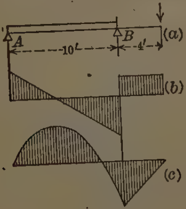

Fig. 79

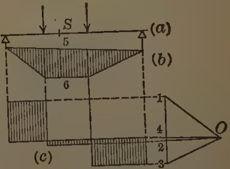

Fig. 80

For example, in Fig. 80, the beam represented is supported at each end and sustai two loads of values 12 and 23; the perimeter of the upper shaded part is an equilibriu polygon and constitutes a moment diagram for the beam as loaded. The bending m ment at any section as S equals the product of the distance represented by the ordina 5-6 and the force represented by the perpendicular from O to the line 1-2-3. The she diagram (Fig. 80*c*) can be constructed from the force polygon by obvious means.

For a beam bearing a distributed load an approximate moment diagram may be constructed thus: draw an equilibrium polygon for the beam under an approximately equivalent series of concentrated loads obtained by imagining the uniform load divided into parts and each part replaced by a concentrated load equal to that part and applied at its center. See Fig. 81, in which the distributed load is divided into three parts. The true bending moment line is curved below the distributed load, and the curve is tangent to the equilibrium polygon at points immediately below the lines of division of the load.

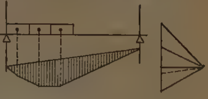

Fig. 81

Properties of Shear and Moment Diagrams. For any part of a beam bearing no load and weight of beam being disregarded, the shear line is horizontal and the moment line is generally inclined; for any part bearing a uniformly distributed load, the shear line is inclined downward to the right, and the moment line is a parabola, convex upward and axis vertical. The shears on either side of a concentrated load differ by an amount equal to the load, and the moment line changes direction there suddenly. At each end of a beam the shear and moment are zero. Where the shear changes sign, there the moment has a maximum or minimum value.

20. Simple Frameworks

A Truss is a framework intended to carry loads, while each member of the truss is subjected only to longitudinal stress, either tensile or compressive. In this article it is assumed, except as otherwise noted, that (a) the truss under consideration is pin-jointed, that is, the members have "eyes" and are pinned together at the joints, (b) each member is continuous between two joints only, and (c) the loads and reactions are applied to the truss at the joints. When these assumptions are fulfilled the forces acting upon any member, consisting of loads, reactions or pin pressures, are applied at its ends only; and the resultants, R_1 and R_2, of the forces at each end act thru both ends, that is, R_1 and R_2 are colinear, and they are equal and opposite. When they are pulls, the member is in tension, and any two parts exert pulls upon each other (Fig. 82); when they are pushes, the member is in compression, and any two parts exert pushes upon each other (Fig. 82). These internal pulls and pushes are each equal to the end pulls or pushes and colinear with them. By force or stress in a member is meant either of the forces which either of the two parts of the member exerts on the other part; the magnitude of a stress is the magnitude of one of the two forces referred to. By analysis of a truss for certain loads is meant the determination of the stresses in its members due to these loads.

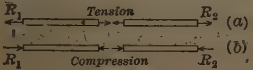

Fig. 82

The assumptions stated above are not realized in all actual trusses; yet if either (a) or (b) is not realized but the joints are properly made, then the methods of analysis here explained, or their equivalent, are used and without practical error; if (c) is not realized, the methods here given require amplification only.

To Determine the Stress in any particular member of a truss due to certain loads: First, determine the reactions on the truss due to the loads; second, imagine the truss separated into two distinct parts (that is pass a section thru the truss) so that the member under consideration is one of the members cut and so that the system of forces, including stresses, acting on either part of the truss is solvable for the desired stress; third, solve the system. (For plane trusses, the system will be coplanar and concurrent, or

nonconcurrent; the first kind can be solved completely if it includes not more than two unknown stresses, and the second if not more than three except when these three are concurrent or parallel.)

To illustrate how to pass the section, suppose the stress in HI (Fig. 83) is required, the truss being supported at its ends and bearing five loads L and one P, and suppose the reactions determined. Trying section 1-1, the force system on the left part of the truss (Fig. 83b) is a nonconcurrent one of seven forces, and includes four unknown stresses, S_1, S_2, S_3, and S_4; it is not solvable for the desired stress S_1. Trying section 2-2, the force system on the lower part (Fig. 83c) is a concurrent one, and includes four unknown

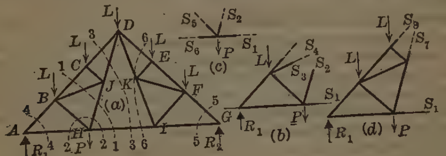

Fig. 83

stresses, S_1, S_2, S_5, and S_6; it is not solvable. Trying section 3-3, the force system on the left part (Fig. 83d) is nonconcurrent with three unknown stresses, S_1, S_7, and S_8; it is solvable. In some instances different sections may be used, each leading to a solution.

An Algebraic Analysis of a Truss is carried out by solving the various force-systems resulting from sections past, as explained in the foregoing, by algebraic methods. The problems to be solved are generally like one of Art. 18, where methods for their solution are given. In the following the unknown stresses will be assumed to be pulls always; then positiv computed stresses will be tension and negativ ones will be compression. In a truss with horizontal chords, the stress in any diagonal equals the vertical shear in the panel in which the member is, multiplied by the secant of the angle which the member makes with the vertical. The stress in either chord member of any panel equals the bending moment at the point where the other chord member and the strest web member of that panel intersect, divided by the height of the truss.

(1) **Roof Truss.** In Fig. 83 angles A and G are 45°, $AH = HI = IG =$ 16 ft; AB, BC, CD, DE, EF, and FG are equal, also HJ, JD, IK, and KD. Loads $L = 800$ lb, load $P = 1200$ lb. The reaction R_1 is found thus: $R_1 \times 48 - 4000 \times 24 - 1200 \times 32 = 0$, or $R_1 = 2800$ lb; also $R_2 = 2400$ lb.

To determine the stresses: Passing section 4-4, the force system on the part within the section (Fig. 84a) is concurrent with two unknowns S_1 and S_2. Taking a vertical y axis, $\Sigma F_y = S_2 \sin 45° + 2800 = 0$, or $S_2 = -3960$ lb, the negativ sign indicating that S_2 is compressive; next with the corrected direction of S_2, $\Sigma F_x = +S_1 - 3960 \cos 45° = 0$, or $S_1 = +2800$ lb, the positiv sign indicating that S_1 is tensile. In a similar manner the stresses in GF and GI might be determined; they are respectively 3394 lb compression and 2400 lb tension. No other section than 4-4 or 5-5 can be past so that the force-system acting on either part of the truss will be concurrent including only two unknown stresses; in fact the only sections leading to solvable force-systems are 3-3 and 6-6. On the left of 3-3 (Fig. 84b) the force-system is nonconcurrent with three unknown: S_3, S_1, and S_5. To determine S_3: $\Sigma M_D = -2800 \times 24 + 1200 \times 8 + 800 \times 8 + 80$ $\times 16 + S_3 \times 24 = 0$, or $S_3 = +1600$ lb tension. One might now solve the system for S_4 and S_5 or pass a section around joint H or I (Fig. 83), each furnishing a solvable con current system. But continuing with Fig. 84b, $\Sigma M_H = -2800 \times 16 + 800 \times 8 - S$ $\times BH = 0$, or $S_5 = -3394$ lb compression; and $\Sigma M_A = 0$ gives $S_4 = +2530$ lb ten sion. Next a section may be past about H or I as stated, or about C; section about H gives a concurrent system (Fig. 84c) with two unknowns, S_6 and S_7. Taking an x axi

at right angles to S_7, $\Sigma F_x = -1200 \cos 45° - 2800 \cos 45° + 1600 \cos 45° + S_6 \cos (71° 34' - 45°) = 0$, or $S_6 = +1897$ lb tension; and taking a vertical y axis, $\Sigma F_y = -1200 + S_7 \cos 45° + 1897 \sin 71° 34' = 0$, or $S_7 = -847$ lb compression. Next passing a section about C, the force-system is concurrent (Fig. 84d) with two unknowns S_8 and S_9. Two resolution equations, the axes being taken along the unknown stresses are simple; they give $S_8 = -556$ lb compression, and $S_9 = -3960$ lb compression. Next passing a section about B gives a concurrent system with one unknown (Fig. 84e) S_{10}. Or, one might pass next a section about J and get a solvable system (Fig. 84f). In similar manner the stresses in the members of the right half of the truss may be determined. When, in the analysis, a force system is reached in which there are fewer unknown stresses than the number of conditions of equilibrium for the system, as in Figs. 82e and f, then a partial check on the preceding computations may be made, thus: determine the unknown stress or stresses and then test whether the force-system satisfies the superfluous or extra equation or equations of equilibrium. Thus for Fig. 84e with the x axis along the two equal stresses,

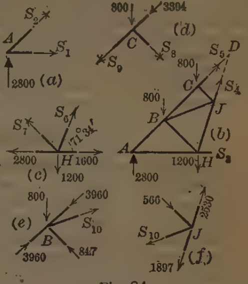

Fig. 84

$\Sigma F_x = S_{10} \times \cos 26° 34' - 800 \cos 45° = 0$, or $S_{10} = +633$ lb tension, and $\Sigma F_y = 847 - 800 \sin 45° - 633 \sin 26° 34' = -2$, or nearly zero, and so the check is satisfactory.

(2) **Howe Bridge Truss.** The truss represented in Fig. 85 is generally constructed all of wood except the "verticals." The "diagonals" are not connected to other members at the various joints but simply butt up against bearing blocks at their ends, and so can be subjected only to compression. Two diagonals in any panel cannot be strest at the same time; when the loading is symmetrical with respect to the middle of the truss, those diagonals represented are the ones strest and they are the main diagonals. The others, not shown, may be strest only when the truss is partially loaded, and they are counter diagonals, or braces, or simply counters.

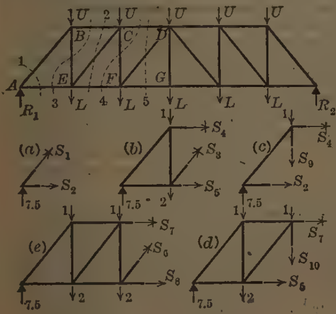

Fig. 85

In the following example the truss is supposed to be loaded symmetrically (see Fig. 85) and the counters are not mentioned. The span is 72 ft, height of truss 15 ft, each upper load U is 1 ton and each lower load L is 2 tons; then each reaction is 7.5 tons. The stress in any diagonal may be found by passing a vertical section thru the truss so as to cut the member under consideration and then solving the force system acting on either part of the truss. Thus, to determine the stress in AB, pass the section 1, and solve the system shown in Fig. 85a for S_1; to determine the stress in EC, pass section 2 and solve the system shown in Fig. 85b for S_3; similarly to determine the stress in FD, etc. It will be noticed that the vertical component of the stress in any diagonal equals the external shear at the section cutting the diagonal; thus (see Fig. 85b) $S_3 \times \cos \alpha = 7.5 - 2 - 1 = 4.5$. The stress in any vertical, except the middle one if there be such, may be found by passing

a section so as to cut only that member and adjaçent chord members and then solving the system of forces acting on either part of the truss for the desired stress. Thus, to determine the stress in BE, pass section 3, and from the system shown in Fig. 85c get $S_9 = 7.5 - 1 = 6.5$ tons; to determine the stress in CF, pass section 4, and from the system shown in Fig. 85d get $S_{10} = 7.5 - 2 - 1 - 1 = 3.5$ tons. The stress in the middle vertical equals the load at its lower end, 2 tons. The stress in any chord member may be found by passing a section cutting that member and the others in the same panel, and then solving the force-system acting on either part of the truss for the desired stress; the solution is easily made from a moment equation, the origin being taken at the intersection of the other two members cut. Thus to determine the stress in CD, pass section 5; the moment equation for the system shown in Fig. 85e with origin at the intersection of S_6 and S_8 is $7.5 \times 24 + 3 \times 12 - S_7 \times 15 = 0$, or $S_7 = 9.60$ tons.

21. Stress Diagrams for Trusses

Graphic Methods for Analyzing Trusses are especially well adapted for solving problems like the preceding. As in the algebraic method, the truss is imagined separated into two parts and then the attention is directed to the forces acting upon either part. Graphic instead of algebraic conditions of equilibrium are then applied to the system of forces to determine the unknowns. In making the imaginary separations of the truss, care should be taken to cut not more than three members, the forces in which are unknown. It is advantageous to make the separation so that not more than two such members are cut. If that be done, a single force polygon will determine the two unknowns, while if three be cut, a force polygon and an equilibrium polygon, or the equivalent, are necessary for determining the three unknowns. In drawing the force polygon, it will be advantageous to represent the forces in the order in which they occur about the joint. A force polygon so drawn will be called a polygon for the joint; and for brevity, if the order taken is clockwise, the polygon will be called a clockwise polygon and if counter-clockwise, it is called a counter-clockwise polygon. If the polygons for all the joints of a truss are drawn separately, then the stress in each member will have been represented twice. It is possible to combine the polygons so that it will not be necessary to represent the stress in any member more than once, thus reducing the number of lines to be drawn. Such a combination of force polygons is called a stress diagram. Each triangular space in the truss diagram is marked by a small letter, also the space between consecutive action lines of the loads and reactions. Then the two letters on opposite sides of any line serve to designate that line, and the same large letters are used to designate the magnitude of the corresponding force.

To construct a stress diagram for a truss under given loads:

(1) Determine the reactions. (2) Letter the truss diagram as directed. (3) Construct a force polygon for all the external forces applied to the truss (loads and reactions), representing them in the order in which their application points occur about the truss, clockwise or counter-clockwise. (4) On the sides of that polygon construct the polygons for all the joints. They must be clockwise or counter-clockwise ones according as the polygon for the loads and reactions was drawn clockwise or counter-clockwise. (The first polygon drawn must be for a joint at which but two members are fastened; the joints at the supports are usually such. Next that joint is considered and its polygon is drawn, at which not more than two stresses are unknown.

(1) **Roof Truss.** Fig. 86 represents a truss sustaining loads of 600, 1000, 1200 and 1800 lb; the right reaction is 2100 lb and the left 2500 lb. $ABCDEFA$ is a polygon for the loads and reactions, these being represented in the order in which their points of application occur about the truss. The polygon for joint 1 is $FABGF$; the force BG acts toward the joint, hence bg is under compression, and GF acts away from the joint, hence

gf is in tension. The polygon for joint 2 is $CDEHC$; the force EH acts away from the joint, hence eh is in tension; and HC acts toward the joint, hence hc is in compression. The polygon for joint 3 is $HEFGH$; the force GH acts away from the joint and hence gh is in tension. If the work has been correctly done, GH is parallel to gh. (In Fig. 86a the polygons are all clockwise, and in Fig. 86b counter-clockwise.)

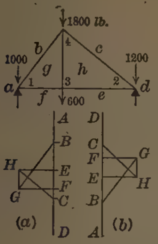

Fig. 86

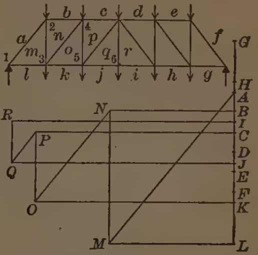

Fig. 87

(2) **Howe Truss.** Fig. 87 represents a Howe truss, 72 ft span and 15 ft high, under five 1-ton loads on the upper chord and five 2-ton loads on the lower. $ABCDEFGHIJKLA$ is a force polygon for all the loads and reactions. Polygon for joint 1 is $LAML$; for joint 2, $MABNM$; for joint 3, $KLMNOK$; for joint 4, $ONBCPO$; for joint 5, $JKOPQJ$; and for joint 6, $IJQRI$.

(3) **Derrick.** Fig. 88a represents a stiff-leg derrick, only one stiff leg, da, shown, and the boom and shown stiff leg in the same vertical plane. For the analysis it is not necessary to determine the reactions first. The polygon for joint 1 may be drawn first; it is $ABCA$, and BC and CA represent compression and tension respectively. The polygon for joint 2 may be drawn next; it is $ACDA$, and CD and DA represent compression and tension respectively. The reaction at 3 equals the resultant of CB and DC, that is DB.

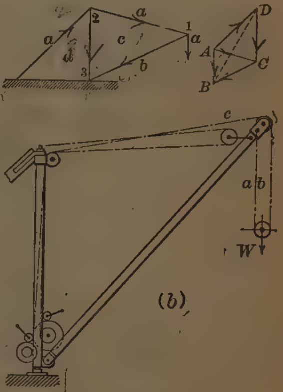

Fig. 88

The foregoing analysis is imperfect because it assumes, in part, a single stay along ac, whereas such derricks usually have a multiple stay and a hoisting cable as shown in Fig. 88b. To determine the reaction P_1 at the top of the mast exerted by the stiff leg and that P_2 at its base: P_1 acts nearly along the axis of the stiff leg, and P_2 in a direction unknown as yet; these forces along with the weights of the mast, boom, and load, constitute a system in equilibrium, and it may be solved for P_1 and P_2 as explained in Art. 18. (If hoisting is accomplished not by a winze mounted on the derrick, as assumed, but by an engine, then there must be included in the system described the pull of the engine.) To determine the reaction Q_1 at the base of the boom and the pull Q_2 of the top stay: Q_2 acts along the stay and Q_1 in a direction unknown as yet; these forces along with the weight of the boom, a pull of $\frac{1}{2}W$ in line a, and a pressure at the top pulley pin identical with the resultant of the pulls $\frac{1}{2}W$ in the lines b and c, constitute a system in equilibrium which may be solved for Q_1 and Q_2. (Art. 18.)

GRAVITY AND INERTIA FUNCTIONS

22. Principles of Center of Gravity

Definitions. The resultant of the weights, or parallel forces of gravity upon all the particles of a body, always passes thru a certain particle or point fixt with reference to the body, no matter how the body is turned about; this particle or point is the CENTER OF GRAVITY of the body. If the body can be supported at its center of gravity, then so supported it would remain at rest in any position. Center of gravity is also called center of mass and center of inertia, especially in discussions relating to the motion of the body. The center of gravity of a line (or length), surface (or area), solid (or volume) is the center of gravity of the line, surface, or solid imagined materialized, that is, conceived as a very slender wire, thin plate, or homogeneous body. Centroid is also used in place of center of gravity as applied to lines, surfaces, and solids. The center of gravity of a line, surface, solid or homogeneous body is a mean point; that is, the distance of the center of gravity from any reference plane is the mean of the distances of all the equal elementary parts of the line, surface, solid, or body from the plane. If the reference plane cuts the line, surface, solid, or body, distances on opposite sides of the plane must be regarded as opposite in signs. SYMMETRY: Two points are symmetrical with respect to a third point if the line joining the two is bisected by the third. Two points are symmetrical with respect to a line or a plane if the line joining them is perpendicular to the given line or plane and is bisected by it. A body, line, surface, or volume is symmetrical with respect to a point, a line, or a plane if all the points of the body, line, surface, or volume can be paired off so that each pair is symmetrical with respect to the point, line, or plane. If a line, surface, solid or homogeneous body is symmetrical with respect to a point, line, or plane, then its center of gravity is at the point in the line, or plane. The STATICAL MOMENT of a body (or weight), line (or length), surface (or area), or solid (or volume) with respect to any plane is the product of the weight, length, area, or volume and the distance of the center of gravity of the body, line, surface, or solid from the plane. The statical moment of a plane line (or length) or plane surface (or area) with respect to a straight line in the plane is the product of the length or area and the distance of the center of gravity of the line or surface from the reference line. A statical moment is regarded as positiv or negativ according as the corresponding center of gravity is on the positiv or negativ side of the reference plane or line. In the foregoing definitions and in the following, the words body, line, surface, and solid are used broadly to include what would ordinarily be described as a collection of bodies, lines, surfaces, or solids.

Methods for Locating Center of Gravity. The statical moment of a body, line, surface, or solid equals the algebraic sum of the statical moments of all the parts into which it is, or is imagined, divided. This principle is the basis of all formulas for locating centers of gravity. If the sum of the statical moments is zero, then the center of gravity is in the reference plane or line as the case may be. The position of a center of gravity is generally conveniently specified by its rectangular coordinates $\bar{x}$, $\bar{y}$ and $\bar{z}$.

(1) The formulas for the coordinates of the center of gravity of a body are

$$W\bar{x} = \int x\,dW \qquad W\bar{y} = \int y\,dW \qquad W\bar{z} = \int z\,dW,$$

in which W denotes the weight of the body, dW the weight of any elementary portion, and x, y, and z the coordinates of the center of gravity of that element; the limits of integration must be assigned so that the integration includes

all elementary parts of the body. The formulas furnish values of $\bar{x}$, $\bar{y}$, and $\bar{z}$ in any case if the body is mathematically regular and such that the integrations can be performed. The following are corresponding formulas for the coordinates of the center of gravity of lines, surfaces, and solids:

$$L\bar{x} = \int x\,dL \qquad L\bar{y} = \int y\,dL \qquad L\bar{z} = \int z\,dL$$

$$A\bar{x} = \int x\,dA \qquad A\bar{y} = \int y\,dA \qquad A\bar{z} = \int z\,dA$$

$$V\bar{x} = \int x\,dV \qquad V\bar{y} = \int y\,dV \qquad V\bar{z} = \int z\,dV$$

in which L, A, and V denote length, area, and volume respectively.

(2) If a body consists of finite parts whose weights and centers of gravity are known, then the coordinates of the center of gravity of the body can be computed, without integration, from

$$W\bar{x} = W_1\bar{x}_1 + W_2\bar{x}_2 + \cdots \qquad W\bar{y} = W_1\bar{y}_1 + W_2\bar{y}_2 + \cdots$$

$$W\bar{z} = W_1\bar{z}_1 + W_2\bar{z}_2 + \cdots$$

in which W denotes the weight of the body, W_1, W_2, etc., the weights of its parts; $\bar{x}_1$, $\bar{y}_1$, $\bar{z}_1$, the coordinates of the center of gravity of W_1; $\bar{x}_2$, $\bar{y}_2$, $\bar{z}_2$ those of the center of gravity of W_2; etc. The following are corresponding formulas for lines, surfaces, and solids:

$$L\bar{x} = L_1\bar{x}_1 + L_2\bar{x}_2 + \cdots \qquad L\bar{y} = L_1\bar{y}_1 + L_2\bar{y}_2 + \cdots \qquad L\bar{z} = L_1\bar{z}_1 + L_2\bar{z}_2 + \cdots$$

$$A\bar{x} = A_1\bar{x}_1 + A_2\bar{x}_2 + \cdots \qquad A\bar{y} = A_1\bar{y}_1 + A_2\bar{y}_2 + \cdots \qquad A\bar{z} = A_1\bar{z}_1 + A_2\bar{z}_2 + \cdots$$

$$V\bar{x} = V_1\bar{x}_1 + V_2\bar{x}_2 + \cdots \qquad V\bar{y} = V_1\bar{y}_1 + V_2\bar{y}_2 + \cdots \qquad V\bar{y} = V_1\bar{z}_1 + V_2\bar{z}_2 + \cdots$$

in which the L's, A's, and V's denote lengths, areas, and volumes.

The center of gravity of two bodies, lines, surfaces, or solids is on the straight line joining the centers of gravity of the two, and the center of gravity of the two divides the joining line into segments inversely proportional to their weights, lengths, areas, or volumes. The center of gravity of three bodies, lines, surfaces, or solids is in the plane of the centers of gravity of the three.

If the center of gravity of the parts of a body, line, surface, or solid lie in a plane, the center of gravity of the whole may be gotten graphically. (1) Let a, b, c, etc., be the centers of gravity of the parts and A, B, C, etc., their weights, lengths, areas, or volumes; then imagine parallel forces of values A, B, C, etc., to act thru a, b, c, etc., and find the line of action of their resultant; repeat the operation for the parallel forces at an angle (as 90°) with their first positions. The intersection of the resultants is the center of gravity sought. (2) Choose any point O (Fig. 89) in the plane of the centers of gravity as origin; measure Oa, Ob, Oc, etc., and form the products $A\overline{Oa}$, $B\overline{Ob}$, $C\overline{Oc}$, etc. Imagine forces whose values equal the products respectively, to act from O in the lines Oa, Ob, Oc, etc., and find their resultant R (Art. 16). The center of gravity sought, r, lies in the line of action of R at a distance from O equal to $R \div (A + B + C + \ldots)$.

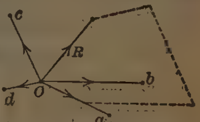

Fig. 89

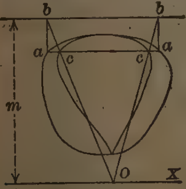

Fig. 90

The center of gravity of an irregular plane figure may be found by cutting out the figure from stiff paper and then determining the center of gravity of the paper experimentally by balancing (see below); this center of gravity gives that of the figure. Or, proceed as follows (Fig. 90): Take a point O and a line bb on opposite sides of the figure at any convenient distance m apart; project any width of the figure parallel to bb as aa on bb, connect the projections bb with O and note the intersections cc; determine other points cc and draw a smooth curve thru them as

shown; measure the area A' within the curve cc; then $A'm$ is the statical moment of the given figure with respect to OX; if A is the area of the given figure and y the distance of its center of gravity from OX, $y=A'm/A$. In a similar way the distance of the center of gravity from a line perpendicular to OX can be determined

Experimental Determination of center of gravity must be resorted to when the body is so irregular that the appropriate formulas foregoing cannot be applied. (1) Method of Suspension: The body is suspended from one point of it, and the direction of the suspending cord is then marked in some way on the body; the operation is repeated for another point of suspension. The center of gravity is at the intersection of the two lines or directions so fixt in the body. (2) Method of Balancing: The body is balanced on a straight-edge, and the vertical plane containing the edge is marked on the body; the operation is re-

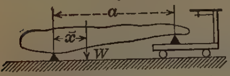

Fig. 91

peated for two more balancing positions of the body. The center of gravity is at the common point of the three planes so fixt in the body. This method is readily applied to a body in the form of a thin plane plate; practically only two balancings are necessary. (3) Method of Weighing: The weigh W of the body is determined, and then it is supported on a knife edg (Fig. 91) and on a point support which rests upon a platform scale; the re action R of the point support is weighed, the horizontal distance a of th point from the knife edge is measured; then the distance from center c gravity to knife edge $\bar{x}$ is Ra/W.

23. Centers of Gravity of Some Lines and Areas

Circular Arc (Fig. 92): the center of gravity is on the axis of symmetry its distance from the center is $\bar{x}=rc/s=r\sin\alpha/\alpha$, the last α being express in radians (1 degree=0.0175 radian). For a semicircle $\bar{x}=2r/\pi=0.6366\,r$; for a quadrant $\bar{x}=2r\sqrt{2}/\pi=0.9003\,r$, and the distance of the center of gravity from the radius drawn to either end of the arc is $2r/\pi=0.6366\,r$. For flat arcs, α small, the distance from its center of gravity to the chord c is closely equal to $2/3h$; the error is less than $1/2\%$ when $\alpha=30°$, and less than 1.1% when $\alpha=45°$.

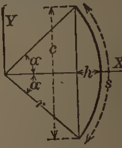

Fig. 92

Triangle: The center of gravity is at the intersections of the medians; its distance (perpendicular) from any side equals one-third the altitude of the triangle measured from that side. When x_1, x_2, x_3 are parallel distances from the vertexes to a plane, then the distance of the center of gravity is $1/3\,(x_1+x_2+x_3)$.

Trapezoid; Let a and b be the parallel bases and h the altitude. For t left-hand diagram in Fig. 92½, where m is the overhang of the right side, t horizontal distance of the center gravity from the left corner is $\bar{x}=2/3b$ $1/3m-1/3a\,(a-m)/(a+b)$. For the rig diagram the same formula applies if is taken as negative. For all cases t distance of the center of gravity abo the base b is $\bar{y}=1/3h\,(b+2a)/(a+$ When a equals b, then $x=1/2\,(b\pm m)$ a $\bar{y}=1/2h$. Geometric determinations

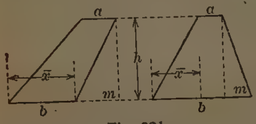

Fig. 92½.

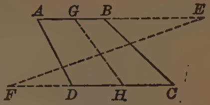
center of gravity: (1) Extend AB (Fig. 93) so that $BE=CD$, and in the o posite direction extend CD so that $DF=AB$; the intersection of FE and median GH is the center of gravity. (2) Divide the trapezoid (Fig. 93) i

triangles by a diagonal as AC; find the centers of gravity G_1 and G_2 of the triangles (construction indicated in the figure); the intersection of G_1G_2 with the median EF is the center of gravity sought.



Quadrilateral: (a) Divide the quadrilateral into triangles by a diagonal AC (Fig. 94) and find their centers of gravity G_1 and G_2; divide it into triangles by the other diagonal and find their centers of gravity G_3 and G_4; the intersections of the lines G_1G_2 and G_3G_4 is the center of gravity sought. (b) Divide the sides into thirds (Fig. 96) and draw lines thru the third points as shown; these lines form a parallelogram whose diagonals intersect at the center of gravity of the quadrilateral.

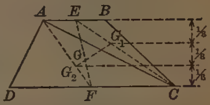


Fig. 93

Circular Sector (Fig. 95a). The center of gravity is on the axis of symmetry at a distance from the center equal to $\bar{x} = \frac{2}{3} rc/s = \frac{2}{3} r \sin\alpha/\alpha$, the last α being exprest in radians (1 degree = 0.0175 radian). For a semicircle $\bar{x} = 4r/3\pi = 0.4244\,r$. For a quadrant $\bar{x} = 4\sqrt{2}\,r/3\pi = 0.6002\,r$, and distance of the center of gravity from each bounding radius is $4r/3\pi = 0.4244\,r$.

Circular Segment (Fig. 95b). The center of gravity is on the axis of symmetry at a distance from the center equal to $\bar{x} = c^3/12A = (2r^3\sin^3\alpha)/3A$, in which A is the area of the segment, or $\frac{1}{2}r^2(2\alpha - \sin 2\alpha)$, the first α being exprest in radians (1 degree = 0.0175 radian).

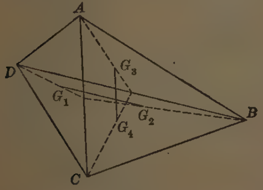

Fig. 94

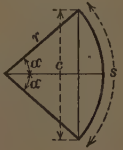

Fig. 95a

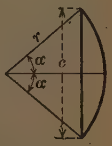

Fig. 95b

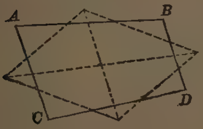

Fig. 96

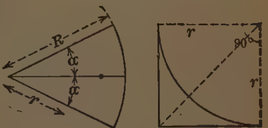

Fig. 97

Sector of a Circular Ring (Fig. 97). The center of gravity is on the axis of symmetry at a distance from the center of the circle which is given by $\bar{x} = \frac{2}{3}(R^3 - r^3)\sin\alpha/(R^2 - r^2)\,\alpha$, the last α being in radians.

The Surface (Fig. 97) bounded by a circular quadrant and the tangents at its extremities. The center of gravity is on the axis of symmetry at a distance from each tangent equal to $0.223\,r$.

Parabolic Segment (Fig. 98): G_1 and G_2 are the centers of gravity of $OXCO$ and $OYCO$ respectively: $x_2 = 3/5\,a$, $y_1 = 3/8\,b$, $x_1 = 3/10\,a$, $y_2 = 3/4\,b$.

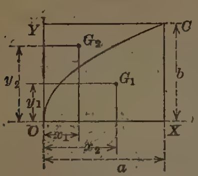

Fig. 98

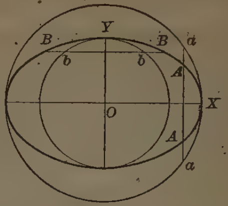

Fig. 99

Symmetric Elliptic Segment (Fig. 99). The center of gravity of $YBBY$ coincides with that of the circular segment $YbbY$, and the center of gravity of $XAAX$ coincides with that of the circular segment $XaaX$.

24. Centers of Gravity of some Volumes

Right Circular Cylinder (Fig. 100). The base XOA is normal to the axis of the cylinder, and the top makes an angle α with the base; the radius of the base is r and the mean height is h; then

$$\bar{x} = (r^2 \tan \alpha)/4\,h;\ \bar{y} = \tfrac{1}{2}\,h + (r^2 \tan^2 \alpha)/8\,h.$$

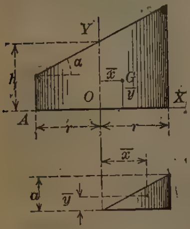

Fig. 100

If the oblique top cuts the base in a diameter, $\bar{x} = 3/16\,\pi r$, and $\bar{y} = 3/32\,\pi a$.

Cone and Pyramid. The center of gravity of the surface (not including base) is on a line joining the apex with the center of gravity of the perimeter of the base at a distance two-thirds the length of that line from the apex. The center of gravity of the solid cone or pyramid is on the line joining the apex with center of gravity of the base three-fourths the length from the apex.

Frustum of a Circular Cone. Let R = radius larger base, r = radius smaller, a = altitude; then distance of center of gravity of the conical surface from larger base is $\tfrac{1}{3}\,a(R + 2\,r)/(R + r)$, from smaller base $\tfrac{1}{3}\,a(2\,R + r)/(R + r)$, from a plane midway between bases $\tfrac{1}{6}\,a\,(R - r)/(R + r)$. The distance from the center of gravity of the solid frustum to the larger base is $\tfrac{1}{4}\,a\,(R^2 + 2\,Rr + 3\,r^2)/(R^2 + Rr + r^2)$.

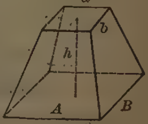

Fig. 101

Frustum of a Pyramid. If the pyramid has regular bases, let R and r be the lengths of sides of the larger and smaller bases, and h the altitude; then the distance from the center of gravity of the surface (not including bases) from the larger base is $\tfrac{1}{3}\,h\,(R + 2\,r)/(R + r)$. If A and a are the areas of the large and small bases of the frustum of any pyramid and h the altitude, the distance from the center of gravity of the solid from the larger base is $\tfrac{1}{4}\,h\,\left(A + 2\sqrt{Aa} + 3\,a\right)/\left(A + \sqrt{Aa} + a\right)$.

Obelisk and Wedge (Fig. 101). The distances from the center of gravity to the base AB is $\tfrac{1}{2}\,h\,(AB + Ab + aB + 3\,ab)/(2\,AB + Ab + aB + 2\,ab)$. If

$b = 0$; the solid is a wedge, and the distance from the center of gravity to the base is $\frac{1}{3} h (A + a)/(2A + a)$.

Sphere Parts. The center of gravity of any zone (surface) (Fig. 102) of a sphere is midway between the bases. Segment (solid): height h (Fig. 103),

Fig. 102

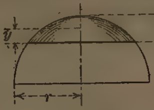

Fig. 103

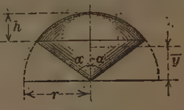

Fig. 104

$\bar{y} = \frac{1}{4} h (4r - h)/(3r - h)$; when $h = r$ (hemisphere), $\bar{y} = \frac{3}{8} r$. Sector (Fig. 104): $\bar{y} = \frac{3}{8} (1 + \cos \alpha)\, r = \frac{3}{8} (2r - h)$.

Ellipsoid. Let the three axes be taken as x, y, and z coordinate axes, and a, b, and c denote the semi-lengths of the corresponding axes of the ellipsoid; the center of gravity of one octant of the solid is given by $\bar{x} = \frac{3}{8} a$, $\bar{y} = \frac{3}{8} b$, and $\bar{z} = \frac{3}{8} c$.

Paraboloid of Revolution formed by revolving a parabola about its axis. Let h = height of the paraboloid, the distance from its apex to the base; then the distance from the center of gravity of the solid to the base is $\frac{1}{3} h$.

25. Principles of Moment of Inertia

Definitions. The MOMENT OF INERTIA of a surface (figure or area) with respect to or about a line is the sum of the products obtained by multiplying the area of each element of the surface by the square of its distance from the line. Thus, if I denotes moment of inertia, A area and r distance of any element dA from the line or axes with respect to which I is taken, then $I = \int r^2\, dA$; the limits of integration are to be so chosen that the integration will include all products like $r^2\, dA$ for the surface. The moment of inertia, obviously, of any surface or figure is the sum of the moments of inertia of its parts. The moment of inertia of a plane figure with respect to a line in the plane is called rectangular, and one with respect to a line perpendicular to the plane is called polar; these are the only moments of inertia of surfaces that are of practical importance A unit moment of inertia is four "dimensions" in length, and is called quadric inch, foot, etc., according as the inch or foot is used as unit length; the corresponding abbreviations are in^4, ft^4, etc. The RADIUS OF GYRATION of a surface (figure or area) with respect to a line is such a length whose square multiplied by the area of the surface equals the moment of inertia of the surface with respect to the same line. Thus if k denotes radius of gyration, A area, and I moment of inertia, $k^2 A = I$, or $k = \sqrt{I/A}$. The square of the radius of gyration of a figure with respect to a line is the mean of the squares of the distances of all the elementary parts of the figure from the line. (See also Art 27.)

The Product of Inertia of a plane surface (figure or area) with respect to a pair of coordinate axes in the plane is the sum of the products obtained by multiplying the area of each element of the surface by its coordinates. Thus if J denotes product of inertia with respect to x and y axes, A area, and x and y the coordinates of any element-area dA, then $J = \int xy\, dA$; the limits of integration are to be so chosen that the integration will include all products like $xy\, dA$ for the surface. A unit product of inertia, like a unit moment of inertia (see foregoing), is four dimensions in length. Unlike moments of inertia, prod-

ucts of inertia may be zero or negativ as well as positiv. If a figure has an axis of symmetry, then its product of inertia with respect to that axis and one perpendicular thereto is zero.

Graphic Determination of Moment of Inertia. When the outline of a surface is so irregular that the integration in the expression for I cannot be performed, then the following may be resorted to: Let $aaaa$ (Fig. 105) be the outline and XX' the axis with respect to which the moment of inertia is desired; at any convenient distance m from XX' draw two parallels (but if XX' does not cut the figure, then only one parallel, the one on the opposite side of the figure from XX'); draw any line as aa parallel to XX' and project the points aa on the nearer parallel; join the projections bb to any point O in XX' and note the intersections cc on aa; project cc on the same parallel; join the projections dd with O and note the intersections ee on aa. In a similar manner determine points like ee for other widths like aa, and connect all points e as shown. Then measure the area of the loops OPO and OQO; denoting this combined area by A'', $I = A''m^2$. (There will be only one loop if only one parallel, bb, is used.)

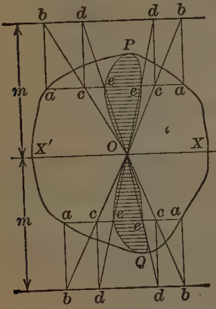

Fig. 105

Transformation Formulas. (1) Let I = moment of inertia of a figure with respect to any line or axis, $\bar{I}$ = that with respect to a parallel axis passing thru the center of gravity of the figure; d = distance between the axes, k and $\bar{k}$ = the radii of gyration with respect to the same axes respectively, and A = area of the figure; then

$$I = \bar{I} + Ad^2 \quad \text{and} \quad k^2 = \bar{k}^2 + d^2$$

These show that with respect to all parallel axes the moment of inertia and the radius of gyration is least for the one passing thru the center of gravity of the figure. (2) Let I_x, I_y, and I_z = the moments of inertia of a plane figure with respect to x, y, and z axes respectively, the axes being at right angles to each other and the x and y axes in the plane; and let k_x, k_y, and k_z = the corresponding radii of gyration; then

$$I_x + I_y = I_z \qquad k_x^2 + k_y^2 = k_z^2$$

(3) Let J = the product of inertia of a plane figure with respect to a pair of coordinate axes in the plane, and $\bar{J}$ = that with respect to a parallel pair whose origin is at the center of gravity; $\bar{x}$, $\bar{y}$ the coordinates of the center of gravity referred to first pair, and A the area of the figure; then $J = \bar{J} + A\bar{x}\bar{y}$. (4) Let XOY and UOV (Fig. 106) be two sets of rectangular coordinate axes with a common origin and in a given plane figure; I_x, I_y, I_u, I_v = moments of inertia of the figure with respect to x, y, u, and v axes respectively; J_{xy} and J_{uv} = its products of inertia with respect to the sets of axes respectively; α = the angle thru which the x axis must be rotated to bring it into the u axis, regarded as positiv or negativ according as the turning is counter-clockwise or clockwise. Then $I_u + I_v = I_x + I_y$, and

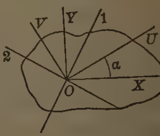

Fig. 106

$$I_u = I_x \cos^2\alpha + I_y \sin^2\alpha - J_{xy} \sin 2\alpha$$
$$J_{uv} = \tfrac{1}{2}(I_x - I_y) \sin 2\alpha + J_{xy} \cos 2\alpha.$$

Principal Axes of Inertia. In general, the moments of inertia of a plane figure with respect to different lines thru any point of the plane are unlike; for one axis the moment is greater and for another less than for any other axis thru the point. The principal axes for a plane figure at a particular point of the plane are the two axes for which the moments of inertia are greater and less than for any other axis thru the point and in the plane; the corresponding moments of inertia are called the PRINCIPAL MOMENTS OF INERTIA of the figure at the point. The principal axes are always at right angles to each other.

With respect to the principal axes, the product of inertia is zero; from this principle the principal axes can readily be found in some cases. Thus, at a corner of a square the principal axes are the diagonal thru that corner and a line perpendicular to it, for with respect to those lines the product of inertia of the square is zero (see under Product of Inertia). In any case, the principal axes of a figure at a point of it can be found from the following formula if the moments of inertia and the product of inertia of the figure with respect to two rectangular axes thru the point and in the plane are known; thus let the two rectangular axes be OX and OY (Fig. 106), I_x, I_y the corresponding moments of inertia, J_{xy} the corresponding product of inertia, and θ the (unknown) angle thru which OX must be turned counter-clockwise to bring it into either principal axis, $O1$ or $O2$; then $\tan 2\theta = 2\,J_{xy}/(I_y - I_x)$, which gives always two values of θ differing by 90° unless J_{xy} and $I_y - I_x$ are both zero. In that case the figure has no principal axis at the point, and the moments of inertia with respect to the different lines thru the point are all equal.

The Principal Moments of Inertia I_1 and I_2 can be computed from

$$I_1 = I_x \cos^2\theta_1 + I_y \sin^2\theta_1 - J_{xy}\sin 2\theta_1,$$

and

$$I_2 = I_x \cos^2\theta_2 + I_y \sin^2\theta_2 - J_{xy}\sin 2\theta_2$$

θ_1 and θ_2 being the two values of θ given by the formula above for principal axes. Or, after I_1 is determined, $I_2 = I_x + I_y - I_1$.

The Inertia-Circle and Ellipse. The inertia-circle is a device for determining the moment of inertia of a plane figure with respect to any line of the plane and the principal axes and principal moments of inertia at any point graphically. To construct the circle, it is necessary to know the moments of inertia and the product of inertia with respect to two rectangular axes thru the point and in the plane figure. Thus if I_u and I_1 and I_2 at O (Fig. 107) are desired, I_x, I_y, and J_{xy} being known: By any scale, lay off $OX = I_x$, $OY = I_y$ and $YA = J_{xy}$, upwards or downwards from XY according as J_{xy} is positiv or negativ; bisect XY and from the middle point C as center describe a circle passing thru A; this is the inertia-circle for the axes xOy. Draw a secant thru A parallel to the u axis, and from its intersection B with the circle draw a perpendicular BU to XY; then $OU = I_u$, by the scale used, (and $BU = J_{uv}$). Lines thru O parallel to AP and AQ are the principal axes at O; and OP and OQ represent the corresponding principal moments of inertia respectively by the scale used.

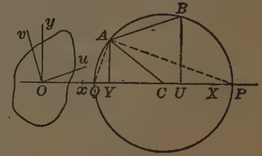

Fig. 107

The inertia-ellipse like the inertia-circle shows the relations between the moments of inertia of a plane figure for different axes thru a point of the plane; for qualitative results the ellipse is preferable, generally, but for quantitative results, the circle. The inertia-ellipse for a plane surface at any particular point has its center at the point and is

so drawn that the distance from any diameter to either parallel tangent equals the radius of gyration of the figure with respect to that diameter. An inertia-ellipse of a figure at its center of gravity is the central inertia-ellipse. In general, the ellipse is determined most readily thus: determine the principal axes at the point in question and the corresponding principal radii of gyration; from the point lay off on each axis in each direction distances equal (by some scale) to the radius of gyration with respect to the other axis; construct the ellipse on those two lengths as axes (Art. 11).

26. Moments of Inertia of Some Plane Figures

Rectangle. Let b = base and h = altitude; about a line thru center parallel to b, $I = \frac{1}{12}bh^3$; about a line thru the center parallel to h, $I = \frac{1}{12}hb^3$; about side b, $I = \frac{1}{3}bh^3$; about side h, $I = \frac{1}{3}hb^3$; about a diagonal $I = \frac{1}{6}b^3h^3/(b^2+h^2)$; about a line thru the center perpendicular to the diagonal $I = \frac{1}{12}(bh^3+hb^3)$.

Square. Make $b = h$ in foregoing. The moment of inertia is $\frac{1}{12}h^4$ for all axes in the plane of the square and passing thru the center.

Hollow Rectangle. Let B and b = outer and inner breadths, and D and d = outer and inner depths; about an axis parallel to B and b and passing thru the center $I = \frac{1}{12}(BD^3 - bd^3)$.

Triangle. Let b = base and h = altitude; about the base $I = \frac{1}{12}bh^3$; about a line thru the center of gravity parallel to the base $I = \frac{1}{36}bh^3$; about a line thru the vertex parallel to the base $I = \frac{1}{4}bh^3$.

Regular Polygon. Let A = area, R = radius of circumscribed circle, r = radius of inscribed circle, and s = length of a side; about any axis thru the center and in the plane of the polygon $I = \frac{1}{24}A(6R^2 - s^2) = \frac{1}{48}A(12r^2 + s^2)$; about a line perpendicular to the plane of the polygon passing thru the center I = double the preceding I.

Trapezoid. Let B = long base, b = short base, h = altitude; about the long base $I = \frac{1}{12}(B + 3b)h^3$; about the short base $I = \frac{1}{12}(3B + b)h^3$; about a line thru center of gravity and parallel to bases $I = \frac{1}{36}(B^2 + 4Bb + b^2)h^3/(B+b)$.

Circle. Let d = diameter and r = radius; about a diameter $I = \frac{1}{64}\pi d^4 = \frac{1}{4}\pi r^4$, and $k^2 = \frac{1}{16}d^2 = \frac{1}{4}r^2$; about a line thru the center and perpendicular to the circle $I = \frac{1}{32}\pi d^4 = \frac{1}{2}\pi r^4$, and $k^2 = \frac{1}{8}d^2 = \frac{1}{2}r^2$.

Semicircle. Let d = diameter and r = radius; about the bounding diameter or about the line of symmetry $I = \frac{1}{128}\pi d^4 = \frac{1}{8}\pi r^4$; about a line thru the center of gravity parallel to the bounding diameter $I = (9\pi^2 - 64)d^4/1152\pi = 0.00686\,d^4 = 0.110\,r^4$.

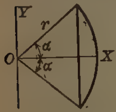

Fig. 108

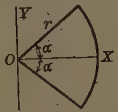

Fig. 109

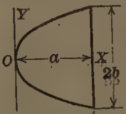

Fig. 110

Hollow Circle. Let D and d = outer and inner diameters, and R and r = outer and inner radii; about a diameter $I = \frac{1}{64}\pi(D^4 - d^4) = \frac{1}{4}\pi(R^4 - r^4)$, and $k^2 = \frac{1}{16}(D^2 + d^2) = \frac{1}{4}(R^2 + r^2)$; about a line thru the center and normal to circle $I = \frac{1}{32}\pi(D^4 - d^4) = \frac{1}{2}\pi(R^4 - r^4)$, and $k^2 = \frac{1}{8}(D^2 + d^2) = \frac{1}{2}(R^2 + r^2)$.

Circular Segment (Fig. 108). Let A = area of the segment;

$$I_x = \tfrac{1}{4}Ar^2[1 - \tfrac{2}{3}(\sin^3\alpha\cos\alpha)/(\alpha - \sin\alpha\cos\alpha)],$$
$$I_y = \tfrac{1}{4}Ar^2[1 + (2\sin^3\alpha\cos\alpha)/(\alpha - \sin\alpha\cos\alpha)].$$

Circular Sector (Fig. 109). Let A = area of the sector; $I_x = \frac{1}{4}Ar^2(1 - \sin\alpha\cos\alpha/\alpha)$, $I_y = \frac{1}{4}Ar^2(1 + \sin\alpha\cos\alpha/\alpha)$; with respect to a line thru O perpendicular to the sector, $I = \frac{1}{2}Ar^2$.

Parabolic Segment (Fig. 110). $I_x = \frac{4}{15} ab^3$, $I_y = \frac{4}{7} ba^3$.

Ellipse. Let $2a$ and $2b$ = lengths of the axes of the ellipse; about the $2a$ axis $I = \frac{1}{4}\pi ab^3$; about the $2b$ axis $I = \frac{1}{4}\pi ba^3$; about a line thru the center and perpendicular to the ellipse $I = \frac{1}{4}\pi ab(a^2 + b^2)$.

27. Moment of Inertia of Bodies

Definitions. The MOMENT OF INERTIA OF A BODY with respect to or about a line is the sum of the products obtained by multiplying the mass of each elementary part by the square of its distance from the line. Thus I denoting moment of inertia, m mass, and p the distance of any element dm from the line of reference, $I = \int p^2\,dm$. The moment of inertia of a body is, obviously, the sum of the moments of inertia of its parts. A unit moment of inertia of a body is one dimension in mass and two in length. The CENTER OF GYRATION of a body with respect to a line is a point at such a distance from the line that if the entire mass of the body were concentrated there, the moment of inertia of the mass-point would be the same as that of the body; the distance of the center of gyration from the line is the radius of gyration with respect to the line. Thus k denoting radius of gyration, $k^2m = I$, or $k = \sqrt{I/m}$. The PRODUCT OF INERTIA of a body with respect to two coordinate planes is the sum of the products obtained by multiplying the mass of each element of the body by the two coordinates of the element with reference to those planes. Thus with respect to YOZ and ZOX (Fig. 111), ZOX and XOY, and XOY and YOZ planes, the products of inertia are respectively $\int xy\,dm$, $\int yz\,dm$, and $\int zx\,dm$. A unit product of inertia is, like a unit moment of inertia, one dimension in mass and two in length. Unlike moments, products of inertia may be zero or negativ as well as positiv.

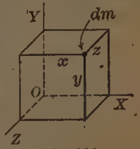

Fig. 111

Transformation Formulas. (1) If I denotes the moment of inertia of a body with respect to any line or axis, $\bar{I}$ that with respect to a parallel line thru the center of gravity, d the distance between the axes, and m the mass of the body, then

$$I = \bar{I} + md^2; \quad \text{also} \quad k^2 = \bar{k}^2 + d^2$$

k and $\bar{k}$ denoting radii of gyration corresponding to the axes named respectively. (2) Let I_x, I_y, and I_z denote the moments of inertia of a body with respect to rectangular axes x, y, and z respectively; J_{xy}, J_{yz}, and J_{zx} its products of inertia with respect to yz and zx planes, zx and xy planes, and xy and yz planes respectively; I the moment of inertia of the body with respect to a line thru the origin of coordinates having direction-angles α, β, and γ; then

$$I = I_x \cos^2\alpha + I_y \cos^2\beta + I_z \cos^2\gamma - 2\,J_{yz}\cos\beta\cos\gamma - 2\,J_{zx}\cos\gamma\cos\alpha - 2\,J_{xy}\cos\alpha\cos\beta$$

Principal Axes and Moments of Inertia. The values of the moments of inertia of a body for all axes thru a given point are in general unequal; for one axis the moment of inertia is greater and for another it is less than for any other axis thru the point. These two axes are at right angles, and they together with one at right angles to their plane and passing thru the point are the principal axes of the body at the point; the corresponding moments of inertia are the principal moments of inertia of the body at the point. If

the point is the center of gravity of the body, then the axes and moments are called central principal axes and central principal moments of inertia.

If $J_{xy} = J_{yz} = 0$, the y axis is a principal axis at the origin,
If $J_{yz} = J_{zx} = 0$, the z axis is a principal axis at the origin,
if $J_{zx} = J_{xy} = 0$, the x axis is a principal axis at the origin.

If a body has a plane of symmetry, then any perpendicular to the plane is a principal axis of the body at the point where the line pierces the plane. If a body has two planes of symmetry at right angles to each other, then their intersection is a principal axis at any point of the intersection, the other two being in the planes of symmetry. If a body has three planes of symmetry their lines of intersection are the central principal axes of the body.

Special Cases. The bodies are supposed to be homogeneous; m = the mass of the body in each instance and δ = its density, that is its mass per unit of volume. In any system, like the C.G.S. or Engineers' (see Art. 29), $m = W/g$ and $\delta = w/g$; wherein W denotes the weight of the body, w its weight per unit volume, and g the acceleration of a freely falling body.

Straight Rod. Let l = its length; about a line making an angle α with the axis of the rod and passing thru its center of gravity $I = \frac{1}{12} ml^2 \sin^2 \alpha$; about a line thru one end of the rod $I = \frac{1}{3} ml^2 \sin^2 \alpha$.

Rod Bent into a Circular Arc (Fig. 112). $I_x = \frac{1}{2} mr^2 [1 - (\sin \alpha \cos \alpha)/\alpha]$; $I_y = \frac{1}{2} mr^2 [1 + (\sin \alpha \cos \alpha)/\alpha]$; about a line perpendicular to the plane of the arc and thru the center of the circle, $I = mr^2$.

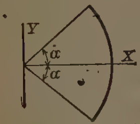

Fig. 112

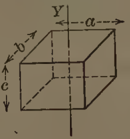

Fig. 113

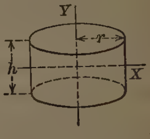

Fig. 114

Right Prism. Let h = its altitude and A = area of base; about any lin perpendicular to the bases, $I = \delta h \times$ moment of inertia of a base about th same line; about a line thru its center of gravity and perpendicular to th axis of the prism $I = \frac{1}{12} \delta A h^3 + \delta h \times$ the moment of inertia of the central cros section about the line.

Right Parallelopiped (Fig. 113). $I_y = \frac{1}{12} m (a^2 + b^2) = \frac{1}{12} abc\delta (a^2 + b^2)$; th y axis passes thru the center of gravity and is parallel to the edge c.

Right Circular Cylinder (Fig. 114). $I_y = \frac{1}{2} mr^2 = \frac{1}{2} \pi r^4 h\delta$; $I_x = \frac{1}{12}$ $(3r^2 + h^2) = \frac{1}{12} \pi r^2 h\delta (3r^2 + h^2)$. The y axis is the axis of the cylinder, and tl x axis is perpendicular to it and passes thru the center of gravity.

Hollow Right Circular Cylinder. Let R and r be the outer and inn radii, and axes taken as in Fig. 114. $I_y = \frac{1}{2} m (R^2 + r^2) = \frac{1}{2} \pi h\delta (R^4 - r$ $I_x = \frac{1}{4} m (R^2 + r^2 + \frac{1}{3} h^2) = \frac{1}{4} \pi (R^2 - r^2) h\delta (R^2 + r^2 + \frac{1}{3} h^2)$.

Right Rectangular Pyramid (Fig. 115). $I_y = \frac{1}{20} m (a^2 + b^2) = \frac{1}{60} abh\delta (a^2$ $b^2)$ and $I_x = \frac{1}{20} m (\frac{3}{4} h^2 + b^2) = \frac{1}{60} abh\delta (\frac{3}{4} h^2 + b^2)$; the y is the axis of the pyı mid, and the x axis passes thru the center of gravity and is parallel to side a

Right Circular Cone (Fig. 116). $I_y = \frac{3}{10} mr^2 = \frac{1}{10} \pi r^4 h\delta$, $I_x = \frac{3}{20} m (r^2$ $\frac{1}{4} h^2) = \frac{1}{20} \pi r^2 h\delta (r^2 + \frac{1}{4} h^2)$, $I_z = \frac{3}{20} m (r^2 + 4 h^2)$; the y is the axis of the co the x is parallel to the base and passes thru the center of gravity, and z is parallel to the base and passes thru the apex.

Frustum of a Cone. Let R and r = radii of larger and smaller bases, h = altitude; about the axis of the frustum $I = \frac{3}{10} m (R^5 - r^5)/(R^3 - r^3) = \frac{1}{10} \pi h \delta (R^5 - r^5)/(R - r)$.

Sphere. Let r = its radius; about any diameter $I = \frac{2}{5} mr^2 = \frac{8}{15} \pi r^5 \delta$.

Hollow Sphere. Let R and r = the outer and inner radii; about any diameter $I = \frac{2}{5} m (R^5 - r^5)/(R^3 - r^3) = \frac{8}{15} \pi \delta (R^5 - r^5)$.

Ellipsoid. Let $2a$, $2b$, and $2c$ = the lengths of the axes; about the axis $2c$, $I = \frac{1}{5} m (a^2 + b^2) = \frac{4}{15} \pi abc\delta (a^2 + b^2)$.

Paraboloid generated by revolving a parabola about its axis. Let h = its height and r = radius of base; about the axis of revolution $I = \frac{1}{3} mr^2 = \frac{1}{6} \pi h r^4 \delta$.

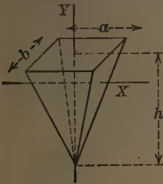

Fig. 115

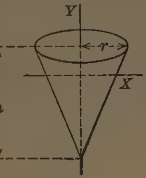

Fig. 116

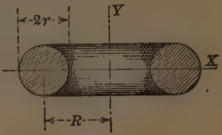

Fig. 117

Ring (Fig. 117). $I_y = m (R^2 + \frac{3}{4} r^2) = \frac{1}{2} \pi^2 R r^2 (4 R^2 + 3 r^2) \delta$, $I_x = m (\frac{1}{2} R^2 + \frac{5}{8} r^2) = \pi^2 R r^2 (R^2 + \frac{5}{4} r^2) \delta$; both axes, x and y, pass thru the center of gravity as shown.

DYNAMICS

28 Dynamical Quantities

Weight and Mass. In common parlance the word weight is used in at least two senses: thus a body is said to be heavy, its weight is 500 pounds, etc., the reference being to the earth-pull or gravity on the body; also a cask is said to contain much sugar, its weight is 500 pounds, etc., the reference here being to quantity of material, matter or stuff of a certain kind (sugar). Doubtless the legal definitions of our standards of weight imply the second sense, since they were framed primarily to standardize weight measures of commodities made in trade. For the sake of clearness, many writers restrict the use of the word weight to one meaning, namely the first, that is earth-pull; and to denote the second, quantity of substance, they employ the term mass. This usage is employed in the present chapter.

Force has been previously defined (Art. 15). Every so-called practical unit of force is a force equal to the earth-pull on a standard of mass, and the name given to such unit force is the same as the name given to the standard or unit of mass. Thus, a force equal to the weight or gravity of a pound mass is a unit of force, and that unit is called a pound force; a force equal to the weight or gravity of a kilogram mass is a unit of force and is called a kilogram force, etc. These units are called gravitational units.

Some writers seeking to make gravitational units of force absolute specify that the pound force, for example, is the weight or gravity of the pound mass at London or at sea level 45° latitude. However, the actual pound forces used in different places are the earth-pulls on pound masses at those places, and hence gravitation units of force as used are not absolute; the magnitudes of the units for two places are as the values of g for those places. To make the unit force absolute and to simplify certain dynamical equations, units of force have been proposed based on the following: In any system of dynamical units the

unit force is one which applied to the unit mass of that system produces the unit acceleration of that system. Thus in the C.G.S. system the unit of force is that force which applied to a gram mass gives it an acceleration of one cm per sec per sec; this unit is called dyne. And, in the F.P.(mass) S. system (never widely used, and now losing favor), the unit is the force which applied to the pound mass gives it an acceleration of one ft per sec per sec; it is called poundal.

Work. When the point of application of a force moves, so that the force has a component along the displacement of its application point, the force is said to do work; also the body exerting the force is said to do work. If the force is constant in magnitude and in direction and the displacement is straight, then the magnitude of the work is the product of the component of the force along the displacement and the displacement; if this component is in the direction of the displacemen the work is regarded as positiv; if opposite, the work is negativ. Thus in the displacements of the body C (Fig. 118) from A to B, the works of the several forces are respectively $+F_1s$, $-F_2s$, $+F_3 \cos \theta \cdot s$, $-F_4 \cos \phi \cdot s$, and o. If the force varies in magnitude or direction, or if the displacement of its application point is curved, the work must in general be computed by an integration; the general expression for work in

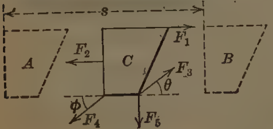

Fig. 118

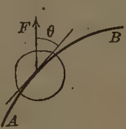

Fig. 119

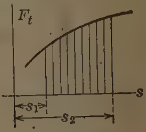

Fig. 120

this case is $\int F \cos \theta \cdot ds$, in which F denotes the force, ds elementary part of the displacement, and θ the angle between F and the direction of the elementary displacement (Fig. 119); the limits of integration must be assigned so as to include the entire displacement A to B. $F \cos \theta$ is the component of F along the tangent to the curve of displacement; denoting this component by F_t, the work is also given by $\int F_t ds$. The work can also be regarded as the product of the force and the component of the displacement along the action line of the force; this component is called the distance thru which the force acts, and so work is also said to equal force times distance thru which it acts. The work done by a force can be represented by a work diagram, which is constructed by plotting a line showing how the component of the force along the displacement F_t varies with the displacement (Fig. 120). The area included between the curve, the displacement axis, and two ordinates represents the work done by the force during the corresponding displacement $s_2 - s_1$. This diagram suggests also that the work done by a force equals the product of the average value of the tangential or working component and the displacement.

The Unit of Work depends on the units used for force and distance; thus, there are the foot-pound, the foot-ton, the dyne-centimeter (for which there is a special name, erg), etc. The joule is a practical electrical unit of work and equals 10 000 000 ergs; also the kilogrammeter, equal to 100 000 ergs. Work is also exprest in horse-power-hours, watt-hours, etc.; the horse-power-hour is the amount of work done in one hour at the rate of one horse-power, and the watt-hour is the amount of work done in one hour at the rate of one watt.

Power. By power of a force or agent doing work is meant the time-rate at which the work is done. Some units of power: foot-pound per second;

dyne-centimeter (or erg) per second; horse-power (abbreviated h.p.) = 550 foot-pounds per second, or 33 000 foot-pounds per minute; watt = one joule (10 000 000 ergs) per second; kilowatt = 1000 watts; the metric or French horse-power = 75 kilogram-meters per second.

1 ft-lb per sec = 0.13820 kg-m per sec	1 kg-m per sec = 7.233 ft-lb per sec
1 Engl. h.p. = 746 watts	1 kilowatt = 1.34 Engl. h.p.
1 Engl. h.p. = 1.0136 Fr. h.p.	1 Fr. h.p. = 0.9863 Engl. h.p.

Energy. When the condition or state of a body, or system, is such that it can do work, it is said to possess energy; and by its amount or store of energy is meant the amount of work which the body can do in passing to some standard state. Thus, a body in motion has energy, and the amount of its energy is the amount of work it can do in coming to rest; also a stretched spring has energy, and the amount of its energy is the amount of work which it can do in assuming its natural unstretched state. Energy is exprest in the same units as work, foot-pound, foot-ton, dyne-centimeter (erg), etc. Energy which a system has in virtue of its velocity is called kinetic energy. The KINETIC ENERGY of a particle of mass m moving with velocity v is $\frac{1}{2} mv^2$, and the kinetic energy of any body is the sum of the kinetic energies of its particles. In translation: kinetic energy = $\frac{1}{2} Mv^2 = \frac{1}{2} (W/g) v^2$, M denoting mass of the body, W its weight, v its velocity, and g acceleration of gravity; the last form gives energy in ft-lbs if W is exprest in lbs, v in ft per sec, and g is taken as 32.2. In rotation: kinetic energy = $\frac{1}{2} I\omega^2 = \frac{1}{2} Mk^2\omega^2 = \frac{1}{2} (W/g) k^2\omega^2 = (W/g) k^2 2\pi^2n^2$, I being the moment of inertia of the body with respect to the axis of rotation, k the corresponding radius of gyration, ω its angular velocity exprest in radians per unit time, W its weight, g the acceleration of gravity, and n the number of revolutions per unit time; the last form gives energy in ft-lbs if W is exprest in lbs, k in ft, n in revolutions per sec, and g is taken as 32.2. POTENTIAL ENERGY is that energy which a system has in virtue of its configuration. The earth and a body elevated above the earth's surface constitute a system having potential energy. Inasmuch as the energy can be withdrawn only from the elevated body it is said to possess the energy. The amount of potential energy possest by an elevated body (rigid or not) $= Wh$, W denoting the weight of the body and h the vertical distance thru which its center of gravity can descend.

Kinetic energy and potential energy are also called mechanical energy. There are other forms of energy which may not be mechanical, as thermal, chemical, and electrical. But the thermal energy of a body is generally regarded as due to the motions of the ultimate particle constituents of the body, thus being kinetic; much of chemical energy is regarded as due to the relative positions of ultimate particles, thus potential; the nature of electric energy is even less understood than that of chemical and thermal energy.

The Impulse of a force which remains constant in magnitude and direction for any time is the product of the magnitude of the force and the time. The unit of impulse depends on the units used to express the force and the time; thus there are the pound-second, dyne-second, etc. If the force F varies in magnitude but is constant in direction, then its impulse for the interval of time $t_2 - t_1$ is $\int_{t_1}^{t_2} F\,dt$. If the force varies in magnitude and in direction, its impulse can be computed from the impulses of its x, y, and z components; thus if F_x, F_y, and F_z denote these components of F, then the component impulses are $\int F_x\,dt$, $\int F_y\,dt$, and $\int F_z\,dt$, and the impulse of F equals the square root of the sum of the squares of the components. The angular impulse of a force about any line for an element of time is the product of the moment of the force about the line and the element of time,

that is, $M\,dt$, if M denotes the moment of the force; and the angular impulse for any interval of time $t_2 - t_1$ is $\int_{t_1}^{t_2} M\,dt$.

The Momentum of a particle is the product of its mass and velocity. The unit of momentum depends on the units of mass and velocity used; the dimensions of unit momentum are the same as those of unit impulse (see preceding). The momentum of a body is the resultant of the momentums of its particles. This resultant is not the scalar but the vector-sum of the momentums, that is, the resultant is to be computed as the resultant of a number of forces is, the separate momentums being regarded as having the directions of the velocities of the several particles and acting at the particles. In a translation the momentum is $Mv = (W/g)\,v$, M denoting the mass of the body, W its weight, v its velocity, and g the acceleration of gravity; the second form gives momentum in lb-sec if W is exprest in lbs, v in ft per sec, and g is taken as 32.2.

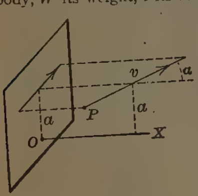

Fig. 121

The angular momentum of a particle about a line is the moment about that line of its momentum; thus, if the particle at P (Fig. 121) has a mass m and a velocity v, its momentum is mv acting in the line v and its angular momentum about OX is $(mv \sin \alpha)\,a$. The angular momentum of a body about a line is the algebraic sum of the angular momentums of its constituent particles. A rotating body has angular momentum about the axis of rotation equal to $I\omega = Mk^2\omega = (W/g)\,k^2\omega = (W/g)\,k^2\,2\pi n$, I denoting the moment of inertia of the body with respect to the axis, k its corresponding radius of gyration, W its weight, ω its angular velocity in radians per unit time and n in revolutions per unit time, and g the acceleration of gravity.

Dimensions of Units. All mechanical and nearly all physical units can be definec in terms of one or more of three units arbitrarily defined, that is, without reference tc other units. These three are fundamental units and the others derived units. Ir theoretical mechanics and physics the fundamental units chosen are those of length mass, and time; in applied mechanics, units of length, force, and time are generally more convenient. A statement of the way in which a derived unit depends on the fundamenta ones is a statement of the dimensions of the derived. Thus a unit of velocity depend on the units of length and time used, but is independent of the third fundamental unit and the magnitude of a unit of velocity varies directly as the unit of length and inversel as the unit of time used. Denoting the first set of fundamental units by L, M and T respectively, and the unit of velocity by V, the dimensional statement is written thus $V = L^1M^0T^{-1}$, and is called the dimensional formula for V.

The dimensional formulas may be used to test the accuracy of equations betwee mechanical quantities. Such an equation, if rationally and correctly deduced, is HOMOGENEOUS; that is, its terms are of the same kind. To ascertain whether terms are th same in kind, substitute for each quantity the dimensional formula for its unit, the treating the symbols L, M or F, and T as quantities, reduce each term; if the reduced term are alike, then the equation is correct dimensionally. Thus in the equation $24\,EIy$ $W(4l^3x - x^4)/l$, E denotes modulus of elasticity, I moment of inertia of an area, W a loa l, x, and y lengths, and the dimensional form is (dropping abstract members) $L^{-2}F^1L^4L^1$ $F(L^3L^1 - L^4)/L^1$, which reduces to $L^3F = L^3F - L^3F$, and so the original equation is corre dimensionally.

29. Dynamical Principles

Laws of Motion. (1) The normal state of the center of mass of a boc is one of rest or uniform rectilinear motion; a departure from this state due to force applied to the body. (2) When a single force acts upon a bod the center of mass sustains an acceleration in the direction of the force ar proportional to the force directly and to the mass of the body inversely;

several forces act on the body, the acceleration is given by the vector sum of the accelerations which would be produced by the forces acting singly. (By vector sum is meant the result reached by adding according to the parallelogram law.) (3) When one body exerts a force upon another the second also exerts one upon the other first, and the two forces are equal, colinear, and opposite. If F = force, m = mass, and a = acceleration, then the second law can be written $a \propto F/m$ or $a = kF/m$, k being a constant whose value depends on units used in F, m, and a. It is possible to make $k = 1$ by proper choice of units. Such choice was made in the so-called absolute systems of dynamical units; first units of length, mass, and time were selected and then as unit of F such a force which produces unit acceleration in unit mass. For example, in the C.G.S. system these units are respectively the centimeter, gram, second, and dyne, the latter about $\frac{1}{981}$ gram weight. The constant k may also be made unity in so-called gravitational systems; units of length, force, and time are first taken (that of force as the weight of something), and then the unit of m as that mass which sustains unit acceleration when acted on by unit force. For example, in the ENGINEERS' SYSTEM, these units are respectively foot, pound force, second, and the unit of m a mass equal to about 32.2 pounds. In any system in which $F = ma$, then also $m = W/g$, m and W being the mass and weight of the body and g the acceleration of gravity, all three quantities being exprest in units of that system.

Laws of Impulse and Momentum. When external forces act upon a body or collection of bodies they produce in general a change in the momentum of the body or collection. In any interval, the change in the component of the linear momentum along any line equals the algebraic sum of the components of the impulses of the forces along that line for the same time; and the change in any interval in the angular momentum about any line equals the algebraic sum of the angular impulses of the forces about that line for the same time. When no external forces are acting, the component linear momentum along any line and the angular momentum about any line remain constant; these are the principles of conservation of linear and angular momentum.

Principles of Work and Energy. In general, the kinetic energy of a body changes value during a change of its position or form, and the external and the internal forces acting on the body do work. The increment in the kinetic energy equals the sum total of work done by all the external and internal forces. In applying this principle, signs must be given to the works of the various forces as explained on p. 1480; then if the total work is positiv, the increment is positiv and there is a real gain in kinetic energy, and if negativ then there is a loss. If the body is a rigid one, the internal forces do no work in any displacement of the body, and the increment in kinetic energy equals the total work done by the external forces acting on the body. If a body or system of bodies is isolated so that it neither receives nor gives out energy, then its total store of energy, all forms included, remains constant; there may be a transfer of energy from one part of the system to another, but the total gain or loss in one part is exactly equivalent to the loss or gain in the remainder. This is the principle of conservation of energy.

30. Rectilinear Motion

Motion of a Point. The velocity of a moving point at any instant is the time-rate at which it is describing distance then; the symbol is v. In uniform motion (equal distances described in all equal intervals of time) the rate is constant and $v = \Delta s/\Delta t$, Δs denoting the distance described in the interval Δt. In non-uniform motion the rate varies, and $\Delta s/\Delta t$ is the average

velocity for the interval Δt; the actual velocity at any instant is the value of ds/dt for that instant. The acceleration of a point at any instant is the rate at which its velocity is changing then; the symbol is a. If v changes uniformly the rate is constant, and $a = \Delta v/\Delta t$, Δv denoting the velocity-change occurring in the interval Δt. If v does not change uniformly $\Delta v/\Delta t$ is the average acceleration for the interval Δt; the actual acceleration at any instant is the value of dv/dt for that instant. The general differential equations of rectilinear motion are $v = ds/dt$, $a = dv/dt = d^2s/dt^2$, $vdv = ads$; their integral forms are

$$s_2 - s_1 = \int_{t_1}^{t_2} v\,dt \qquad v_2 - v_1 = \int_{t_1}^{t_2} a\,dt \qquad v_2^2 - v_1^2 = \int_{s_1}^{s_2} a\,ds$$

in which s_1, v_1, and t_1 are corresponding or simultaneous values of s, v, and t, likewise s_2, v_2, and t_2.

Space-time, velocity-time, acceleration-time, velocity-space, acceleration-space curves respectively are graphs showing the relations between s and t, v and t, a and t, v and s, a and s (Figs. 122–126; they do not correspond to the same motion). (1) In the s-t diagram, the slope of the curve at any point represents the corresponding velocity. If AB

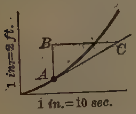

Fig. 122

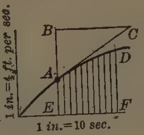

Fig. 123

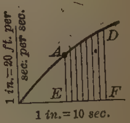

Fig. 124

and BC are measured by the s and t scales of the drawing respectively, then the slope equals the velocity; thus if $AB = 0.2$ in and $BC = 0.4$ in, $v = 0.4 \div 4 = 0.1$ ft per sec. (2) In the v-t diagram, the slopes represent the accelerations; if AB and BC are measured by the v and t scales respectively, then the slope equals the acceleration; thus if $AB = 0.3$ in and $BC = 0.5$ in, $a = 1.2 \div 5 = 0.24$ ft per sec per sec. The area included between any two ordinates (as AE and DF), the curve and the t axis represents the displacement of the moving point in the time EF. If the area is computed by multiplying its average ordinate measured by the velocity scale (thus giving the average velocity) by EF measured by the time scale, then the product equals the displacement; thus if the average ordinate is 0.35 in, and EF is 4 sec; the displacement $= 1.4 \times 4 = 5.6$ f

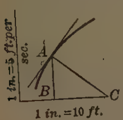

Fig. 125

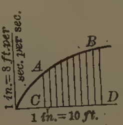

Fig. 126

(3) In the a-t diagram the slope represents the rate at which the acceleration is changing. The area included between any two ordinates (as AE and DF), the curve, and the t axis represents the velocity change in the time EF. Thus if the average ordinate is 0.3 in and EF is 2 sec then the velocity change $= (0.3 \times 20) \times 2 = 12$ ft per sec. (4) In the v-s diagram, the subnormals represent the accelerations. If the length of the subnormal is multiplied by the square of the velocity scale number and the product divided by the space scale number, the result will equal the acceleration; thus suppose that the subnormal $BC = 1/3$ inch, then $a = (1/3 \times 25) \div 10 = 0.83$ ft per sec per sec. (5) In the a-s diagram, the area included between two ordinates (as AC and BD), the curve, and the s axis represents the change in the velocity square. If the area is computed by multiplying the mean ordinate measured by the acceleration scale by CD measured by the space scale, the product equals the change in the velocity square; thus if the average ordinate $= 0.3$ in, and $CD = 0.4$, then the change $= 2.4 \times 4 = 9.$

Uniformly Accelerated Motion, constant acceleration. Let v_1 and v_2 denote the velocities at times t_1 and t_2, s_1 and s_2 the corresponding values of space, an

a = acceleration. Then the velocity change is $v_2 - v_1 = a(t_2 - t_1)$; the space traversed is $s_2 - s_1 = \frac{1}{2}(v_1 + v_2)(t_2 - t_1) = v_1(t_2 - t_1) + \frac{1}{2}a(t_2 - t_1)^2$; also $v_2^2 - v_1^2 = 2a(s_2 - s_1)$.

Falling Body. The acceleration due to gravity (denoted by g) is approximately 32.2 ft per sec per sec. It changes slightly with elevation above sea level and with latitude; denoting elevation in feet by e and latitude by ϕ, then in ft per sec per sec

$$g = 32.0894\,(1 + 0.0052375 \sin \phi)(1 - 0.0000000957\, e)$$

At the equator sea level $g = 32.0894$ and at the poles 32.254; the extreme values for the United States are roughly 32.19 (in latitude 49° sea level) and 32.09 (in latitude 25° and 10 000 ft above sea).

A body dropt without initial velocity falls in a vacuum according to the laws

$$v = gt \qquad h = \tfrac{1}{2}gt^2 \qquad v^2 = 2gh$$

wherein v = velocity and h the descent at the time t. A body projected downward in a vacuum with initial velocity v_1 moves according to

$$v = v_1 + gt; \qquad h = v_1t + \tfrac{1}{2}gt^2, \qquad v^2 = v_1^2 + 2gh.$$

These three formulas apply to upward projection if the sign + is changed to −; h then denotes ascent in the time t, after projection. The total ascent (to highest position) and the corresponding time are respectively $v_1^2/2g$ and v_1/g.

Simple Harmonic Motion. If a point moves in a circle with constant speed, then the motion of the projection of the point on any diameter of the circle is simply harmonic; other motions resembling this are also called simply harmonic. Simple harmonic motion may also be defined as any rectilinear motion in which the acceleration is always directed toward a fixt point in the path and is proportional to the distance between that and the moving point. Taking the first definition, let P (Fig. 127) be the point moving in the circle and regard the motion of its projection on the vertical diameter. The period is the time of one revolution of P, or one complete oscillation of Q; the frequency is the number of revolutions of P, or oscillations of Q, per unit time; the amplitude is half the length of the path of Q or the radius of the circle; the displacement at any time is the ordinate of Q from the center of the path; the phase is the angle at any time from OX to OP (thus when Q is at the top of its path the phase is 90°, when at the center going down, 180°, when at the lowest point, 270° or − 90°). If, in the description of a simple harmonic motion, time is reckoned from the instant when the phase angle is not zero, then that motion is said to have a lead or a lag according as the initial phase (angle) is between 0 and 180° or 0 and −180°, and the value of the angle is called lead or lag as the case may be. Let ε = lead or lag, t = time elapsed after starting (motion from P_0 to P), ω = angular velocity of OP; T = period, n = frequency, r = amplitude, y = displacement, v = velocity of Q and a = its acceleration. The following are the general relations between the quantities involved:

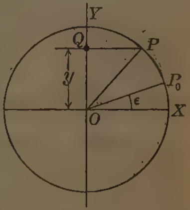

Fig. 127

$$n = 1/T \qquad \omega = 2\pi n = 2\pi/T \qquad y = r \sin(\omega t + \varepsilon)$$

$$v = \omega r \cos(\omega t + \varepsilon) = \omega\sqrt{r^2 - y^2} \qquad a = -\omega^2 r \sin(\omega t + \varepsilon) = -\omega^2 y$$

If the time is reckoned from the instant when Q is in its mid-position, $\epsilon = 0$. The three curves (Fig. 130) OA, $O'B$, OC are the space-time, velocity-time, and acceleration-time curves for one complete period of a simple harmonic motion; $\epsilon = 0$; Ot represents the period; the values of y, v, and a marked are for position Q shown. In Fig. 128 the curve is the

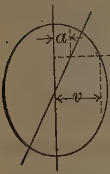

Fig. 128

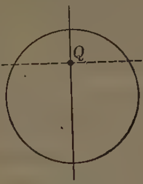

Fig. 129

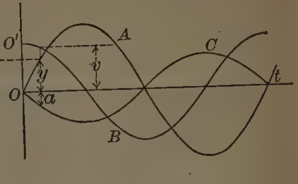

Fig. 130

velocity-space curve, and the inclined line the acceleration-space curve. They show how v and a vary with the displacement of the moving point; thus for the moving point Q v and a have values as marked.

Translation is a motion of a body such that the lines joining all pairs of points of the body remain fixt in direction. In any interval of time all points describe identical paths; at any instant all points have identical velocities and identical accelerations. Translations in which each point of the body describes straight lines are the common ones, and translation is defined sometimes as any rectilinear motion of a body. The resultant of all the forces acting on the body passes thru the center of gravity of the body; that force and the acceleration have at each instant the same direction, and $R = ma = (W/g)\,a$, wherein R = resultant force, a = acceleration, m and W = mass and weight of the body respectively, and g = the acceleration of gravity. Also if a_x = the x component of the acceleration at any instant and ΣF_x = the algebraic sum of the x components of all the external forces, then $\Sigma F_x = ma_x$; and similarly for y and z axes, the three axes being fixt and rectangular.

For example, consider the motion of a parallel rod of a locomotive, weighing 275 lb running at constant velocity of 60 mi per hr on a level track, the driver diameter being 5.5 ft and the crank length 1 ft. The forces acting on the rod are its weight and the pressures of the crank pins at its ends; these latter each are represented (Fig. 131) by their horizontal and vertical components. Since the resultant of all these forces acts thru the center of gravity, $V_1 = V_2$; also $2\,V_1 - 275 = (W/g)\,a_y = 8.55\,a_y$ and $H_1 - H_2 = (W/g)\,a_x = 8.55\,a_x$. To determine a_x and a_y: The velocity of the center of either crank pin relative to the locomotive is $(88 \times 1)/2.75 = 32$ ft per sec (60 miles per hr = 88 ft per sec), and the relative motion of the pin being circular at constant velocity, the relative acceleration is toward the center of the crank-pin circle at all times and equals $32^2/1 = 1024$ ft per sec per sec. This is also the absolute acceleration of the crank pin, since the locomotive is assumed to have no acceleration. But the rod has the same acceleration as the crank pin; hence $a_x = 1024 \sin\theta$ and $a_y = 1024 \cos\theta$. In the lowest position of the rod $\theta = 0$, $a_x = 0$, $a_y = 1024$, $H_1 = H_2$, $V = \frac{1}{2}(8755 + 275) = 4515$. In a mid-position when $\theta = 90°$, $a_x = 1024$, $a_y = 0$, $H_1 - H_2 = 8755$, and $V = \frac{1}{2}\,275 = 137.5$. In the highest position, $\theta = 180°$, $a_x = 0$, $a_y = -1024$, $H_1 = H_2$, and $V = \frac{1}{2}(275 - 8755) = -4240$, the negativ sign meaning that V acts downward on the rod.

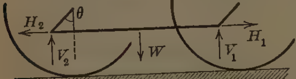

Fig. 131

If the translation is rectilinear and R is constant in value, then

$$Rt = mv_2 - mv_1 \quad \text{and} \quad Rs = \tfrac{1}{2}\,mv_2^2 - \tfrac{1}{2}\,mv_1^2$$

wherein v_1 and v_2 are the values of v at ends of any interval of time t, and s the distance described in that time. These formulas are the principles of impulse and momentum, and of work and energy for this special motion. If the translation is not rectilinear: According to the principle of impulse and momentum $\Sigma \int_{t_1}^{t_2} F_x dt = m v''_x - m v'_x$ and similar equations for y and z directions; the left-hand member is the algebraic sum of the x components of the impulses of the forces acting on the body for the time $t_2 - t_1$, and v'_x and v''_x are the x components of the velocity at the times t_1 and t_2. According to the principle of work and energy $\Sigma \int_{s_1}^{s_2} F_t \, ds = \frac{1}{2} m v_2^2 - \frac{1}{2} m v_1^2$; the left-hand member is the algebraic sum of the works done by all the forces acting on the body whilst its velocity changes from v_1 to v_2, and the displacement is $s_2 - s_1$.

31. Curvilinear Motion

Curvilinear Motion of a Point. If the motion is uniform (equal distances traversed in all equal intervals of time), $v = \Delta s / \Delta t$, and if non-uniform, $v = ds/dt$, just as in rectilinear motion; the velocity of the moving point is directed along the tangent to the path at the point. But acceleration formulas for rectilinear motion do not hold for this case; here it is important to note that the velocity varies in direction continually, and that acceleration is the rate at which the velocity-changes (including magnitude and direction) occur. These complete velocity-changes for a given motion are exhibited by the HODOGRAPH for the motion. A hodograph is constructed by drawing from any point O' (Fig. 132) vectors which represent the velocities of the moving point at a number of its successive positions and then joining the free ends of the vectors by a smooth curve. The velocity-change occurring in any motion as from A to B is represented by the vector $A'B'$. If Δt is the time in which this occurred, then the magnitude of the average acceleration for that time is (chord $A'B'$)$/\Delta t$, $A'B'$ being measured by the scale of the hodograph diagram, and the direction of that average acceleration is that of the vector $A'B'$. The actual acceleration at A, say, is the limit of this average as B is taken closer and closer to A; that is, a at A is the value of ds'/dt at A' (s' denoting distance on the hodograph), and the direction of a is that of the tangent at A'. It will be noticed that the acceleration of the moving point is represented by the velocity of its corresponding point in the hodograph (A' is A's corresponding point).

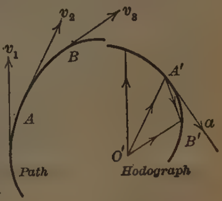

Fig. 132

Velocities and accelerations may be resolved; let α, β, and γ denote the direction angles of v (with respect to x, y, and z axes), v_x, v_y, and v_z the components of v parallel to these axes (axial components), x, y, and z the coordinates of the moving point. Then $v_x = v \cos \alpha = dx/dt$, $v_y = v \cos \beta = dy/dt$, $v_z = v \cos \gamma = dz/dt$. Let a_x, a_y, and a_z denote the axial components of a, and λ, μ, and ν the direction angles of a; then $a_x = a \cos \lambda = dv_x/dt = d^2x/dt^2$, $a_y = a \cos \mu = dv_y/dt = d^2y/dt^2$, $a_z = a \cos \nu = dv_z/dt = d^2z/dt^2$. Let a_t and a_n denote the components of a along the tangent and normal to the path, ϕ the angle between the tangent and a, θ that between normal and a, and r the radius of curvature at the moving point; then $a_t = a \cos \phi = dv/dt = d^2s/dt^2$, $a_n = a \cos \theta = v^2/r$. The tangential acceleration corresponds to change in value of velocity, and the normal acceleration to change in direction of velocity. When a point moves in a circle with constant speed v, then $a_t = 0$ and $a = a_n = v^2/r$, and a is directed along the radius toward the center of the circle.

Motion of a Projectile. In the following formulas air resistance is neglected; v_0 = velocity of projection, θ = angle of projection (Fig. 133), x and

y = coordinates of the projectile at any time t after projection, v = velocity, v_x and v_y = x and y components respectively of v, r = range on the horizontal plane thru O, and h = greatest height attained. The path of the projectile, or the trajectory, is a parabola as represented, and its equation is $y = x \tan \theta - gx^2/2\, v_0^2 \cos^2 \theta$. Also

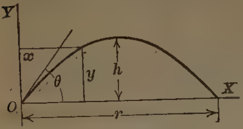

Fig. 133

$$v_x = v_0 \cos \theta \quad v_y = v_0 \sin \theta - gt \quad v = \sqrt{v_0^2 - 2\,gy}$$
$$x = v_0 \cos \theta \cdot t \qquad y = v_0 \sin \theta \cdot t - \tfrac{1}{2}\, gt^2$$
$$h = \sin^2 \theta \cdot v_0^2/2\, g \qquad r = \sin 2\,\theta \cdot v_0^2/g$$

If the direction of projection is horizontal, $\theta = 0$; the equation of the path is $y = -gx^2/2\, v_0^2$, and $x = v_0 t$ and $y = -\tfrac{1}{2}\, gt^2$.

Relative Motion. Description of motion requires the use of coordinate axes or other equivalent means of reference for the specification of positions of the moving point. Motion relative to a body is described by means of coordinate axes fixt in or on the body. Thus, suppose that in a given time a body A (Fig. 134) moves from A' to A'', and a point B from B' to B'': In the first position the coordinates of B are 0.3 and 0.2 in, and in the second 0.5 and 0.4. Then the x and y components of the relative displacement of B with respect to A are $0.5 - 0.3 = 0.2$ and $0.4 - 0.2 = 0.2$, and the total relative displacement is $\sqrt{0.2^2 + 0.2^2} = 0.28$ in. Motion relative to a point is described by means of coordinate axes having the point as origin and their directions remaining constant (relative to the body to which the motion of the point itself is referred). Thus suppose that in a certain time a point A moves from A' to A'' and another B from B' to B'' (Fig. 135); the x and y component displacements of B relative to A are 0.2 and 0.1 in respectively and the displacement of B relative to A is $\sqrt{0.2^2 + 0.1^2}$. The displacements, velocities, and accelerations of two points relative to each other at any instant are equal and opposite. The velocities of three points A, B, and C relative to each other are related as shown in Fig. 136; V_{ab} means velocity of A relative to B and V_{ba} means velocity of B relative to A. Among three points there are six relative velocities, and

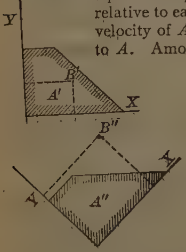

Fig. 134

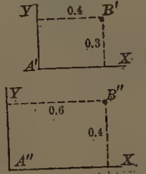

Fig. 135

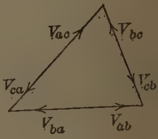

Fig. 136

when any two (except the velocities of two points with respect to each other) are known, the others can be computed by compounding as may be seen from the figure. Among three points there are six relative accelerations; their relations are similar to those of the velocities, and the figure shows the relation, V being now taken to mean acceleration.

Force and Acceleration. The forces acting on a body and the motion of its center of gravity are simply related; the algebraic sum of the components of all the external forces acting on the body along any line equa

the product of the mass of the body and the component of acceleration of its center of gravity along that line. In general, the principle leads to

$$\Sigma F_x = m\bar{a}_x, \quad \Sigma F_y = m\bar{a}_y, \quad \Sigma F_z = m\bar{a}_z$$

wherein m = mass = weight ÷ g; the left-hand members are the sums of the components of the forces along three rectangular axes, and $\bar{a}_x$, $\bar{a}_y$, and $\bar{a}_z$ are the corresponding components of the acceleration of the center of gravity. Or, if the directions of resolution be taken along the tangent to the path described by the center of gravity, the principal normal and a line perpendicular to the principal normal and tangent (the binormal), then

$$\Sigma F_t = m\bar{a}_t \quad \Sigma F_n = m\bar{a}_n \quad \Sigma F_b = 0.$$

The resultant of the normal components, ΣF_n, is called the centripetal force on the body; it is always directed inward toward the center of the curved path just as a_n is. The reaction corresponding to ΣF_n, exerted by the body on those that exert the centripetal force, is called centrifugal force.

For example, consider a car rounding a curve of radius r at a constant speed v. Imagine the rail pressure on each wheel resolved into three components, one parallel to the rails, one parallel to the ties, and one perpendicular to the track; call the resultants of these sets of components respectively R_1, R_2, and R_3 (Fig. 137). Also let P_1 and P_2 denote the pulls at the front and rear ends of the car. The components of the rail pressures parallel to the rails, P_1, and P_2, are practically parallel to the tangent to the path of the center of gravity of the car at that point. The velocity of the car is constant, so $\bar{a}_t = 0$; also $\bar{a}_n = v^2/r$. Hence

$$\Sigma F_t = P_1 - P_2 - R_1 - (W/g)\,\bar{a}_t = 0$$
$$\Sigma F_n = R_2 \cos\delta + R_3 \sin\delta = (W/g)\,\bar{a}_n = (W/g)\,v^2/r$$
$$\Sigma F_b = R_3 \cos\delta - R_2 \sin\delta - W = 0.$$

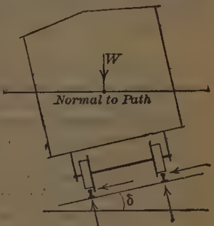

Fig. 137

The first equation shows that $P_1 - P_2 = R_1$, and the second and third solved simultaneously give $R_2 = (W/g)(v^2/r)\cos\delta - W\sin\delta$ and $R_3 = (W/g)(v^2/r)\sin\delta + W\cos\delta$. To make $R_2 = 0$, $(W/g)(v^2/r)\cos\delta = W\sin\delta$ or $\tan\delta = v^2/gr$. This value of tilt of track will not necessarily make each component rail pressure parallel to ties zero, but the resultant of all such components will be zero.

32. Rotation

Rotation of a Body is motion such that one straight line in the body or in its extension remains fixt. This line is the axis of the rotation, and all points of the body not on the line describe circles whose centers are on the line. All lines of the body perpendicular to the axis describe equal angles in equal times; angle described by the body means the angle described by any of the lines just mentioned. The angular velocity of the body at any instant is the rate at which it is describing angle then; the symbol is ω. In uniform rotation (equal angles described in all equal intervals of time) the rate is constant and $\omega = \Delta\theta/\Delta t$, $\Delta\theta$ denoting the angle described in the interval Δt. In non-uniform rotation, the rate varies and $\Delta\theta/\Delta t$ is the average angular velocity for the interval; the actual value of ω at any instant is the value of $d\theta/dt$ for that instant. The angular acceleration of a rotating body is the rate at which its angular velocity is changing; the symbol is α. If the ω changes uniformly the rate is constant and $\alpha = \Delta\omega/\Delta t$, $\Delta\omega$ denoting the velocity-change in the interval Δt. If ω does not change uniformly, then the rate varies, and $\Delta\omega/\Delta t$ is the average angular acceleration for the interval; the actual value of α at any instant is the value of $d\omega/dt$ at that instant.

The general differential equations of rotation are $\omega = d\theta/dt$, $\alpha = d\omega/dt = d^2\theta/dt$
$\omega d\omega = \alpha d\theta$; their integrated forms are

$$\theta_2 - \theta_1 = \int_{t_1}^{t_2} \omega\, dt \qquad \omega_2 - \omega_1 = \int_{t_1}^{t_2} \alpha\, dt \qquad \omega_2^2 - \omega_1^2 = 2\int_{\theta_1}^{\theta_2} \alpha\, d\theta$$

in which θ_1, ω_1, and t_1 are corresponding or simultaneous values of θ, ω, an
t, likewise θ_2, ω_2, and t_2. If the angular velocity is constant, the angul
displacement in the interval $t_2 - t_1$ is $\theta_2 - \theta_1 = \omega(t_2 - t_1)$; if the angul
acceleration is constant the velocity-change $\omega_2 - \omega_1 = \alpha(t_2 - t_1)$, the chan
in the velocity square, $\omega_2^2 - \omega_1^2 = 2\alpha(\theta_2 - \theta_1)$, and $\theta_2 - \theta_1 = ½(\omega_1 +$
$(t_2 - t_1)$ The relations between θ, ω, and t can
represented by curves exactly analogous to the cur
described on page 1486. The corresponding variab
are θ and s, ω and v, and α and a.

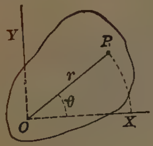

Fig. 138

Let the irregular line in Fig. 138 represent a body rota
about a line thru O perpendicular to the paper, OP a lin
the body and OX and OY fixt axes of reference; also θ = a
XOP, $r = OP$, v and a velocity and acceleration respectivel
P, a_t and a_n the components of a perpendicular and parall
OP, and ω and α the angular velocity and acceleration of
body. If the radian is used in θ, ω, and α, then

$$v = r\omega, \quad a_t = r\alpha, \quad a_n = r\omega^2, \quad a = r(\alpha^2 + \omega^4)^{1/2}$$

any units of time and length may be used. If n = the angular velocity in revolu
per unit time, $\omega = 2\pi n$, and this value may be substituted for ω in the foregoing
the rotation is uniform $\alpha = 0$, and $a = r\omega^2 = v^2/r = 4r\pi^2 n^2$.

Relation between Forces and Motion. The angular acceleration
rotating body depends only on the moments of all the external forces a
on the body about the axis of rotation and on the moment of inertia o
body about the same axis. If ΣM = the algebraic sum of moments o
forces, I the moment of inertia, m the mass of the body, W its weight, a
its radius of gyration with respect to the axis of rotation, then

$$\Sigma M = I\alpha = mk^2\alpha = (W/g)\, k^2\alpha$$

Let ω_1 and ω_2 = the angular velocities of a rotating body at time t_1 a
later time t_2; then according to the principle of angular impulse and mome

$\Sigma \int_{t_1}^{t_2} M\, dt = I\omega_2 - I\omega_1$. The left-hand member is the algebraic sum o
angular impulses, about the axis of rotation, of all the external forces f
time $t_2 - t_1$. If the moments of all the forces are constant during the
the left-hand member becomes $\Sigma M(t_2 - t_1)$. According to the pri

of work and energy $\Sigma \int_{s_1}^{s_2} F_t ds = ½ I\omega_2^2 - ½ I\omega_1^2$. The left-hand mem
the algebraic sum of the works done on the body by all the external
for the interval $t_2 - t_1$.

Centrifugal Force. Suppose that P is a particle of a body rotatin
angular velocity ω, and let dm = mass of P, r = the radius of the circle de
by P. The resultant of all the forces acting on P may be resolved in
components, one along the radius r and one along the tangent to the
P; the radial or normal component = $dmr\omega^2$ and acts from P toward
of rotation; the tangential component = $dmr\alpha$. The normal compo
called the centripetal force on P; it (and the other component also) is
on P by other things (neighboring particles, usually). P reacts on th
things with a force whose radial and tangential components equal
above but in the opposite directions. The normal component, dm

ward, is called the centrifugal force of P; the resultant of the centrifugal forces of all the particles is the centrifugal force of the body; in general the resultant of the centrifugal forces of all the particles is not a single force, but in certain common cases there is a single force resultant. Thus if m = mass of the body($= W/g$), $\bar{r}$ the radius of the circle described by the center of gravity G (Fig. 139), n = revolutions per unit time ($\omega = 2\pi n$), and the body is homogeneous, then (*a*) when the body is symmetrical about a plane perpendicular to the axis of rotation, the centrifugal force $= m\bar{r}\omega^2$ and acts in the line OG; (*b*) when the body is symmetrical about a line parallel to the axis of rotation, the centrifugal force $= m\bar{r}\omega^2$ and it acts in the line OG; (*c*) when the body is symmetrical about a plane containing the axis of rotation, the centrifugal force $= m\bar{r}\omega^2$, acts in the plane of symmetry, is parallel to OG at a distance from any XY plane equal to $\left(\int dmxz\right) \div m\bar{r}$. If ω is in radians per sec, n in rev per min, $\bar{r}$ in ft, W (weight of body) in lb, $\bar{v}$ (velocity of center of gravity) in ft per sec, then centrifugal force in lbs is

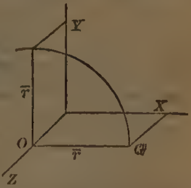

Fig. 139

$$\frac{W}{g}\bar{r}\omega^2 = \frac{W}{g}\frac{\bar{v}^2}{\bar{r}} = \frac{W\bar{r}}{g}\frac{4\pi^2 n^2}{3600} = \frac{W\bar{r}n^2}{2937} = 0.000341\, W\bar{r}n^2$$

When a body is rotating with constant angular velocity, then the resultant of all the actual external forces acting on the body (weight, reactions of axle bearings, belt pulls, etc.) is equal and opposite to the resultant centrifugal force of the body. For example, in Fig. 140 PC is a rod supported by a pivot at P and by a cord AB so that the rod can be rotated about AP. During rotation it is under the action of the pivot pressure represented by components P', P'', and P''' (not shown), the pull of the cord T, the weight of the rod W, air resistance, and the driving force F (not shown). When the speed is constant, then the resultant of all these is as described under (*c*) above. If air resistance and pivot friction are negligible, no driving force is required to maintain speed, and $P''' = 0$; T, P', and P'' can be determined as follows (supposing $PC = 6$ ft, $PB = 5$ ft, $PG = 3$ ft, $ABP = 90°$, $APB = 30°$, $W = 100$ lbs, and $n = 60$ rev per min): Since the resultant of T, P', P'', and W is horizontal, the sum of their vertical components $= 0$, or $T \sin 30 + P'' - 100 = 0$; the sum of their horizontal components $= m\bar{r}\omega^2$, or $T \cos 30° + P' = (100/32.2)\, 1.5\, (2\pi 60/60)^2 = 184$; the resultant acts at a point Q whose distance above PX equals $\int dmxz \div m\bar{r} = 3.46$ ft, and $PQ = 4$ ft; the moment sum of all the forces about $Q = 0$, or $-T \times 1 - 100 \times 1/2 + P' \times 3.46 + P'' \times 2 = 0$. The three equations solved simultaneously give $T = 157.5$, $P' = 47.5$, and $P'' = 22.5$ lb.

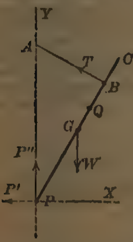

Fig. 140

33. Balancing

The reacting forces which support a rotating body depend in general not merely on the weight of the body and applied forces but also on the speed, the mass, and shape of the body; moreover, the components of the supporting forces which depend on the speed, mass, and shape change direction continually. Thus in the preceding illustration, when the rod is not rotating $T = 30$ lb, $P' = 26$ lb, and $P'' = 85$ lb, values quite different from those for motion. Or, consider a body weighing 100 lbs mounted on a shaft supported in bearings equally distant from the body and the center of gravity 1 in from the axis of the shaft. When the system is at rest, the bearing

pressures (due to the body) = 50 lbs each and act vertically, but when the system rotates at constant speed the bearing pressures have additional components each equal to ½ $(100/32.2)(1/6)\,4\pi^2n^2$, n being the speed in rev per sec. These components are said to be due to centrifugal action or centrifugal force, and will be called centrifugal components. If the center of gravity of the rotating system is in the axis of rotation, the system is said to have standing balance; such a system with shaft horizontal would not turn of itself from any position into which it might be placed (see Fig. 141). If the centrifugal forc of the rotating system is zero, then th system is said to have or be in runnin

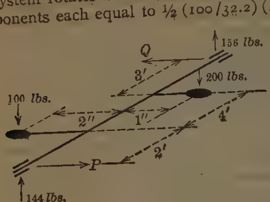

Fig. 141

balance. Standing balance is a necessary condition for running balance bu not a sufficient one; thus in Fig. 141 there is standing but obviously not run ning balance. In fact the centrifugal forces of the two bodies are equa $(100/32.2)(1/6)\,4\pi^2n^2$ and $(200/32.2)(1/12)\,4\pi^2n^2$ or $20.4\,n^2$, and opposite bu not colinear and so they constitute a couple. The centrifugal components o the reactions of the bearings are therefore each $20.4\,n^2 \times 4 \div 9 = 9.07\,n^2$, an directed as shown, P and Q. If these bearings were not firmly supported, the the rotating system would wobble.

Balancing a system out of running balance requires the rearrangement of the rotati material or the addition or removal of material. Car wheel-pairs are balanced expe mentally by running them in spring-supported bearings and adding material here a there to the wheels, by trial, until steady running is secured. An unbalanced system c always be balanced by the addition of two bodies rotating about any two arbitrar selected points on the axis of rotation; moreover the weights of these bodies and th exact positions relative to the rotating system can be computed provided that the centr ugal force of the unbalanced system is known or if the unbalanced system can be divic up into parts the centrifugal forces of which are known. Thus suppose that it is desi to balance the body of weight W (Fig. 142 or 143), out of center a distance r (center

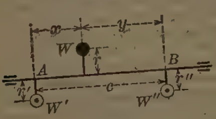

Fig. 142

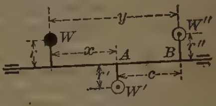

Fig. 143

gravity to axis of shaft $= r$) by means of two bodies rotating about A and B. In o that there may be running balance: (1) the centers of gravity of the three bodies and axis of the shaft must be in a plane, and (2) the sum of moments of the centrifugal fo of the three bodies must be zero about any point in the plane. Condition (2) requ that the middle one of the three bodies, counting along the shaft, shall be alone on side of the shaft, and further, that

$$W'r' = Wry/c \quad \text{and} \quad W''r'' = Wrx/c$$

where W' and W'' are the weights of the balancing bodies rotating about A and B re tively and r' and r'' are their distances out of center. Any unit of weight and of dis may be used in these formulas.

For example, consider the balancing of the cranks and crank pins on a pair of locom drive wheels. In Fig. 144 the cranks are set 90° apart, the planes of rotation of centers of gravity are 62 in apart, and the planes of rotation of the centers of grav the pins are 72 in apart; for each crank pin $W = 25$ lbs and $r = 12$ in; for the unbal part of each crank $W = 30$ lbs and $r = 5$ in.

The counter (or balancing) weights are to rotate about A and B with radii $=r$ inches say. To balance P_1 requires a_1 and b_1 (see figure), such that for a_1, $Wr = (25 \times 12)66/60 = 330$, and for b_1, $Wr = (25 \times 12)6/60 = 30$ in-lbs; similarly to balance P_4 requires a_4 and b_4, and for a_4, $Wr = 30$ and for b_4, $Wr = 330$ in-lbs. To balance P_2 requires a_2 and b_2 and so that for a_2, $Wr = (30 \times 5)61/60 = 152.5$ in-lbs, and for b_2, $Wr = (30 \times 5)1/60 = 2.5$ in-lbs; similarly to balance P_3 requires a_3 and b_3, and for a_3, $Wr = 2.5$ and for b_3, $W_r = 152.5$ in-lbs. These eight bodies a_1, b_1, a_2, b_2, etc., would balance the cranks and pins; it remains to find two substitutes for the eight. Now a_1 and a_2 can be combined, giving $Wr = 330 + 152.5 = 482.5$; a_3 and a_4, giving $2.5 + 30 = 32.5$; b_1 and b_2, giving 32.5; and b_3 and b_4, giving 482.5 in-lbs. The centrifugal forces of a' and a'' (whose $Wr = 482.5$ and 32.5) have a simple resultant, and a single body whose centrifugal force is identical with that resultant can be found thus: treat 482.5 and 32.5 as tho they were forces acting from A to a' and A to a'' and find their resultant; it is 484 in-lbs directed along Aa, the angle $a'Aa$ being nearly 4°; then any body the radius to whose center of gravity lies along Aa and whose $Wr = 484$ in-lbs will serve as one counterweight. In a similar manner the other counterweight may be determined; its $Wr = 484$ and its radius lies along Bb. (It should be noted that the effects of coupling and connecting rod are not considered.)

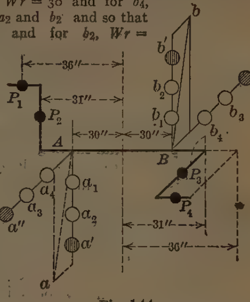

Fig. 144

34. Pendulums.

The Compound or Physical Pendulum is a body suspended on a horizontal axis so it can oscillate freely under the influence of gravity. Let G (Fig. 145) be the center of gravity of the pendulum, O the center of suspension, $a = OG$, and $k =$ the radius of gyration of the pendulum with respect to its axis of suspension, and $T =$ the time of one oscillation (from one extreme position of the pendulum to the opposite extreme position); then if the oscillation is small, $T = \pi\sqrt{k^2/ag}$. If $\alpha =$ the maximum angle which OG makes with the vertical, that is, if 2α is the complete angle described by the pendulum in one oscillation, then more correctly,

Fig. 145

$$T = \pi\sqrt{\frac{k^2}{ag}}\left[1 + (½)^2 \sin^2\frac{\alpha}{2} + (¼ \cdot ¾)^2 \sin^4\frac{\alpha}{2} + \cdots\right]$$

If $\alpha = 8°$, the bracket is only 1.00122 and nearer unity for smaller values of α. T for a given pendulum is hence practically independent of a, if a be small; that is, for small angles a pendulum is practically isochronous. The point Q in the line OG extended and $OQ = k^2/a$ is called the center of oscillation corresponding to the center of suspension O; it is also called center of percussion (Art. 37). The centers of suspension and oscillation are interchangeable, that is, the times of oscillation about axes thru O and Q are equal. This property is made use of in pendulum determinations of g as follows: the pendulum is made so that it can be suspended from two points O at a known distance d apart; then the times of oscillation for the two points O are compared and by trial are made equal by shifting a weight along the stem of the pendulum; either of these points then is the center of oscillation for the other as center of suspension, and $d = k^2/a$; then $g = \pi^2 d/T^2$.

A Simple Pendulum is a very small sphere supported by a cord; its length is the distance from the center of the sphere to the point of suspension. A physical and a simple pendulum whose times of oscillation are equal are said to be equivalent. A seconds pendulum is one whose time of oscillation is one second. The length of the equivalent seconds pendulum at New York is 39.101 inches.

The Conical Pendulum consists of a body suspended from a fixt point and so that it can rotate about a vertical axis thru the point. The height of the pendulum h (Fig. 146) depends only on the angular velocity; thus for n revolutions per unit time $h = g/4\,\pi^2 n^2$ If g is taken as 32.2 ft per sec per sec, then n must be taken in rev per sec; h will be in feet. If n is less than $\sqrt{g/l} \div 2\,\pi$, the ball will not fly out or remain in any deflected position. If P = tension in the cord, l = length of pendulum, W = weight, then $P = Wl\;4\,\pi^2 n^2/g$.

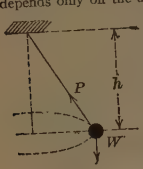

Fig. 146

35. Uniplanar Motion

Uniplanar Motion is a motion such that each point of the moving body remains at a constant distance from a fixt plane. Examples: motion of the connecting rod of a steam engine, rolling of a wheel, rotation of a fly wheel, etc. All straight lines of the body which are parallel to the plane of the motion describe equal angles during any displacement of the body, and by angle described by the body is meant the angle described by any of the lines mentioned. The angular velocity of the body at any instant is the rate at which it is describing angle then. The angular acceleration at any instant is the rate at which its angular velocity is changing then. Any displacement may

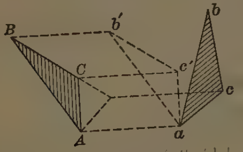

Fig. 147

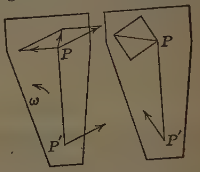

Fig. 148

be accomplished by a translation of the body which will bring one line of it which is perpendicular to the plane of the motion into final position followed by a rotation of the body about that line into final position. T the displacement of a body from ABC to abc (Fig 147) may be accomplish by a translation from ABC to $ab'c'$ followed by rotation about a into posi abc. The amount of translation depends on the line of the body selected axis of the rotation; the amount of the rotation does not The actual state of (uniplanar) motion of a body at any instant may be regarded as consisting of two components, a translational and a rotational. And the velocity v of any point P of the body (Fig. 148) may be regarded as the resultant of two velocities, one the actual velocity v' of a second point P', and the other the velocity of P about (relative to) P', $r\omega$, where ω = angular velocity of the body and $r = PP'$. Likewise the acceleration a of P may be regarded as the resultant of the actual acceleration a' of P' and the acceleration of P about (relative to) P'.

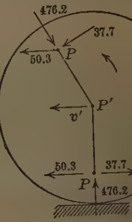

Fig. 149

For example, when a wheel 8 ft in diameter rolls uniformly at 2 rev per sec, or $\omega = 12.56$ radians per sec, then taking P' at the center (Fig. 149), $v' = \pi 8 \times 2 = 50.3$ ft per sec, and $a' = 0$; the velocity of a point P 3 ft from the center relative to P' is 37.7 ft per sec direc shown, and the actual velocity of P is the resultant of 50.3 and 37.7; the accelerat P relative to P' is $3\,\omega^2 = 476.27$ ft per sec per sec (see page 1490) directed as and since $a' = 0$, the acceleration of P is 476.2.

Uniplanar Displacement can also be accomplished by a single rotation about some line. Thus the displacement from ABC to abc (Fig. 147) can be made by a rotation about the intersection of the perpendiculars to Aa and Bb at their centers. Any uniplanar motion may be regarded as a continual rotation about a line which in general is continually shifting its position in space and in the body or its extension This line is called INSTANTANEOUS AXIS (of rotation), and any point of it the instantaneous center. In uniplanar motion, the velocity of any point of the body at any instant equals the product of the angular velocity of the body then and the distance of the point from the instantaneous center, and the direction of the velocity is perpendicular to the line joining the point and the instantaneous center; the velocities of different points of the body are as their distances from the instantaneous axis. The instantaneous center may be determined when the directions of the velocities of any two points of the body (the line joining which is parallel to the plane of the motion) are known, provided these directions are not parallel, as follows: at each of the two points draw a line parallel to the plane of motion and perpendicular to the direction of the velocity of that point, and determine their intersection; this is the instantaneous center.

For example, consider the motion of the connecting rod of an engine. The velocity of the crank end of the rod is perpendicular to the crank and the velocity of the other end is parallel to the guides; hence for any particular position of the rod the instantaneous center is at the intersection of the crank (radius) extended and a line perpendicular to the guides at the guide end of the rod.

The relation between the external forces and the motion produced is exprest thus: take x and y axes of reference parallel to the plane of motion; then

$$\Sigma F_x = m\bar{a}_x \qquad \Sigma F_y = m\bar{a}_y \qquad \Sigma M = I\alpha = mk^2\alpha = (W/g)\,k^2\alpha$$

wherein ΣF_x and ΣF_y denote the sums of the x and y components of all the external forces, $\bar{a}_x$ and $\bar{a}_y$ the x and y components of the acceleration of the center of gravity, α the angular acceleration of the body, m its mass, W its weight, ΣM the algebraic sum of the moments of the external forces about an axis thru the center of gravity and perpendicular to the plane of motion, I the moment of inertia, and k the radius of gyration of the body with respect to the same axis. For example, consider a cylinder of radius r and weight W rolling down an inclined plane. The forces acting on the cylinder are its weight W and the reaction of the plane regarded as replaced by its two components N and F (Fig. 150); taking the x axis along the plane and the y normal to it, the three formulas become $(W \sin\phi - F) = (W/g)\bar{a}$, $N - W\cos\phi = 0$, and $Fr = \frac{1}{2}(W/g)\,r^2\alpha$, $\frac{1}{2}(W/g)\,r^2$ being the moment of inertia of the cylinder with respect to its axis. (It is assumed that there is no indentation of the roadway, that is, no rolling resistance.) If there is no slipping, then $\bar{a} = r\alpha$, which equation combined with first and third above gives $\bar{a} = \frac{2}{3}g\sin\phi$, $\alpha = \frac{2}{3}(g/r)\sin\phi$, and $F = \frac{1}{3}W\sin\phi$; also $N = W\cos\phi$.

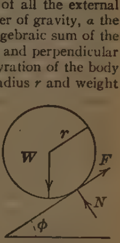

Fig. 150

The Kinetic Energy of translation and rotation combined is $\frac{1}{2}m\bar{v}^2 + \frac{1}{2}\bar{I}\omega^2$, where m denotes the mass of the body, $\bar{v}$ the velocity of its center of gravity, $\bar{I}$ its moment of inertia with respect to a line thru the center of gravity and perpendicular to plane of the motion, and ω its angular velocity. The first term is sometimes called the translational and the second the rotational part of the kinetic energy. It is also given by $\frac{1}{2}I\omega^2$, where I denotes the moment of inertia of the body with respect to its instantaneous axis (at the instant for which the energy is to be figured) and ω is the angular velocity.

For example, take a cylinder of radius r and weight W rolling at n revolutions per unit time: $m = W/g$, $v = 2\pi rn$, $\bar{I} = \frac{1}{2}(W/g)\,r^2$ (see page 1478), and $\omega = 2\pi n$; hence the kinetic energy $= 3\,(W/g)\,\pi^2r^2n^2$, one-third of which is rotational. Also $I = \bar{I} + (W/g)r^2 = \frac{3}{2}(W/g)r^2$; hence according to the second formula the kinetic energy is $\frac{1}{2}(3\,W/2\,g)\,r^2\,4\,\pi^2n^2 = 3\,(W/g)\,\pi^2r^2n^2$ as before.

36. Three-dimensional Motion

Any motion of a body may be regarded as consisting of two compone one a translation equal to that of the center of gravity and the oth rotation about some axis thru the center of gravity. These motions ma said to be produced independently by the forces acting on the body; (a) the acceleration of the center of gravity is the same as if the whole were concentrated at the center of gravity and acted upon by forces e in magnitude to and same in direction as the actual external forces; and (b angular acceleration is the same as if the center of gravity were fixt anc actual external forces applied. The reasonableness of this will probabl seen from this: imagine each force acting on the body replaced by a acting at the center of gravity G and a couple; the resultant of all the f acting at G is a single force R, and the resultant of all the couples is a s couple C; R cannot turn the body but gives it a motion of translation and C cannot move G but merely turns the body about some line thr In general C does not cause turning about a line perpendicular to the of C, only so if the plane of C is perpendicular to one of the principal tral axes of the body (see page 1491). To determine the acceleration center of gravity, take fixt x, y, and z axes outside the body and resol external forces F_1, F_2, etc., into x, y, and z components; then

$$\Sigma F_x = m\bar{a}_x \qquad \Sigma F_y = m\bar{a}_y \qquad \Sigma F_z = m\bar{a}_z$$

m denoting the mass of the body. To determine the angular accele of the body, take moments of all the forces F_1, F_2, etc., about the three c principal axes; calling the sums of the moments about these axes ΣM_1, and ΣM_3; the components of the angular acceleration α_1, α_2, and α components of the angular velocity ω_1, ω_2, and ω_3; then

$$\Sigma M_1 = I_1\,\alpha_1 + (I_3 - I_2)\,\omega_2\,\omega_3, \quad \Sigma M_2 = I_2\,\alpha_2 + (I_1 - I_3)\,\omega_3\,\omega_1,$$
$$\Sigma M_3 = I_3\,\alpha_3 + (I_2 - I_1)\,\omega_1\,\omega_2$$

wherein I_1, I_2 and I_3 denote the three central principal moments of of the body. In any motion of a body: the kinetic energy may be co in two parts, (1) the kinetic energy of the whole body moving with a equal to that of the center of gravity and (2) the sum of the kinetic e of the constituent particles of the bodies their velocities relative to the center of gr

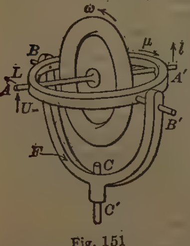

Fig. 151

Gyrostat (Fig. 151). The wheel ω a can rotate about AA', the supporting ring can rotate about BB', and the supportin F can rotate about CC'. If the disk or spinning rapidly in the direction indicat and an upward force U be applied at A, AA' will not rotate about BB' but abou the direction indicated by the arrowhe downward force causes rotation in the direction. A horizontal force L to the le cause the axle AA' to rotate not about about BB' in the direction indicated arrow l; a force to the right would cause in the opposite direction. These rotations of the axle of spin are ca cessional motions, the wheel being said to precess. The precession o of spin, AA', tends to convert the existing spin of the wheel into a s the axis of the applied moment and in the direction required by that

A Mono-rail Car, as its name implies, runs on a single rail; and the Brennan car is wholly above the rail. Stability of this car is furnished by two gyrostats mounted in the car as shown in plan and elevation (Fig. 152). W is one of the gyrostat wheels (W' the other); it is mounted rigidly on the axle A, the bearings of which are on the frame or case C. (These cases wholly enclose the gyrostat wheels, and a vacuum is maintained in the cases to reduce the windage of the wheels; the wheels are driven electrically—indeed the wheels are motor armatures—in opposite directions.) The case C has trunnions T and T supported in bearings on the double frame F, which also supports the other gyrostat case C'. The double frame F is supported on an axle X parallel to the rail, on which the whole gyrostat system can turn. To the two upper trunnions T and T' are keyed two spur-toothed segments which mesh at G; thus the cases C and C' can rotate on their trunnions only together, in opposite directions, and equal amounts. R and R' are wheels or rollers which turn on bearings fixt to the cases C and C'. Rigidly fastened to the car are four shelves M, M', N, and N'; as shown in the plan these do not extend beyond the line OO'. When for any reason the axles A and A' are at OP and $O'P'$ say, or OQ and $O'Q'$, and the car is tipping either way relative to the gyrostat system, then one shelf, and only one, will come up against an axle end or roller; for instance when the axles are at OP and $O'P'$ and the car tips clockwise, then the shelf M comes up against the axle A.

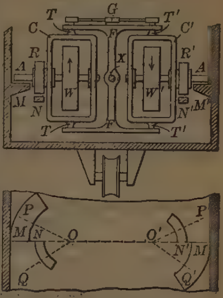

Fig. 152. (After Perry)

When the car is running straight, erect, and balanced, the axles A and A' are in line, across the car, and this is the normal position of the gyrostats. Now suppose a disturbance, as a wind pressure on the left side, tips the car clockwise; the shelf M comes up against the axle A and causes precession of A away from the reader, which continues as long as there is contact at A. The rapidly rotating axle slips on the shelf M and is itself subjected to a friction which tends to hurry the precession, the effect of which is to increase the pressure on the shelf. This pressure down arrests the tipping and pushes the car back against the wind to the neutral position, in which the wind and gravity moments are balanced. This neutral position is reached with a certain momentum, and the car is carried past it, the shelf M recedes from A with the axles of the gyrostats in positions as OP and $O'P'$, and eventually the shelf N' comes up under the roller R'. The upward pressure on the roller causes precession of A' toward the reader, which continues as long as there is contact at the shelf N'. The friction of the roller on its axle tends to retard this precession, and the correcting pressure of the roller on the shelf N' is not so great as that of the axle A on M (in similar circumstances), and the gyrostats are returned to the normal position with the car still tilted to the left of the neutral position. But the gyrostats reach the normal position with velocity and swing beyond it; the roller R' runs off the end of the shelf N' and the axle A' comes into contact with the shelf M'. The pressure of M' on A' causes precession of A' toward the reader, the friction on A' tends to hurry the precession, and A' reacts strongly on the shelf M', bringing it to its neutral position and beyond. Eventually M' recedes from A', the shelf N coming up against the roller R, with the gyrostats in the positions OQ and $O'Q'$. The shelf N, like N', brings the gyrostats into normal position and then shelf M into play; and so the operations described are repeated. But the oscillations of the car and the swings of the gyrostats rapidly decay, and the car settles down into its neutral position quickly. Geared together and spinning in opposite directions, the two gyrostats work together in the above described actions. A single gyrostat might furnish the stability on a straight track, but two gyrostats are essential for running on curves. In Oct., 1909, Mr. Brennan operated a mono-rail car 40 ft long, weighing 22 tons, and designed to carry a load of 10 to 15 tons; it is furnished with an 80 and a 20 H.P. petrol-electric set for running the car and the gyrostats; each gyrostat weighs about 3/4 ton, is 3 ft 6 in in diameter, and is run at 3000 R.P.M.; the vacuum of the gyrostat cases is equivalent to about 1/2 to 5/8 in of mercury. The car was run on a curve of 105 ft radius at 7 miles per hour, and over reverse curves of 35 ft radius without "appreciable disturbance" of the level of the car floor.

37. Impact

Direct Central Impact is such that before collision the centers of gravi of the bodies move along the same straight line. Central impact is collisio during which the forces which the bodies exert on each other are direct along the line joining the centers of gravity. In any collision, the forc which the two bodies exert on each other are equal and opposite at ea instant; hence the total impulses of these forces during the collision are equ and opposite, and according to the principle of impulse and momentum t changes in the momentum of the bodies produced by the collision must equal and opposite; or, otherwise stated, the total momentum of the t bodies is unchanged by the collision. Or, for direct central impact:

$$m_1v_1 + m_2v_2 = m_1V_1 + m_2V_2$$

wherein m_1 and m_2 = the masses of the bodies, v_1 and v_2 their velocities bef and V_1 and V_2 their velocities after the collision; but in numerical substi tion velocities in one direction are given the same sign and those in the ot direction the opposite sign.

Experiments on direct central impact of spherical bodies have shown that the rela velocities of spheres after impact are always less than before the impact and that t relative velocities are opposite in direction. The ratio of the relative velocities impact to that before impact is called coefficient of restitution; it seems to depend on the material of the impinging spheres. For glass the coefficient is 15/16, for steel cork 5/9, ivory 8/9, wood about 1/2, clay and putty 0. If e = the coefficient, then

$$(v_1 - v_2) = -e\,(V_1 - V_2)$$

This equation and the preceding one solved simultaneously show that

$$V_1 = v_1 - \frac{(1+e)\,m_2}{m_1+m_2}(v_1 - v_2) \qquad V_2 = v_2 - \frac{(1+e)\,m_1}{m_1+m_2}(v_2 - v_1)$$

During impact there is, in general, loss of kinetic energy; the loss is $\frac{1}{2}(v_1 - v_2)^2(1 - e^2)\,m$ (m_1+m_2). Bodies for which $e = 0$ are said to be inelastic; and those for wh is nearly 1 are said to be nearly perfectly elastic. When a sphere is dropt on a zontal surface of a large body from a height h, and if H = the height of rebound, $H = e^2h$. This equation furnishes a means of computing e.

Force of a Blow. By this is meant the actual pressure between bodies in collision. This pressure or force varies during the collision zero at the beginning up to a maximum value and then down to ze the end. Curves showing how the force varies with respect to the tim with respect to the displacement of the point of contact during the coll are quite dissimilar. The average values of the force as shown by thes curves are unequal. The first is called the time-average and the secon space-average force of the blow. Let F_t and F_s denote these averages re tively and t and s the total time and displacement; then F_tt = the im exerted on either body, and if the impact is direct and central, F_ss = the done on either body by the force of the blow. When any object is stru a hand-hammer for example, the momentum of the hammer is changed; c the change M, then $F_tt = M$, or $F_t = M/t$. That is, for a given char momentum the time-average force of a blow varies inversely as the ti the impact. The energy of the hammer is also changed, and callin change E, then if the energy dissipated (in vibration of the hammer) is gible, $F_ss = E$, or $F_s = E/s$. That is, for a given change in energy the average force of a blow varies inversely as the space thru which the forc (It is assumed in the preceding that no other force than that of the affects the momentum and the energy changes.)

A pile-driver hammer of weight W falling a height h to a pile which it drives a s is given an amount of energy equal to $W(h+s)$ by gravity before the hammer is a

This energy is delivered to the pile and is wasted against resistance between earth and the ile, in vibration of the pile and adjacent earth. Calling the space-average resistance R nd neglecting the energy lost in vibration, then $Rs = W(h+s)$, or $R = W(1+h/s)$. This ormula is in use for computing the bearing capacity of a pile; h being the drop of the ammer and s the penetration of the pile in the last blow (or average penetration for ast few blows), W weight of hammer, and R ultimate bearing capacity, safe capacity eing generally taken as ⅕ or ⅙ of R. As 1 is small compared to h/s, the formula may be ritten, safe load = ⅕ or ⅙ Wh/s.

Ballistic Pendulum. This is a device formerly used to measure the velocity f a projectile; it is essentially a pendulum with a massive bob into which the rojectile may be fired and arrested (Fig. 153). Let v = velocity of the proectile, m its mass, M the mass of the pendulum ($=W/g$, W denoting its eight and g acceleration of gravity), k its radius of gyration with respect o the axis of suspension (for determination of which see below), a the istance from the axis to the center of gravity and r that to the path of the rojectile, and θ deflection of pendulum caused by projectile; then

$$v = \sqrt{2ga(1-\cos\theta)}\,(m + Mk^2/r^2) \div (mk/r)$$

f the weight of the bob is large compared to that of the suspending rod, then $k/r = 1$ nearly. If a pendulum in its vertical position is struck a horizontal low thru the center of gravity and perpendicular to the axis of suspension, he whole pendulum tends to move in the direction of the blow. But such ranslation is prevented by the support which exerts a sudden reaction oppoite to the blow. If the pendulum is struck below the center of gravity the low tends to produce a translation in its direction and a rotation about the enter of gravity. There would still be a sudden reaction of the support on he pendulum to overcome the tendency to the motion there unless the ranslation and the rotational velocities of the center of suspension, which he blow tends to produce, are equal. That point f impact for which the blow produces no sudden eaction at the center of suspension is called CENTER F PERCUSSION; it coincides with the center of oscilation (see page 1493). Its distance from the center f suspension $= k^2/a$.

Fig. 153

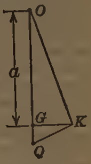

Fig. 154

The distance k^2/a can be determined experimentally thus: et the pendulum oscillate and ascertain the time T of one wing, extreme to extreme position; then $k^2/a = gT^2/\pi^2$; if is taken in ft per sec per sec and T in sec, then k^2/a is in ft. et k_g be the radius of gyration of the pendulum with respect o a line thru its center of gravity and parallel to the axis of uspension. When k_g is known the center of percussion (Fig. 154) can be located graphically thus: at G draw GK perpendicular to OG and make $OG = k_g$; join O and K and draw a perpendicular to OK at K; Q is the intersection f this perpendicular and OG extended.

The Moment of Inertia I of an irregular or nonhomogeneous body with espect to a specified line can be determined best experimentally; thus proeed as described above to determine k^2/a, then $I = (W/g)k^2 = WT^2/a\pi^2$. f the specified line passes through the center of gravity of the body then, ince the body would not oscillate about such line, proceed thus: determine I about any parallel line distant a from the center of gravity, then the desired moment of inertia $= I - (W/g)a^2$. If it is impossible or inconvenient to suspend the body at the specified line, then suspend and oscillate it about any ine parallel to the specified line, and determine I as explained about such parallel line; calling the distances of the parallel and specified lines from the center of gravity a and b respectively, then the desired moment of inertia $= I - (W/g)a^2 + (W/g)b^2 = I - (a^2 - b^2)W/g$.

FRICTION

38. Static Friction

Static Friction, or FRICTION OF REST is the friction between two bodies when there is a tendency to but not an actual slipping of one relative to the other. Let P (Fig. 155) = a pull applied to a body A which is supported by a body B, R = the reaction of B on A; then the component F of R along the surface of contact is the friction, and the component N perpendicular to the surface is the normal pressure. So long as there is no slipping $F = P$, and the greatest value of F obtains when slipping impends; this value of F is called limiting friction. The coefficient of static friction for two bodies is the ratio of their limiting friction to the accompanying normal pressure; it is denoted by f. The angle between R and N changes as F changes, and its greatest value obtains when motion impends; this value is called the angle of friction for the two bodies, and it will be denoted by ϕ. When a body A is supported on an inclined plane B, and no forces act on A except its own weight and the supporting force, then that inclination of the plane to the horizontal which will just cause slipping of A is called the angle of repose for A and B; it also will be denoted by ϕ because the angles of repose and friction for two bodies are equal. Also the tangents of these angles equal the coefficient of friction,

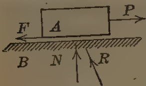

Fig. 155

$$F \leqq fN \qquad\qquad f = \tan\phi$$

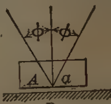

Fig. 156

Suppose the body A (Fig. 156) is supported by a body B, let Q denote the resultant of all the forces acting on A excepting the supporting force, and suppose that the line of action of Q cuts the surface of contact at a; then the cone with vertex at a, axis normal to the contact surface and apex angle equal to double the angle of friction, is called a cone of friction for the bodies A and B. If Q fall within the cone, motion will not ensue for any value of Q, but if without, then Q will move A.

The coefficient of static friction for two bodies A and B may be determined thus: (1) Place A on B as in Fig. 155 and determine the pull P which will just start A; then $f = P$ divided by the weight of A. Or (2) tilt B and determine the inclination at which gravity will start A down; then f = the tangent angle of that of inclination. In either method, several determinations must be made to obtain a fair average value of the coefficient.

Coefficients of Static Friction depend on the nature of the materials, character of rubbing surfaces, and kind of lubricant, if any be used. Early experimenters reported (Coulomb 1871, Rennie 1828, Morin 1834, and others) that the coefficient is independent of the intensity of normal pressure and altho this announcement was clearly subject to the limitation of the range of the experiments performed, yet it was generalized and long accepted as a universal law of friction. But the universality of the law has been questioned. Morin himself pointed out that length of the time of contact of the two bodies influences the coefficient and obviously the coefficient changes when the intensities of pressure get so high as to affect the character of the surfaces in contact. Messiter and Hanson report practical constancy of coefficient for yellow pine and spruce (Eng. News, 1895, vol. 33, p. 322), the first for a range from 100 to 1500 lbs per sq in and the second for a range from 100 to 800. They report for planed or sandpapered yellow pine: f = 0.25–0.33, average 0.29, for 100 to 1000 lb per sq in; for spruce: f = 0.18–0.53; average 0.42, for 100 to 800 lb per sq in. The variation depends on relation of grain of wood to direction of slide.

Coefficients of Static Friction

Compiled by Rankine from Experiments by Morin and others

Dry masonry and brickwork	0.6 to 0.7	Masonry on dry clay	0.51
Masonry and brickwork, with damp mortar	0.74	Masonry on moist clay	0.33
Timber on stone	about 0.4	Earth on earth	0.25 to 1.0
Iron on stone	0.7 to 0.3	Earth on earth, dry sand, clay, and mixt earth	0.38 to 0.75
Timber on timber	0.5 to 0.2	Earth on earth, damp clay	1.0
Timber on metals	0.6 to 0.2	Earth on earth, wet clay	0.31
Metals on metals	0.25 to 0.15	Earth on earth, shingle and gravel	0.81 to 1.11

Coil Friction. When a rope wholly or partially encircles a pulley or drum (Fig. 157) the tensions P_1 and P_2 may be quite different on account of the friction on the rope. The difference is greatest when slipping impends; if α = arc of contact in radians, ε = Naperian base = 2.718, the maximum ratio $P_2/P_1 = \varepsilon^{f\alpha}$.

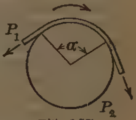

Fig. 157

Maximum Ratios P_2/P_1 (Slipping Impending)

$\alpha/2\pi$	$f=\frac{1}{4}$	$f=\frac{1}{3}$	$f=\frac{1}{2}$	$\alpha/2\pi$	$f=\frac{1}{4}$	$f=\frac{1}{3}$	$f=\frac{1}{2}$
0.1	1.17	1.23	1.37	0.7	3.00	4.33	9.00
0.2	1.37	1.51	1.87	0.8	3.51	5.34	12.34
0.3	1.60	1.87	2.57	0.9	4.11	6.58	16.90
0.4	1.87	2.31	3.51	1.0	4.81	8.12	23.14
0.5	2.19	2.85	4.81	2.0	23.1	66.0	535.5
0.6	2.57	3.51	6.59	3.0	111.	535	1239.0

Belting. The foregoing formula, $P_2/P_1 = \epsilon^{f\alpha}$, applies also. Single (thickness) leather belt varies from 3/16 to 7/32 inch thick; double leather (two thicknesses glued) belt varies from 3/8 to 1/2 inch thick. Cement splices are nearly as strong as the belt; lace joints average about 70% as strong as the belt, and metal fastenings generally less. Working strengths of 400 lbs per sq in for endless (cement spliced) belts and 200 to 300 for laced belts are safe, but smaller values are advised by F. M. Taylor (Trans. Am. Soc. M. E., 1894, vol. 15, p. 204). These figures correspond to about 100 lbs per inch of width for cemented single belt, 50 to 75 for laced single belt, and twice these values for double belt.

The horse-power which a belt transmits is given by $(T-Z)\,Cv/550$, wherein T = total tension in tight side of belt in pounds, v = velocity of belt travel in ft per sec, Z = a quantity depending on centrifugal action (table below), C = a quantity depending on coefficient of friction and angle of wrap on the pulley (table below). The formula is Nagle's (Trans. Am. Soc. M. E., 1881, vol. 2, p. 91) but modified by Kimball and Barr.

For a leather belt which weighs 0.035 lb per cu in when:

v (ft per sec) =	30	60	70	80	90	100	110	120	130	140	150
Z (lbs) =	32.5	47.0	64.2	83.4	105	130	158	188	220	256	293

Values of C, in formula h.p. $=(T-Z)\,Cv/550$

f \ α	90°	100°	110°	120°	130°	140°	150°	160°	170°	180°
0.15	0.210	0.230	0.250	0.270	0.288	0.307	0.325	0.342	0.359	0.376
0.25	.325	.354	.381	.407	.432	.457	.480	.503	.524	.544
0.35	.423	.457	.489	.520	.548	.575	.600	.624	.646	.667
0.45	.507	.544	.579	.610	.640	.667	.692	.715	.737	.757
0.55	.578	.617	.652	.684	.713	.739	.763	.785	.805	.822
1.00	.792	.825	.853	.877	.897	.913	.927	.937	.947	.956

39. Sliding Friction

Kinetic Friction, Friction of Motion, or sliding friction, is the friction between two bodies when sliding actually occurs. The coefficient of kinetic friction for two bodies is the ratio of the kinetic friction to the corresponding normal pressure between them. One of the so-called laws of friction states that the kinetic coefficient is less than the static coefficient and implies that there is a sudden or abrupt change in the values of the coefficients. Experiments by Jenkin and Ewing (Phil. Trans. Roy. Soc., 1877, vol. 167, Part 2) on the kinetic coefficients at speeds as low as 0.0002 ft per sec, about ¾ ft per hour, lead them to conclude that "it is highly probable that the kinetic coefficient gradually increases when the velocity becomes extremely small, so as to pass without discontinuity into the static coefficient." Experiments by Kimball (Am. Jour. Sci., 1877, vol. 13, p. 353) also indicate that there is no abrupt change from static to kinetic coefficient. Moreover they show that the kinetic coefficient may be greater than the static. For dry surfaces, the kinetic coefficient probably decreases progressively from the value of the static coefficient, as the velocity increases as indicated by the following table from Galton and Westinghouse's experiments (Proc. Inst. Mech. Engrs., 1879).

Coefficients of Friction at Various Speeds for Cast-iron Brake Shoes and Steel-tired Wheels

Velocity		Coefficients			Number of tests
Mi per hr	Ft per sec	Max.	Min.	Mean	
0+	0+	....	....	0.330	....
5−	7−	0.340	0.156	.273	20
7.5	11	.325	.123	.244	28
10	14.5	.281	.161	.242	54
15	22	.280	.131	.223	78
20	29	.240	.133	.192	69
25	36.5	.205	.108	.166	70
30	44	.196	.098	.164	94
35	51	.197	.087	.142	80
40	59	.194	.088	.140	70
45	66	.179	.083	.127	77
50	73	.153	.050	.116	55
55	81	.136	.060	.111	67
60	88	.123	.058	.074	12

The foregoing given coefficients were obtained from measurements taken very soon after application of brakes.

The rubbing of dry surfaces abraids them and decreases the kinetic coefficient. The following table shows how this coefficient changed with lapse of time after rubbing began.

Coefficient of Friction as Affected by Time of Rubbing

Cast-iron brake shoes on steel-tired wheels

Miles per hour	Time after applying brakes				
	0+	5 sec	10 sec	15 sec	20 sec
20	0.182	0.152	0.133	0.116	0.099
27	.171	.130	.119	.081	.072
37	.152	.096	.083	.069	....
47	.132	.080	070	....	....
60	.072	.063	058	....	....

The discrepancies between the two tables are due in part to the fact that the values at time 0+ in the second table are averages based on comparatively few experiments. In the second table preceding there is a wide variation from the mean value of the coefficient for each velocity. The variation was due in part at least to differences in intensities of pressure in the various runs of each velocity. In general, the coefficients decrease with increase of intensity.

Coefficients of Friction for Wheels Skidded on Rails

Galton-Westinghouse Experiments

Wheels skidded on rails gave much smaller coefficients than brake shoes, as shown by the adjacent table.

Approximate velocity		Steel tire on	
Ft per sec	Mi per hr	Steel rail	Iron rail
0+	0+	0.242	0.247
10	6.8	.088	.095
20	13.6	.072	.073
40	27.3	.070	....
50	34.1	.065	.070
60	40.9	.057	....
70	47.7	.040	.060
80	54.5	.038	....
88	60	.027	....

Kinetic Coefficients for Brake Shoes

From Experiments by Ernest Wilson (Eng. News, 1909, vol. 62, p. 736)

The adjacent table furnishes additional information on the variation of the kinetic coefficient with the intensity of pressure and on the velocity; also on the influence of water lubrication.

Pivots. Let W = load (lbs), μ = coefficient of kinetic friction, n = speed (r.p.m.), m = moment of the frictional resistance about the axis of the shaft (in-lbs), w = work done against friction per revolution (in-lbs), P = power lost

thru friction (h.p.), dimensions as marked in figures (ins). Flat Pivot (Fig. 158): $m = \frac{2}{3}\mu Wr$; $w = \frac{4}{3}\pi\mu Wr = 4.187\,\mu Wr$; $P = \frac{4}{3}\pi\mu Wrn/396\,000 = \mu Wrn/94\,700$. Collar Bearing (Fig. 159): $m = \frac{2}{3}\mu W(R^3 - r^3)/(R^2 - r^2)$;

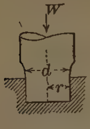

Fig. 158

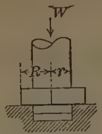

Fig. 159

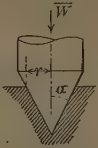

Fig. 160

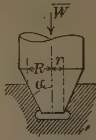

Fig. 161

$w = 2\pi m$; $P = 2\pi mn/396\,000 = mn/63\,000$. Conical Pivot (Fig. 160): $m = \frac{2}{3}\mu Wr/\sin\alpha$; $w = \frac{4}{3}\pi\mu Wr/\sin\alpha$; $P = \frac{4}{3}\pi\mu Wrn/396\,000 \sin\alpha = \mu Wrn/94\,700 \sin\alpha$. Frustrated Conical Pivot (Fig. 161): $m = \frac{2}{3}\mu W(R^3 - r^3)/(R^2 - r^2)\sin\alpha$; $w = 2\pi m$; $P = 2\pi mn/396\,000 = mn/63\,000$.

Journal Friction. The coefficient of journal friction is the ratio of the frictional resistance at the journal to the pressure between journal and bearing. The pressure is not uniformly distributed over the surface of contact between journal and bearing. By nominal (intensity) of pressure is meant the whole pressure divided by product of length and diameter of bearing.

For example, suppose a fly wheel and shaft weighing 6000 lbs are supported midway between two bearings, the diameter of the wheel is 8 ft (or 96 in), that of the journal is 6 in, and that a force of 10 lbs applied to the rim is necessary to overcome friction to maintain a constant speed. Then the frictional resistance is $(10 \times 48) \div 3 = 160$ lbs, 80 at each journal; the pressure at each journal is 3000 lbs, and the coefficient of journal friction is $160 \div 3000 = 0.053$. If the length of bearing is 10 in, the nominal (intensity) of pressure is $3000 \div (6 \times 10) = 50$ lbs per sq in.

Energy lost at journals, work done against friction. Let W = total load on bearing (lbs), d = diameter of journal (ins), f = coefficient of journal friction, n = number of revolutions per minute; then

work done per revolution (ft-lbs) $= fW\pi d/12$
work done per minute ft-lbs $= fW\pi dn/12$
power lost (h.p.) $= fW\pi dn/396\,000 = fWdn/126\,000$

Coefficients of Journal Friction depend on (1) the method of lubrication, (2) the lubricant, (3) its temperature, (4) the velocity of rubbing, and (5) the intensity of pressure (lbs per sq in) on the bearing.

(1) The relative intensities of friction for different methods of lubrication are as follows according to Tower (Proc. Inst. Mech. Engs., 1883) and Goodman (Mechanics Applied to Engineering, 1896).

Method	Tower	Goodman
Bath	1.00	1.00
Saturated pad	....	1.32
Ordinary pad	6.48	2.21
Siphon	7.06	4.20

Tower found that in bath lubrication the load is completely oil borne, in other words that a continuous film separates journal and bearing. For any given pressure there seems to be a minimum velocity below which the oil film will not form. H. F. Moore also found (Am. Mach., 1903) that this pressure-velocity relation is approximately $p = 7.47\sqrt{v}$, p being in lbs per sq in, and v in ft per min. Moore used mineral oil at 90° temperature. The friction then is wholly fluid friction and not solid. (2) In the following table the figures are based on mean actual frictional resistances at the surface of the journal at speed of 300 r.p.m. with all nominal loads from 100 to 310 lbs per sq in; the temperature was 90°; the journal was steel, 4 in diameter and 6 in long; the bearing

a gun-metal brass embracing somewhat less than half the circumference of the journal. The relative frictional resistances for various lubricants, according to Tower, are 1.00 for sperm oil, 1.06 for rape oil, 1.29 for mineral oil, 1.35 for lard oil and olive oil, 2.17 for mineral grease. Tower states also: "the numbers represent the relative thickness or body of the various oils, and also in their order, tho perhaps not exactly in their numerical proportions, their relative weight carrying power. Thus sperm oil, which has the highest lubricating power, has the least weight-carrying power; and tho the best oil for light loads, would be inferior to the thicker oils if heavy pressures or high temperatures were to be encountered." (3) The coefficient decreases with increased temperature; see Figs. 162 and 164. But if the temperature gets so high as greatly to lower the viscosity, the lubricant gets squeezed out and then the coefficient increases. (4) In general the coefficient increases with increase of speed; see Figs. 163 and 165 and accompanying explanations. But at the lower speeds the coefficient may decrease with increase of speed (see Fig. 163). (5) The coefficient decreases with increase of intensity of pressure (see Figs. 163 and 166). But the intensity may become so great that the lubricant gets squeezed out and then the coefficient increases and seizing occurs.

Coefficient of friction

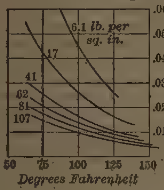

Fig. 162

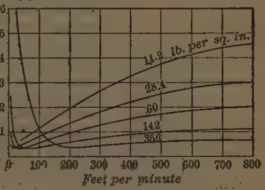

Fig. 163

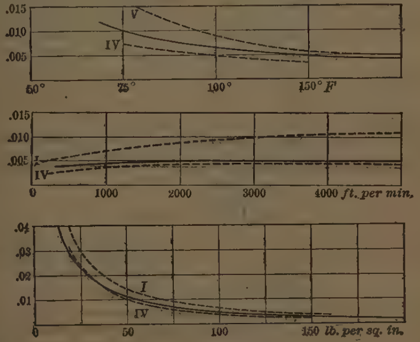

Figs. 164, 165, 166

Figs. 162 and 163 show the relation between coefficient and temperature, and coefficient and velocity. Sellers bearing, length 13 in and diameter 2.75 in; ring oiler; "gas motor oil"; oil temperature 77°; velocity 846 ft per min. (Stribeck, Zeit. Ver. Deutsch. Ing., 1902, vol. 46. p. 1341.) Figs. 164, 165, and 166 show respectively relations between coefficient and temperature, velocity, and pressure. In 164, $p = 92.5$ lbs per sq in and $v = 197$ ft per min; in 165, $p = 92.5$ lbs per sq in and $t = 112°$; in 166, $t = 112°$; and $v = 197$ ft per min. The heavy line represents an average law for forced lubrication on five differ-

ent journals as described below, and the other curves relate to the two journals which departed most widely from the average. (Lasche, Zeit. Ver. Deutsch. Ing., 1902, vol. 46.)

Number	Journal	Bearing
I	steel	white metal
II	nickel steel	white metal
III	nickel steel	mercury alloy
IV	nickel steel	bronze
V	ingot iron	white metal

* For 258 pounds per square inch.

40. Rolling Friction

Rolling Resistance (OR FRICTION). When a roller or wheel is made to roll, the reaction of the roadway has a component opposite to the direction of rolling, and this component is the rolling resistance. Thus R (Fig. 167) represents the reaction of the roadway, and its horizontal component is the rolling resistance. The distance c is called coefficient of rolling resistance. Let W = weight of roller or the load on the roadway and P = driving force; when applied as in Fig. 167, then $Pr = Wc$; when at the top of the roller $P\,2r = Wc$. When a roller is interposed between a load and roadway so that there is rolling resistance at two places, then $P\,2r = W\,2\,c$. Few determinations of the coefficient c have been made; it has been reported as independent of W and r, and also as independent of W but varying with $\sqrt{r}$. "Laws" of rolling

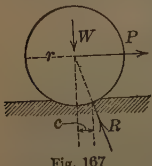

Fig. 167

resistances certainly remain to be established. The following are some reported values of the coefficient of rolling resistance.

Lignum vitæ roller on oak track, 0.019 inch.
Elm roller on oak track, .032.
Cast-iron wheel (20 in diam) on cast-iron rail, 0.018–0.019.
Railroad wheels (39.4 in diam) 0.020–0.022.
Iron or steel wheels on wood track, 0.06–0.10.

Roller Bearings offer less resistance than ordinary bearings. C. H. Benjamin has made a comparison (Machinery, N. Y., Oct., 1905) between the friction in a flexible roller, a solid roller, and ordinary bearing. The speed was 560 revolutions per minute and the loads varied from 113 to 456 lb. Under 470 lb load the flexible bearing developed end thrust of 13.5 lb and the solid roller bearing one of 11 lb.

Coefficients of Journal Friction

Diameter of journal	Flexible rollers			Solid rollers			Babbitt bearing		
	Max.	Min.	Mean	Max.	Min.	Mean	Max.	Min.	Mean
$1\frac{1}{16}$	0.032	0.012	0.018	0.033	0.017	0.022	0.074	0.029	0.043
$2\frac{3}{16}$	.019	.011	.014	......	......	......	.088	.078	.082
$2\frac{7}{16}$	.042	.025	.032	.028	.015	.021	.114	.083	.096
$2\frac{15}{16}$	.029	.022	.025	.039	.019	.027	.125	.089	.107

Stribeck (Zeit. Ver. Deutsch. Ing., 1902, vol. 46, p. 1463) from experiments of four different makes of roller bearings, proposes the following: Let W = load on bearing (lb), n = number of rollers, l = length of each (in), r = radius of convex bearing surface for rollers (in), d = diameter of rollers (in), D = diameter of circle described by centers of rollers (in), $2r+d=D$, c = coefficient of rolling resistance, f = coefficient of friction such that fW = total resistance to turning as tho applied tangentially at surface of bearing and fWr = moment of resistance to turning; then $f=1.2\,cD/rd$, and c has following values:

for $5W/lnd$ =	50	75	100	150	200 lb per sq in
c =	0.0041	.0032	.0028	.0022	.0019 inch

He also states that the resistance of roller bearings is nearly independent of velocity; that the value of the highest roller pressure is 5 times the average, that is, $5\,W/n$; and he proposes as formula for safe load in lbs on the bearing $kldn/5$, where k may be taken from 85 to 155 lbs per sq in for unhardened rollers and bearing surfaces. F. R. Jones proposes (Machine Design, Part II) as formula for safe load for a well-made solid roller journal bearing of six or more rollers $100\,000\,d\text{-}ln/3\,v$, where v is the velocity of the convex bearing surface in ft per min; but values of v less than 50 should not be used in the formula; for such velocity the safe load is practically the same as for $v=50$.

Ball Bearings. Stribeck reports extensive tests (Zeits. Ver. Deutsch. Ing., 1901, vol. 45, p. 121) from which the following is taken. The ball cases were grooves, cross-sections of which were arcs of circles of radius $\frac{2}{3}\,d$, thus affording two points of contact for each ball, $d=\frac{7}{8}$ in, $D=4$ in.

Coefficients of Friction for a Ball Bearing

Load in pounds	Revolutions per minute		
	65	385	780
840	0.0033	0.0035	0.0037
1 870	.0020	.0021	.0022
2 420	.0017	.0018	.0019
3 480	.0016	.0016	.00165
4 500	.0015	.0015	.0015
6 600	.0015	.0013	.0013
10 800	....	....	.0011

Stribeck also states that when the number of balls, n, in a race is between 10 and 20, the greatest pressure on any ball is about $5\,W/n$, where W is the load per race; then if P is the safe load for a single ball, the safe load per race is $Pn/5$. Of course, in a good thrust bearing the load is uniformly distributed among the balls. He also recommends as safe loads per ball $2100\,d^2$ for two-point bearing balls, and from $500\,d^2$ to $750\,d^2$ for three- or four-point bearings.

41. Efficiency of Machines

Efficiency. A machine in operation receives and transmits or deliv energy. The energy received is called input, that transmitted or delive is called output; the latter is also called the useful work of the machi The output is always less than the input, some of the energy miscarry as it were. The difference between output and input is the lost work, simply loss. The efficiency of a machine is the ratio of output to inp The efficiency of a combination or succession of machines, the first receiv energy, transmitting to the second, the second to the third, etc., is the c tinued product of their separate efficiencies.

Efficiency of Some Machine Elements

(Kimball and Barr, Elements of Machine Design.)

Common bearing, singly	96–98
Common bearing, long lines of shafting	95
Roller bearing	98
Ball bearings	99
Spur gear cast teeth, including bearings	93
Spur gear cut teeth, including bearings	96
Bevel gear cast teeth, including bearings	92
Bevel gear cut teeth, including bearings	95
Belting	96–98
Pin-connected chains, as used on bicycles	95–97
High-grade transmission chains	97–99

In some simple machines, the energy is supplied by means of a single force calle effort; for example in a hoisting tackle, the pull applied is the effort. The force ag which the useful work is done is called load; in the illustration the weight of the body is the load. The mechanical advantage of a machine is the ratio of the load effort. While the effort works or acts thru any particular distance, the load acts t definite distance also; the ratio of the former to the latter distance is called the ve ratio of the machine. Mechanical advantage depends on efficiency of the mac velocity ratio does not. In any case mechanical advantage = ve ratio × efficiency.

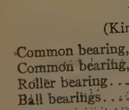

Fig. 168.

Inclined Plane and Wedge. Let W = weight of f = coefficient of static friction, ϕ = angle of repose = of friction and $f = \tan\phi$, α = inclination of plane and clination of P (Fig. 168), θ being positiv as shown and tiv when the inclination of P to the horizontal is less th (1) To start the body up, $P = W \sin(\phi+\alpha)/\cos(\theta$ P is least when $\theta = \phi$, its value then being $W \sin(\phi+\alpha)$. (2) α is greater than ϕ, gravity would overcome friction and the body, prevented by some pull as P, would slip down. To prevent slipping

$$P = W \sin(\alpha-\phi)/\cos(\theta+\phi)$$

P is least when $\theta = -\phi$, its value then being $W \sin(\alpha-\phi)$. When α than ϕ, there is no danger of slipping. To start the body down

$$P = W \sin(\phi-\alpha)/\cos(\theta-\phi)$$

this is least when $\theta = -\phi$, its value then being $W \sin(\phi-\alpha)$. When th is being dragged up, let ϕ = angle of kinetic friction, that is, the angle tangent equals the kinetic coefficient, and e = efficiency. Then

$$e = \sin\alpha \cos(\theta-\phi)/\cos\theta \cdot \sin(\phi+\alpha)$$

e is maximum when P is minimum, that is, when $\theta = \phi$.

To start the wedge (Fig. 169) against the resistances R, $P = 2\,R \tan(\alpha + \phi)$, ϕ being the angle of static friction. If the forces R continue to act and P ceases, the wedge will be pushed up if α is greater than ϕ. If α is less than ϕ, the pull required to start the wedge out is $P = 2\,R \tan(\phi - \alpha)$. The efficiency of the wedge is $\tan \alpha / \tan(\alpha + \phi)$. In Fig. 170 there are three rubbing surfaces here assumed equally rough. To start the wedge in, $P = R \tan(\alpha + 2\,\phi)$ and the efficiency is $(\tan \alpha) / \tan(\alpha + 2\,\phi)$. To pull the wedge out, when α is less than $2\,\phi$, $P = W \tan(2\,\phi - \alpha)$.

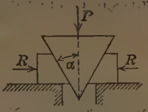

Fig. 169

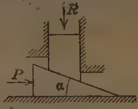

Fig. 170

Screw. Let p = pitch, r = mean radius of screw thread, d = diameter, α = angle of pitch ($\tan \alpha = p / \pi d$), f = static, and μ = kinetic coefficient, and ϕ_s and ϕ_k = the corresponding angles of friction ($f = \tan \phi_s$ and $\mu = \tan \phi_k$). The turning moment required to raise or lower a load W is

$$Wr\,(f \cos \alpha \pm \sin \alpha) / (\cos \alpha \mp f \sin \alpha)$$

the upper sign for raising and the lower for lowering the load. The efficiencies for raising and lowering are $(\tan \alpha) / \tan(\alpha + \phi_k)$ and $[\tan(\alpha - \phi_k)] / \tan \alpha$.

The following table gives highest and lowest efficiencies of some screws tested by Albert Kingsbury (Trans. Am. Soc. M. E., 1896, vol. 17, p. 96). Mean diameter of thread = 1.352 in, pitch = 1/8 in, depth of nut 1 1/16 in, area of rubbing surface of thread about 1 sq in; the threads were cut carefully and worn to good condition before tested; speed about one-half r.p.m. There were 5 screws and 4 nuts as follows: S1 mild steel; S2 wrought iron; S3 cast iron; S4 cast bronze; S5 mild steel, case-hardened; N1 mild steel; N2 wrought iron; N3 cast iron; N4 cast bronze.

Efficiencies of Square Threaded Screws (Kingsbury)

Pressure on thread, lbs per sq in	Lubrication	Highest	Lowest
10 000	machinery oil	0.20, S5 N4	0.11, S3 N3
10 000	lard oil	0.25, S4 N4	0.09, S3 N3
10 000	machinery oil and graphite	0.15, S5 N1	0.03, S5 N4
3 000	machinery oil	0.19, S5 N2	0.11, S2 N4

Tackle. Fig. 171 represents a fixt pulley, Fig. 172 a movable pulley lifting and Fig. 173 a movable pulley lowering the load. Let P = pull in lead line or off side, Q = that in following or on side; then $k = P / Q$, where k is a coefficient always greater than unity. Its value depends on the stiffness or rigidity of the rope and the pin friction; this has been proposed:

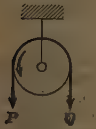

Fig. 171

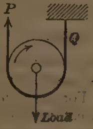

Fig. 172

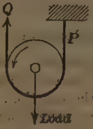

Fig. 173

$$k = 1 + Cd^2/a + 2\,fr/a$$

where d = diameter of rope, a = distance center of pin to center of rope, r = pin radius, f = coefficient of axle or pin friction, C an experimental coefficient. $C = 0.46$ has been recommended for hemp rope; with that value, and $a = 4\,d$, $r = d/2$, and $f = 0.08$,

for d =	1/2	3/4	1	1 1/2 inches
k =	1.08	1.11	1.13	1.19

Some experiments by the American Bridge Co. (Trans. Am. Soc. C. E. 1903, vol. 51, p. 161) indicate that C itself depends on rope diameter. Th following table gives values of C adopted and k computed from the formul preceding with $f=0.08$; values of d, a, and r are in inches.

	Hemp rope				Wire rope
d	1¼	1½	1¾	2	¾
a	3⅞	4⁹⁄₁₆	5⅜	6½	7⅜
r	⅞	1	1⅛	1⅜	2½
C	0.46	0.40	0.38	0.34	1.8
k	1.20	1.21	1.23	1.23	1.15

It may be noted that the pin friction contributes little to the value of k; in the cases abov 0.02 for the hemp and about 0.01 for the wire rope. The efficiencies for a single pull are: if fixt $1/k$, movable lifting $(1+k)/2k$, movable lowering $2/(1+k)$. Following tab gives the ratios of load to pull for tackles of manila rope, as determined by experimen of American Bridge Co., see Engr. Record, 1903, vol. 48, p. 307.

Ratios of Load to Lead-line Pull for Manila Rope

No. of Parts	Diameter of rope in inches							
	¾	⅞	1	1¼	1½	1¾	2	2¼
2	1.93	1.92	1.93	1.92	1.91	1.91	1.91	1.90
3	2.73	2.68	2.74	2.68	2.67	2.64	2.65	2.63
4	3.48	3.37	3.50	3.37	3.36	3.30	3.32	3.28
5	4.12	3.95	4.16	3.95	3.93	3.84	3.87	3.80
6	4.71	4.48	4.77	4.48	4.45	4.33	4.37	4.28
7	5.23	4.92	5.30	4.92	4.89	4.72	4.78	4.65
8	5.71	5.32	5.80	5.32	5.28	5.08	5.14	5.00
9	6.12	5.66	6.23	5.65	5.61	5.37	5.45	5.27
10	6.50	5.96	6.63	5.96	5.91	5.64	5.72	5.52
11	6.83	6.22	6.98	6.21	6.15	5.85	5.94	5.72
12	7.14	6.45	7.30	6.44	6.38	6.04	6.15	5.90
13	7.40	6.64	7.58	6.63	6.56	6.20	6.31	6.04
14	7.64	6.82	7.85	6.81	6.73	6.34	6.46	6.17

Number of parts means number of runs of rope to movable block. Efficiency in cent for any case = ratio divided by number of parts. Example: The fixt and mova blocks of a tackle are each double (two sheaves in each), and the rope is fastened to fixt block; rope diameter is one inch. Then the number of parts is 4 and the load is 3 times the pull; the efficiency is $3.50/4=87.5$ per cent.

42. Muscular Exertion or Labor

Power and Work of Men and Animals. The power or rate of work of any agent (man or beast) depends on several factors, the principal ones which are the duration and form of the exertion. For example, in raising own weight (climbing a stairs) man has worked (against gravity) at the aver rate of 1½ horse-power for 6 seconds; but only at the average rate of ab ⅛ horsepower for a day of 10 hours, and in this case the (necessary) desce were made without effort on his part. In one day a man can do about t times as much work pulling horizontally as in lifting weights.

Daily total work or performance depends on resistance overcome, velo at which it is overcome, and length of the working day. The possible d performance of any agent in any given form of exertion depends on pr choice or adjustment of these three factors. This is well illustrated by a c

brated example developed by Dr. J. F. Taylor: At a certain steel works the regular performance of men loading pig iron onto cars from piles on the ground was 12½ tons per day; the men best adapted to such labor were induced to work according to a suitable program of working and resting, whereby their output reached 47½ tons per day. It may be noted that this performance was not all work in the mechanical sense, but partly transport, see following paragraphs.

In trials, horses have overcome resistance equal to one-half their own weight thru 100 ft of distance. A draft or resistance of one-fourth the weight of the horse is regarded as heavy. For steady work during a day of 10 hours, a draft equal to $^1/_{10}$ to $^1/_8$ of the weight of the horse exerted at 2.5 miles per hour, is regarded as full demand on the animal. Under these circumstances a 1000-lb horse works at 0.67 to 0.83 horsepower.

The following two tables in the main are from Rankine on the authority principally of Coulomb, Navier and Poncelet.

Work by Man and Horse

Kind of Exertion	R	v	Rv	T	Rvt
Man					
1. Raising own weight up stair or ladder	143	0.5	72.5	8	2 088 000
2. Hoisting weight with rope and pulley	40	0.75	30	6	648 000
3. Lifting weights by hand	44	0.55	24.2	6	522 720
4. Carrying weights upstairs, returning unloaded	143	0.13	18.5	6	399 600
5. Shovelling up earth to height 5 ft 3 in	6	0.13	7.8	10	280 800
6. Wheeling earth in barrow up slope 1 : 12, returning unloaded	132	0.075	9.9	10	356 400
7. Pushing or pulling horizontally (capstan or oar)	26.5	2.0	53	8	1 526 400
8. Turning a crank or winch	12	5.	62.5	?	
	18	2.5	45	8	1 296 000
9. Working a pump	20	14.4	288	2 min.	
	13.2	2.5	33	10	1 188 000
10. Hammering	15	?	?	?	480 000
Horse					
11. Cantering and trotting, drawing light railway carriage	22½	14⅔	447⅔	4	6 444 000
	30½				
12. Walking, drawing cart or boat	50				
	120	3.6	432	8	12 441 000
13. Walking, drawing a gin or mill	100	3.0	300	8	8 640 000
		6.5	429	4½	
14. Trotting, drawing a gin or mill	66	......	......	......	6 950 000

Explanation of Table. R = resistance overcome in pounds; v = effective velocity in feet per second, or distance through which R is overcome divided by total time occupied, including time of moving unloaded if any; Rv = effective power, foot-pounds per second; T = hours per working day; Rvt = daily work, in foot-pounds. In item 6, 132 is the weight of earth in the barrow, and .075 is the vertical velocity of the laborer when pushing the loaded barrow. Therefore Rv and Rvt (for this item) do not include all the mechanical work done by the laborer.

Transport by Men and Draft Animals. When a man stands and support a load on his back he is subject to more or less fatigue and ordinarily he regard himself as working. But he is doing no work in the technical or mechanica sense, "overcoming resistance thru distance." When he is walking under thi load, he does some mechanical work, for he lifts the load slightly at each step but even this is a small part of his exertion. In order to express amount o exertion involved in transporting loads horizontally, where the main effort i to support the load, Rankine uses product of load and distance transported, an he calls the product transport. Thus like work transport is product of forc and distance but in the latter case the force and distance are at right angles t each other, whereas in the former they are directed along the same line. Trans port then may be exprest in foot-pounds. Railroad traffic engineers use similar concept, freight (hauled) or traffic, and measure it in ton-miles.

Transport by Man and Horse

Kind of Exertion	L	v	Lv	T	Lvt
Man					
1. Walking unloaded, transferring own weight	140	5	700	10	25 200 000
2. Carrying burden, returning unloaded	140	$1\frac{2}{3}$	233	6	5 032 800
3. Traveling with burden	90	$2\frac{1}{2}$	225	7	5 670 000
4. Carrying burden, 30 seconds only	252	0	0		
	126	11.7	1574.2		
	0	23.1	0		
5. Wheeling load L in 2-wheeled barrow, returning unloaded	224	$1\frac{2}{3}$	372	10	13 428 000
6. Wheeling load L in 1-wheel barrow, returning unloaded	132	$1\frac{2}{3}$	220	10	7 920 000
Horse					
7. Carrying burden, walking	270	3.6	972	10	34 992 000
8. Carrying burden, trotting	180	7.2	1 296	7	32 659 200

Explanation of Table. L is the weight or load transported in pounds; v is "effecti velocity" as in preceding table; Lv = rate of transport in foot-pounds per second; T hours per working day; and Lvt = transport in foot-pounds per day.

CHEMISTRY

1. The Chemical Elements

The following atomic weights were published by the International Committee on Atomic Weights in 1917. No table appeared in 1918.

Names of the more important elements, including those of metallurgical interest, are in SMALL CAPITALS.

Name	Symbol	Atomic weight	Nature
ALUMINUM	Al	27.1	Metal
ANTIMONY (stibium)	Sb	120.2	Metal
Argon	A	39.88	Inert gas
ARSENIC	As	74.96	Metalloid
BARIUM	Ba	137.37	Metal
Bismuth	Bi	208.0	Metal
Boron	B	11.0	Metalloid
Bromine	Br	79.92	Liquid
Cadmium	Cd	112.40	Metal
CALCIUM	Ca	40.07	Metal
CARBON	C	12.005	Metalloid
Cerium	Ce	140.25	Metal
Cesium	Cs	132.81	Metal
CHLORINE	Cl	35.46	Gas
CHROMIUM	Cr	52.0	Metal
Cobalt	Co	58.97	Metal
Columbium (Niobium)	Cb	93.1	Metal
COPPER (cuprum)	Cu	63.57	Metal
Dysprosium	Dy	162.5	Metal
Erbium	Er	167.7	Metal
Europium	Eu	152.0	Metal
FLUORINE	F	19.0	Most active gas
Gadolinium	Gd	157.3	Metal
Gallium	Ga	69.9	Metal
Germanium	Ge	72.5	Metal
Glucinum (Beryllium)	Gl	9.1	Metal
GOLD (aurum)	Au	197.2	Metal
Helium	He	4.00	Inert gas
Holmium	Ho	163.5	Metal
HYDROGEN	H	1.008	Lightest gas
Indium	In	114.8	Metal
Iodine	I	126.92	Metalloid
Iridium	Ir	193.1	Metal
IRON (ferrum)	Fe	55.84	Metal
Krypton	Kr	82.92	Inert gas
Lanthanum	La	139.0	Metal
LEAD (plumbum)	Pb	207.20	Metal
Lithium	Li	6.94	Lightest metal
Lutecium	Lu	175.0	Metal
MAGNESIUM	Mg	24.32	Metal

Name	Symbol	Atomic weight	Nature
MANGANESE	Mn	54.93	Metal
MERCURY (hydrargyrum)	Hg	200.6	Metal
MOLYBDENUM	Mo	96.0	Metal
Neodymium	Nd	144.3	Metal
Neon	Ne	20.2	Inert gas
NICKEL	Ni	58.68	Metal
NITROGEN	N	14.01	Gas
Osmium	Os	190.9	Metal
OXYGEN	O	16.00	Gas
Palladium	Pd	106.7	Metal
PHOSPHORUS	P	31.04	Metalloid
Platinum	Pt	195.2	Metal
POTASSIUM (kalium)	K	39.10	Metal
Praseodymium	Pr	140.9	Metal
Radium	Ra	226.0	Metal
Rhodium	Rh	102.9	Metal
Rubidium	Rb	85.45	Metal
Ruthenium	Ru	101.7	Metal
Samarium	Sa	150.4	Metal
Scandium	Sc	44.1	Metal
Selenium	Se	79.2	Metalloid
SILICON	Si	28.3	Metalloid
SILVER (argentum)	Ag	107.88	Metal
SODIUM (natrium)	Na	23.00	Metal
Strontium	Sr	87.63	Metal
SULFUR	S	32.06	Metalloid
TANTALUM	Ta	181.5	Metal
Tellurium	Te	127.5	Metalloid
Terbium	Tb	159.2	Metal
Thallium	Tl	204.0	Metal
Thorium	Th	232.4	Metal
Thulium	Tm	168.5	Metal
TIN (stannum)	Sn	118.7	Metal
TITANIUM	Ti	48.1	Metal
TUNGSTEN (Wolfram)	W	184.0	Metal
Uranium	U	238.2	Metal
VANADIUM	V	51.0	Metal
Xenon	Xe	130.2	Inert gas
Ytterbium (Neoytterbium)	Yb	173.5	Metal
Yttrium	Yt	88.7	Metal
ZINC	Zn	65.37	Metal
Zirconium	Zr	90.6	Metal

A Chemical Element is a substance that cannot by any means at our disposal b separated into two or more different substances. CHEMICAL COMPOUNDS are pure sub stances which can, by chemical means, be separated or decomposed into different element

or which can be made by combining different elements. The MOLECULES of a compound are regarded as aggregates of smaller particles of the elements, known as ATOMS, into which the compound can be broken up, the atoms of any given element being regarded as all precisely alike in every respect. The atoms are considered the smallest mass-elements which occur separately in the structure of molecules of either compounds or elementary substances, so far as can be determined by ordinary analysis. The molecule of an element consists of a definite (usually small) number of its atoms. The molecule of a compound consists of one or more atoms of each of its several elements, the numbers of the various kinds of atoms and their arrangement being definite and fixt, and determining the character of the compound.

2. Chemical Reactions

A Chemical Compound is represented by means of the symbols of the elements concerned. Thus, HCl, hydrochloric or muriatic acid gas, indicates a compound made up of one atom each of hydrogen and chlorine; NaOH, sodium hydroxide or caustic soda, contains sodium, oxygen, and hydrogen. The elements do not always combine atom for atom, as in these examples, but several atoms of each of different kinds may combine; as, H_2O, water; HNO_3, nitric acid; Na_2SO_4, sodium sulfate, etc. Each of these formulas represents a molecule or the smallest portion of the compound that can exist. Chemical reactions are represented by means of equations thus: $2\ H + O = H_2O$ represents the formation of water by the union of two atoms of hydrogen with one of oxygen. $CaCO_3 + 2\ HCl = CaCl_2 + H_2O + CO_2$ indicates that when one molecule of calcium carbonate ($CaCO_3$) is acted on by two molecules of hydrochloric acid, the products formed are calcium chloride, water, and carbon dioxide gas. The masses of the atoms of different elements are found to bear constant, definite ratios to one another. Oxygen, which is taken as the standard, has an atomic mass of 16. The atomic weight of carbon is 12, which means that its atom has $12/16 = 3/4$ the mass of an atom of oxygen. So, too, the atomic mass of bismuth is $208 = 208/16 = 13$ times that of oxygen.

When two or more elements unite, the molecule of the compound formed must have a mass equal to the sum of the masses of the constituent atoms. The molecular mass of phosphorus pentoxide, P_2O_5, for instance, can be calculated as follows: $2\ P = 2 \times 31.04 = 62.08$, and $5\ O = 5 \times 16 = 80$; therefore $P_2O_5 = 62.08 + 80 = 142.08$. A chemical equation can be interpreted not only qualitatively but quantitatively, and from the relative masses of the atoms of the reacting substances the amount of each product formed may be calculated. The equation $C + 2\ O = CO_2$ means, then, that one atom of carbon (atomic weight = 12.005) combines with two atoms of oxygen to form one molecule of carbon dioxide (carbonic acid gas). This molecule must have the molecular weight $12.005 + (2 \times 16) = 44.005$. In other words 12.005 parts by weight of carbon yield 44.005 parts by weight of carbon dioxide. When calcium carbonate (limestone) is heated we get quicklime and carbon dioxide, as represented thus: $CaCO_3 = CaO + CO_2$. Consulting the table of atomic weights it is seen that $40.07 + 12.005 + (3 \times 16) = 100.075$ parts of calcium carbonate will yield $40.07 + 16 = 56.07$ parts of quicklime and $12.005 + (2 \times 16) = 44.005$ parts of carbon dioxide. Or, to get 56.07 parts of lime 100.075 parts of calcium carbonate are required. In other words, 1 ton of pure limestone will yield the amount of lime determined by the proportion $100.075 : 56.07 :: 1$ ton : $x = 0.56$ ton. Or the amount of material required to produce 1 ton of lime may be calculated as follows: $100.075 : 56.07 :: x : 1$ ton. Here $x = 1.78$ tons of calcium carbonate. These calculations assume that the materials are free from moisture and other impurities. A limestone containing only 90 percent of calcium carbonate would yield only 90 percent as much actual quicklime tho the weight obtained would be equal to that of the quicklime plus the mineral impurities not driven off in burning.

Classification of the Elements. The chemical elements are usually divided roughly into base-forming and acid-forming. These correspond, in general, with the metals and non-metals or metalloids. This division does not hold strictly, for there are many metals that yield compounds with

acid properties and some of the metalloids form bases. Acids are compounds of the elements with hydrogen and often with oxygen also. The hydrogen can be replaced by metals, forming salts. Bases are compounds of metals with oxygen and hydrogen. When a base and an acid react, the hydrogen and oxygen of the base combine with the hydrogen of the acid to form water, while the metal and the remainder of the acid combine to form a salt. Thus, sodium hydroxide, $NaOH$, combines with HCl, hydrochloric acid, to form H_2O, water, and $NaCl$, sodium chloride (common salt): $NaOH + HCl = H_2O + NaCl$. Another example is the action of sulfuric acid, H_2SO_4, upon calcium hydroxide (slaked lime), CaO_2H_2, the products being calcium sulfate, $CaSO_4$, and water: $CaO_2H_2 + H_2SO_4 = CaSO_4 + 2H_2O$.

It will be noticed that the sodium atom of sodium hydroxide replaces the hydrogen atom of hydrochloric acid, while in calcium sulfate a calcium atom has replaced two hydrogen atoms of sulfuric acid. Other metal atoms have the power of replacing still more hydrogen atoms of acids, as shown by the compounds aluminum chloride, $AlCl_3$, and platinic chloride, $PtCl_4$. Any atom which can be combined with or substituted for a single hydrogen atom is said to be univalent, hydrogen being the standard univalent atom. Any atom, e.g. oxygen or calcium which can replace or combine directly with two univalent atoms, is said to be bivalent, etc. The number of univalent atoms which any given atom can replace or directly combine with is known as valence of the given atom. We say that chlorine is uni- (mono-) valent because it forms the compound HCl; oxygen in water, H_2O, is bi- (di-) valent; nitrogen in ammonia, NH_3, is tri- (ter-) valent; carbon in methane, CH_4, is quadri- (tetra-) valent. The metal calcium is said to be bivalent because it combines with two atoms of chlorine to form $CaCl_2$ or one atom of oxygen to form CaO. A more complex instance is aluminium oxide, Al_2O_3. Here three oxygen atoms having the combined valence 6 unite with two aluminium atoms, the valence of each of the latter being ½ of $6 = 3$.

A given element may have different valences in different compounds. Copper, for instance, forms two chlorides, $CuCl$ and $CuCl_2$, in which its valence is 1 and 2 respectively. Sulfur yields the oxides SO_2 in which its valence is 4, and SO_3 in which it is 6.

3. Chemistry of Lime and Plaster

Quicklime, or calcium oxide (CaO), is made by heating limestone, marble, or shells (oysters, etc.) to a high temperature in kilns. The calcium carbonate ($CaCO_3$), of which the raw material is mainly composed, loses carbon dioxide gas (CO_2), leaving behind calcium oxide mixt with mineral impurities either in their original state or as new compounds formed at the high temperature of the kiln. SLAKED LIME, or calcium hydroxide (CaO_2H_2), is formed by the direct combination of quicklime with water. When only a little more than the exact amount of water necessary for the reaction is used, the slaked lime may be obtained as a fine, dry powder. Great heat is evolved at the same time, and fires have been caused by the accidental wetting of stored quicklime. Lime exposed to the air readily absorbs moisture, forming calcium hydroxide, and this then takes up carbon dioxide, which regenerate calcium carbonate. Hence, air-slaked lime is a mixture of calcium hydroxide and calcium carbonate, or if sufficient time has elapsed, calcium carbonat alone. As air-slaked lime is of no value for mortar, all quicklime should b tested before use by placing several lumps in a little water to see whether i slakes readily.

In making common mortar, a considerable excess of water is used, so that the sand ma be more thoroly incorporated with it and to give a better bond with the bricks. The fir setting of mortar is due to loss of the excess water, partly by evaporation, but mainly b its being absorbed by the pores of the bricks. The carbon dioxide of the air also begi to change the outer layer into calcium carbonate. This action proceeds more rapid as the mortar becomes drier and more porous, until finally only calcium carbonate and t sand are left. The mortar in very old buildings contains considerable calcium silica formed by the slow action between the calcium carbonate and the silica of the sand.

The dampness of recently plastered walls is largely due to the water formed by the action of carbon dioxide on slaked lime ($CaO_2H_2 + CO_2 = CaCO_3 + H_2O$). The burning of charcoal in such rooms hastens the drying, not so much by raising the temperature as by furnishing carbon dioxide in much larger amount than is normally present in the air.

Plaster of Paris is made by heating natural gypsum, a form of calcium sulfate containing "water of crystallization" ($CaSO_4$), to about 125° C. until three-fourths of the water has been driven off. The resultant plaster is chiefly $CaSO_4 . \frac{1}{2} H_2O$, with some $CaSO_4$. It sets very rapidly when mixt with the proper amount of water. When gypsum is burnt at higher temperatures than 125° C., it loses more and more of its water and sets with increasing slowness. At 200° C., it loses all its water and becomes "dead-burnt," having lost its power of setting.

The setting process seems to be due to the solution of part of the $CaSO_4 . \frac{1}{2} H_2O$, which then combines with water to re-form $CaSO_4 . 2 H_2O$, which is less soluble and crystallizes out in the form of fine needles. More of the $CaSO_4 . \frac{1}{2} H_2O$ then dissolves, and so on, until the reaction is complete, each successive lot of crystals interlacing with those previously formed. The setting is accompanied by about one percent increase of volume, which accounts for the sharp outlines obtained in making plaster casts. Theoretically, plaster should be mixt with a little more than 18.3 percent of its weight of water, but twice as much as this is at times used to increase its plasticity and to retard its setting. The hardness of plaster may be increased by mixing it with solutions of alum, borax, and so forth.

Stucco is simply plaster mixt with a dilute solution of glue; it sets comparatively slowly. Floor plaster is made by heating gypsum to much higher temperatures than that at which plaster of Paris is made, it being changed first into "dead-burnt" plaster and then into another modification known as "floor" or "estrich" plaster. The product formed is probably a basic sulfate of calcium or else a mixture of calcium sulfate and oxide. It requires several days to set, which it does with no change of volume, forming a mass considerably harder and stronger than ordinary plaster.

4. Combustion and Fuels

Carbon is the principal constituent of solid, liquid, and gaseous fuels, it being either free, as in charcoal and coke, or combined with hydrogen, oxygen, or with both. In burning, the carbon and hydrogen combine with oxygen from the air, yielding, when combustion is complete, carbon dioxide and water vapor. When insufficient air is admitted over the bed of fuel, or into the fire-box when liquid or gaseous fuels are used, much of the fuel may be lost, either as free carbon (smoke, soot) or in the form of unburned gases, especially carbon monoxide. It is almost impossible to attain complete combustion of solid fuels by forcing air under the grate and thru the bed of coals, because part of the carbon dioxide formed near the grate is reduced to carbon monoxide on passing thru the overlying layers of hot fuel. This monoxide, which has a high heating value, can be burned completely only when a plentiful supply of air is admitted over the bed of fuel. The blue flames seen when anthracite, coke, or charcoal is burned are due to carbon monoxide.* It is not economical to supply sufficient air by forced draft thru the fuel, because the excessive temperatures rapidly burn out the grate bars, and also because of the increased mechanical wear on the boiler tubes due to the greater number of fine particles of coal and ash driven thru them.

Wood consists mainly of lignin and cellulose, compounds of carbon with hydrogen and oxygen, together with varying amounts of water and mineral matter. The latter largely remains behind in the ash.

Charcoal is made by piling wood into heaps which are covered with earth, leaving a few small openings to admit a limited amount of air and allow the products of combustion to escape when the wood is ignited. When sufficient

wood has burned to insure thoro charring ("destructive distillation") of the remainder, the openings are closed and the pile allowed to cool completel By this method of making charcoal only a little tar is obtained and all th volatile constituents are allowed to escape. When wood is heated in close retorts, large amounts of tar, creosote, wood or methyl alcohol, acetone, an pyroligneous (acetic) acid, etc., are obtained. The yield of charcoal is al nearly doubled. Charcoal consists of carbon and the mineral matter of th wood. Its value in metallurgy is due to its low content of phosphorus an sulfur. The calorific value of charcoal is about 75 percent that of anthracit

Peat is formed by the partial decay of mosses and other bog plants under wat Even when comprest and dried it contains much water and its mineral content may high. Its calorific value is 3000 to 4000 cal per kg.

Lignite, or brown coal, is a stage beyond peat in the formation of coal. It contai much moisture and ash and is often high in sulfur content. Its calorific value is 4000 5500 cal per kg. Owing to its large amount of volatile matter, lignite burns with a lo smoky flame.

Bituminous Coal is formed by the further transformation of lignite by he and pressure. It comprises many varieties, including gas, coking, steam, a cannel coals. They differ principally in their content of volatile matter, t "fat" coals having at times as high as 50% of compounds of carbon and hydr gen, which are readily driven off by heating. The length of flame of burni bituminous coal depends on the percentage of volatile matter.

Anthracite Coal. Produced by the further action of heat and pressu upon bituminous coal, whereby nearly all the volatile constituents are driv off, leaving mainly carbon and mineral matter. These coals burn with lit flame and smoke, and do not cake. Their calorific value may be 9000 to 9 cal per kg.

Coke. As charcoal is the residue left by heating wood in retorts or partia burning it with a limited air supply, so coke is made by heating bitumin coals. In some types of coke ovens the gaseous and liquid products form by the destructive distillation are allowed to escape into the air; with ot types of ovens this loss is not permitted and valuable by-products are obtain such as ammonia, fuel and illuminating gas, and coal tar. Coke is mai carbon, but contains also the mineral constituents of the coal. It is low volatile matter and sulfur. Upon this and its infusibility and resistance crushing depends its value as a fuel in blast furnaces. Its calorific va is about 90 per cent that of the much more expensive anthracite.

Chemical Examination of Coal and Coke. The heating value of any can be determined conveniently by means of one of the numerous form bomb calorimeters. But this leaves unanswered many questions which h a very practical bearing, for example the percentages of volatile mat sulfur, and ash, and the amount of coke the coal will yield. In gene the lower the percentage of ash the better the quality of the fuel. The mineral constituent that has any heating value is the sulfur of pyr But as sulfur is injurious in practically all metallurgical operations and oxides of sulfur have a corroding effect upon boiler tubes, etc., a coal in either pyritic or organic sulfur is undesirable. Gas coals and coal use in certain metallurgical operations requiring long reducing flames sh be high in volatile matter. Coals that are to be worked economically coke may be low in volatile matter, but must possess the property of part fusing or caking together when heated in the ovens.

In taking samples, for calorimetric determinations or for chemical analysis, the acce method is to select a large number of pieces, representing as nearly as possible in etc., the whole load. These must be chosen from all parts of the coal to be tested and t

from the top and down thru the whole mass. These lumps should then be broken into nearly uniform size, thoroly mixt together, and a smaller sample obtained by "quartering." If this sample is still too large it should be further broken up and again quartered until a sample that can readily be enclosed in air-tight jars is obtained. In sampling at the mine, the coal should be cut from a freshly exposed face, and the sample, after quartering to suitable size, should fairly represent not only the actual coal but also the interpenetrating veins of shale, etc., if these are regularly mined with the coal. It is very important to prepare the sample, not only with great care but also as rapidly as possible, to minimize the inevitable loss of moisture in breaking up the lumps. This explains the necessity of placing the fuel sample in air-tight receptacles, such as fruit jars with rubber rings. The volatile matter in coal is highly explosive when mixt with air in the proper proportion, so that care should be taken to ensure thoro ventilation of all places where coal, especially bituminous, is stored.

5. Liquid and Gaseous Fuels

Crude Petroleum is the most important of the liquid fuels. It owes its importance not only to its comparative cheapness but also to the ease with which it is handled and its high efficiency, which is two or more times that of anthracite. It is usually burned in the form of a spray obtained by means of a blast of air or superheated steam. Petroleum residues and coal-tar residues are also burned to some extent. Their calorific value is not as great as that of crude petroleum, but may run as high as 16 000 cal.

Gasoline is one of the lower-boiling distillates obtained from crude petroleum. It consists of a mixture of several hydrocarbons containing varying percentages of carbon and hydrogen. Its value as a fuel depends on its great volatility. When mixt with the proper amount of air the vapors form a mixture which is readily ignited and burns with explosive violence. If the vapor is largely in excess of the proportion needed for complete combustion the force of the explosion is weakened, so that, apart from the actual loss of unburned gases, the fuel is not used economically. There is a similar loss in power when too much air is present. For the complete combustion of one cubic foot of the vapor of the hydrocarbon hexane, C_6H_{14}, 45.2 cubic feet of air are required, while the same volume of heptane (C_7H_{16}) vapor requires 52.4 cubic feet of air, or 16 percent more.

Denatured Alcohol as a fuel for explosion engines is used to only a very limited extent at present. Whether or not it can ever compete successfully with gasoline will depend on its cost, relative efficiency, etc. Denatured alcohol is grain alcohol which has been rendered unfit for drinking by the addition of bone oil, wood alcohol, or other ill-smelling substances prescribed by law.

Natural Gas is the most efficient as well as the cheapest of all fuels, tho its use is of course limited by the distance to which it can be economically piped. It consists mainly of methane, CH_4, with 10 percent or less of hydrogen and other gases. Methane is also known as marsh gas, from its abundant formation when vegetable matter decays under water. The name fire damp refers to its occurrence in coal mines, where it is one of the causes of explosions.

Coal Gas, which is made by distilling bituminous coal in retorts, contains 80 to 85 percent of a mixture of nearly equal parts of hydrogen and methane, with much smaller amounts of oxygen, nitrogen, carbon monoxide and dioxide, etc. It is used to some extent in gas engines, and as a fuel.

Water Gas is formed by the action of superheated steam upon white-hot coal or coke. The steam gives up its oxygen to the carbon of the fuel, forming carbon monoxide, CO, and leaving hydrogen, thus, $C + H_2O = CO + 2\ H$. The reaction is endothermic, that is, it requires the addition of heat, so that it is necessary to cut off the steam every few minutes and reheat the fuel by an air blast. Water gas consists of about 45 percent each of hydrogen and carbon monoxide, with small percentages of oxygen, nitrogen, carbon

dioxide, etc. The first two gases burn with very hot, non-luminous flames. For use a
an illuminant it must be "enriched" with naphtha or other similar oil.

Producer Gas is made in much the same way as water gas, except that only air and n
steam is past thru the incandescent coal or coke. The carbon is burned to carbo
monoxide, which makes about 25 percent of the gas. Small amounts of hydrogen
methane, and carbon dioxide are present. There is also nearly 65 percent of nitroge
from the air which is used. This is unavoidable, tho the presence of such a large amoun
of inert gas reduces the thermal efficiency. The reaction whereby carbon is burned t
carbon monoxide is accompanied by the evolution of about one-third the total heatin
value of the fuel. It is evident that if the gas can be burned without allowing it to coo
a great saving of heat can be effected. This is not always feasible and it is the practis
with some forms of producers, to pass some steam with the air, thus making a mi
water-producer gas. The heat which would otherwise be lost is used up in forming wat
gas, and the resultant fuel gas has an increased fuel value. It is much more economic
to convert the fuel into producer gas and use it in explosion engines than to burn it und
steam boilers.

6. Explosives

The Fundamental Property of an explosive is that when ignited or su
jected to a sudden shock it shall decompose, or its components rea
suddenly yielding a relatively large volume of highly heated gas. Th
definition includes not only gunpowder, nitroglycerin, and similar substanc
but mixtures of inflammable gases and vapors with air; or even coal dust, fi
sawdust, or flour suspended in the air. The last three have all been the cau
of disasters, the reason being that when some of the particles are ignit
the flame is rapidly communicated to adjacent ones, yielding large volum
of highly heated gaseous products of combustion, in addition to which t
surrounding air is also heated. Thus, one gram of anthracite, of speci
gravity 1.5, occupies a volume equal to only ⅔ cubic centimeter. If it co
tains 95 percent of carbon, it will yield when burnt about 1761 cc, or 2642 tim
its own volume, of carbon dioxide measured at 0° C. and 760 mm pressu
If suspended as dust in a large volume of air and burned in a fraction o
second, it is evident that the large amount of hot gases must expand w
explosive violence.

Gunpowder is a mixture of 75 parts by weight of saltpeter, or potassiu
nitrate, 15 parts of charcoal, and 10 parts of sulfur, made by grinding
ingredients together with enough water to moisten the mass. It is th
comprest into a cake and broken into grains, which are glazed by revolv
with graphite and sorted into sizes by sieves. The larger grains are used
blasting, and the smaller ones for small arms. BLASTING POWDER is frequen
made with the cheaper Chile saltpeter, or sodium nitrate, which produce
cheaper and less powerful powder than that made from ordinary saltpe
Chile saltpeter, however, has the disadvantage of absorbing moisture fr
the air, and powder made from it cannot be kept too long or stored in a da
place. The proportions used are 73 parts of Chile saltpeter, 16 parts
charcoal, and 11 parts of sulfur.

Guncotton, Nitrocellulose, typical of the second class of explosives, is m
by the action of a mixture of nitric and sulfuric acids upon cotton. W
only moderately strong acids are allowed to act on the cotton for a sl
time, the product is pyroxylin, or soluble nitrocellulose, used for mak
collodion and celluloid. By longer action with more concentrated ac
guncotton is formed. It is then washt in a machine of the kind used
making paper pulp to remove all traces of acids that might cause spontane
explosions. While still moist, it is comprest into blocks or sticks. G
cotton is usually stored and transported in a moist condition, and can be

ploded without drying. It is comparatively safe to handle, as ordinary shocks do not explode it readily. In the open, it burns with extreme rapidity.

Nitroglycerin is made by the cautious addition of glycerin to a well-stirred and cooled mixture of the strongest nitric and sulfuric acids. The oily product is washt to remove all traces of acids that might cause spontaneous explosion. Under the most favorable conditions, nitroglycerin is not safe to handle. The fact that it is a liquid with consequent liability to leakage from containers greatly increases the danger of transportation and storage. For this reason, it is commonly mixt with some absorbent or transformed into a gelatinous mass.

Dynamite is a mixture of nitroglycerin with infusorial earth, powdered "rottenstone," or similar porous material, known as "dope." Instead of these inactive dopes that take no part in the explosion, explosive mixtures are often used to absorb the nitroglycerin. Gunpowder is one of these. Dynamite consisting of 40 percent nitroglycerin, 44 percent sodium nitrate, 15 percent wood pulp, and 1 percent calcium carbonate, is an example of dynamite with an active dope.

Explosive gelatin is a jelly-like mass made from a solution of soluble nitrocellulose in nitroglycerin. Too powerful for common work; it is used with success for very hard rock in tunnels. Gelatin dynamite is a mixture of explosive gelatin with a dope such as sodium nitrate and wood pulp; it is not so powerful as the straight gelatin. Smokeless powder is a general term covering many modifications of explosive gelatin, and mixtures of nitrocellulose with nitrobenzene, etc.; they are usually given fanciful names, as ballistite, cordite, indurite, and so forth. Nitroglycerin and mixtures containing it are all liable to freeze at moderately low temperatures. They cannot be used satisfactorily in that condition, and should not be thawed by placing them near a fire or on steam pipes but by leaving them in a warm chamber kept at a temperature not over 90° F.

Picric Acid, or trinitrophenol, is made by the action of nitric and sulfuric acids upon phenol (carbolic acid). It is a yellow, crystalline substance, formerly used only as a dye for silks and so forth. For years it was not known as an explosive, but it is now known that it will explode with great violence when detonated. If ignited, it usually burns without exploding and is not very susceptible to shock. Lyddite, melinite, and shimose are composed of picric acid. Some of the salts, or picrates, are exploded by slight blows.

Nitrocellulose, Nitroglycerin, and Nitrostarch, are true nitrates, as they all contain the atomic group NO_3. They are chemically quite different from the true nitro-compounds, such as picric acid, which contain the atomic group NO_2. Benzene, toluene, naphthalene, and other substances obtained from coal tar yield nitro-compounds when treated with nitric acid. The best known of these is trinitrotoluene, or "TNT," which was used in such enormous quantities in the great war. These are all more or less unstable and are used as components of explosives, mixt either with ammonium nitrate or other nitrates, or with chlorates, which are good oxidizing agents, or they may be used in dynamite because they lower the freezing point of the nitroglycerin. Rack-a-rock, roburite, bellite, and securite are typical of the explosives made from these nitro-compounds and oxidizing agents.

A Detonator contains a high explosive, too powerful and unstable to be employed alone, which by its sudden disruptive force brings about the instantaneous explosion of a large amount of a more stable explosive. The ones commonly in use consist of copper capsules containing a definite amount of a mixture of chlorate of potash and mercury fulminate, which is exploded either by a fuse or a wire heated electrically. The fulminate is made by mixing a solution of mercury in strong nitric acid with alcohol. The gray, crystalline powder which is precipitated must be well washed to remove all acid. It is sensitive to shock and may explode even when wet.

Explosives must be selected with reference to the character of the work. For quarryi[ng] building stone, those that act slowly, with little shattering effect, must be chosen. Wh[en] the stone is to be crushed after quarrying, or for breaking up rock so that it can be handl[ed] by a steam shovel, a quick shattering effect is desired. In all open work, the charact[er] of the gases arising from the explosion may be disregarded, but in tunnels or min[es] especially if not well ventilated, this factor is of great importance. No explosive is abs[o]lutely safe in this respect. In coal mines, where the presence of fire damp (methan[e]) is a menace, no explosive giving a long flame or a high heat of detonation should [be] used. Even in the absence of gas, there is danger of igniting the coal dust.

Explosives should be stored in a dry place so that the sodium or ammonium nitra[te] will not take up enough moisture to lessen their power. But if in too dry a place, th[ey] may lose the moisture they naturally contain, which will change their speed of explosi[on] and thus modify the character of the results obtained. Explosives should not be sto[red] for a longer time than absolutely necessary, on account of the possibility of chemi[cal] changes taking place in the nitro-compounds most of them contain.

PHYSICS

7. Physical Properties of Solids

The properties of substances nominally the same differ so widely tha[t it] would be misleading to give more than two or three significant figures [in] most cases without such detailed specification of conditions as would ma[ke] the tables too voluminous. Lower and upper limits of values found [for] different specimens are given when warranted by the data available.

Mohs's Scale of Hardness: 1. Talc, 2. Gypsum, 3. Calc spar, 4. Fluorspar, 5. Apatite, 6. Feldspar, 7. Quartz, 8. Topaz, 9. Sapphire, 10. Diamond.

Density. The terms True Density and Apparent Density are used in describing certain porous bodies to distinguish between the density of the substance and the average density of the substance plus the pores. The terms Density and Specific Gravity are synonymous in engineering work.

Thermal Conductivity. The value given in the tables is the number of gram-calories that will pass per second thru every square centimeter of a plane section within the substance when the temperature is uniform over the section and falls along the normal to it at the rate of 1° C. per cm.

1 gm-cal per sec per sq cm for a temperature gradient of 1° C. per cm = 360 kg-cal per hr per sq m for a temperature gradient of 1° C. per m = 2.91×10^3 Btu per hr per sq ft for a temperature gradient of 1° F. per in.

Electrical Resistivity. Each value given in the table of metals and alloys is the resistance in microhms between the opposite faces of a cube 1 cm on each edge when at 18° C. (64.4° F.). This increases bR for every degree C., or $5/9\ bR$ for every degree F., that the temperature of the substance exceeds 18° C. 1 microhm to the sq cm of cross-section per cm of length = 6.015 ohms to the circular mil of cross-section per ft of length.

9. Light and Illumination

Speed of Light in a vacuum is approximately 300 000 kilometers per second. All kinds of light move with the same speed in a vacuum.

The waves of the easily visible portion of the spectrum vary in length from 0.0000 33 to 0.0000 77 centimeters. According to Rowland the length of a wave corresponding to Frauenhofer's band *A* is between 0.000 7594 and 0.0000 7671 cm.

When a ray of light strikes the plane surface of a transparent body, it is refracted toward the normal to that plane. The ratio of the sine of the angle between the original ray and the normal to the sine of the angle between the refracted ray and the normal is called the index of refraction, the value of which is 1.0003 for air, 1.33 for water, 1.51 for soft crown glass and 1.55 for rock salt for sodium light entering from a vacuum.

The ratio of the speed of light in a vacuum to that in any substance is equal to the index of refraction of the substance.

The ratio of the electromagnetic to the electrostatic units of electrical quantity and current is equal to the speed of light in a vacuum exprest in centimeters per second, that is, approximately 3×10^{10}.

The International Candle is the unit of light employed since July 1, 1909, for all photometric standardization by the national standardizing laboratories of America, France, and Great Britain. By May 1, 1910, it was in use by all the large manufacturers of electric lamps in the United States as the unit for rating lamps. This is 1.6% smaller than the unit previously employed in the United States, but the same as the former pentane candle of England and the bougie décimale of France. The Hefner unit of Germany is 9/10 of the international candle.

1 International Candle = 1 Pentane Candle = 1 Bougie Décimale = 1 American Candle = 1.11 Hefner Unit = 0.104 Carcel Unit.

The Energy consumed by incandescent electric lamps producing a given illumination has been materially reduced by the introduction of graphitized and especially of metallic filaments capable of standing higher temperatures than the old-type carbon filament. The watts per mean horizontal candle power required on the average by the best makes of lamps are as follows for four kinds of filaments: 3.1 for standard carbon, 2.5 for metallized (graphitized) carbon, 2.0 for tantalum, and 1.25 for tungsten.

Lamps with Frosted Globes fall to 80% of their initial candle power (which marks the end of their useful life) in about 60% to 70% of the time required for plain lamps to deteriorate to the same extent. Hyde has shown that most, if not all, of this effect can be accounted for by the diffusing action of the frosting causing a much greater proportion of the light to pass several times thru the strongly absorbing film of carbon that is deposited on the inside surface of the bulb. (Bull. Bureau of Standards, 3, 341, 1907.)

Standard Specifications for the purchase of incandescent electric lamps are published by the Bureau of Standards, Washington, D.C.

10. Microscopes and Telescopes

Magnification, increasing visibility of detail, is secured by bringing the image of an object nearer to the eye, or by any other means of increasing the visual angle which the object subtends. Vision with the unaided normal eye is, however, most distinct at a distance of 25 to 30 cm, because the accommodating mechanism of the eye is unable to focus sharply on the retina points nearer than this. A magnifying optical system produces in effect the required increase in the visual angle while forming an image (real or virtual) farther from the eye than the least distance of distinct vision. Often the arrange-

ment is such that the eye views a virtual image at an infinite distance, so the muscles of accommodation may be completely relaxed.

The Simple Microscope (Fig. 1). A single converging lens if pl closer to an object than the principal focal length produces an enla virtual image, which is seen on looking thru the lens. The magnifica produced is $1 + d/f$ for an eye whose least distance of distinct vision A simple plano-convex lens, with the plane side toward the eye, gives images for magnification less than eight diameters, that is, with focal len greater than a 3 cm. The image be much impr especially where magnification is siderable, by the special combina of lenses design reduce spherical chromatic aber so as to give a fairly large field of view approximately free from dist and color.

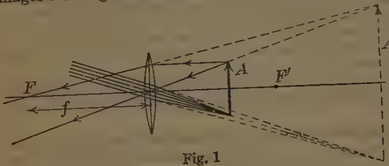

Fig. 1

The Ramsden, or Positiv, Eyepiece (Fig. 2) consists of two conv lenses, usually plano-convex, with their convex surfaces facing each of equal focal length, and separated by ⅔ the focal length of either. A virtual image of the object or real image A is formed by the field-lens L_1 at A'. The eye-lens L_2 forms an image of this at infinity. This eyepiece is fairly, but not quite, achr

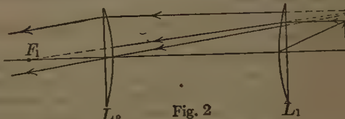

Fig. 2

The Huyghens, or Negativ, Eyepiece (Fig. 3). Two converging usually plano-convex, with the plane surfaces toward the eye, are so ar as to divide equa tween them the de produced on i light parallel to a to the axis. Th lens L_1 has thre the focal length eye-lens L_2, and are separated difference in the lengths. Light which if unhindered would converge at A is deviated form an image at A', of which L_2 forms an image at infinity. This is highly achromatic and free from disturbing spherical aberration.

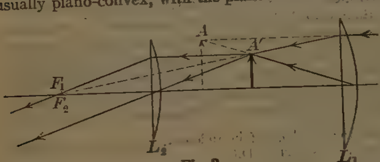

Fig. 3

For Measuring Microscopes and Telescopes, in which the eyepiece is fi cross-hairs, the positiv eyepiece is far more suitable than the negativ because of the hairs being formed by both lenses is corrected for both chromatic and aberration, and because the cross-hairs can be easily adjusted to suit differen altering their distance from the eyepiece.

The Compound Microscope (Fig. 4) in its simplest form consists of two c lenses. The objective L_1 forms within the tube a real, inverted, magnified of the object A. This image is viewed thru the eyepiece L_2 and further mag **microscope** is usually fitted with either a Huyghens or a Ramsden eyepiece, ac

the purpose for which it is to be used. The objective is also generally a combination of several lenses to overcome spherical and chromatic aberration while admitting as much light as possible. In microscopes of the highest power a drop of oil of cedar is placed between the slide and the objective; this is known as "immersion." The smallest interval that can be optically resolved is about 0.00005 mm, and the limit of resolution of the microscope is attained when the total magnification is about 1200.

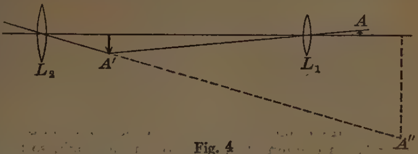

Fig. 4

The Astronomical Refracting Telescope differs from the compound microscope in that the objective forms a reduced image of a distant object. The objective is generally a compound lens consisting of a convex lens of crown and a concave lens of flint glass. A Huyghens or a Ramsden eyepiece is ordinarily used; but the best instruments employ eyepieces embodying later improvements.

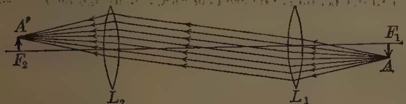

Fig. 5

The Terrestrial Telescope (Fig. 5) produces an erect image by an inverting system between the eyepiece and the inverted image formed by the objective. One form of inverting system consists of two converging lenses of equal focal length so placed that the inverted image A formed by the objective is at the principal focus of the first lens. An erect image A' is then formed at the principal focus of the second lens, and is magnified by an eyepiece.

Galileo's Telescope (Fig. 6) consists of a convex lens L_1 for objective and a concave lens L_2 for eyepiece. The light from L_1 converging so that if unhindered it would form at A' a real, inverted image of the distant object A, is intercepted by L_2 and rendered parallel or slightly divergent as if it came from A'', which is a virtual, erect image of A. The use of the diverging eye-lens limits considerably the angular field of view. Ordinary field-glasses and opera-glasses are Galilean telescopes.

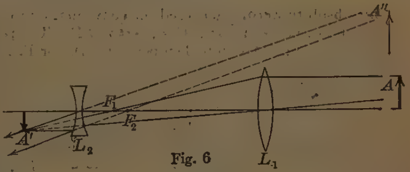

Fig. 6

The Prism Binocular (Fig. 7) secures the wide field of view that accompanies the use of a converging eyepiece, while at the same time it avoids the inconvenient length of the ordinary terrestrial telescope. This is accomplished by employing four total reflections within two right-angled prisms to invert the image formed by the objective. Otherwise the construction is the same as that of the astronomical telescope. This prism construction permits a considerable shortening of the telescope by separating the prisms, since the light traverses the distance between them three times. In addition the stereoscopic effect due to binocular vision may be greatly increased by placing the centers of the objectives much farther apart than the pupils of the eye. The increased field of view is obtained at a sacrifice of illumination.

Fig. 7

In **Reflecting Telescopes** the object lens is replaced by a concave mirror. Being strictly achromatic, reflecting telescopes are valuable for certain classes of astronomical work. Mirrors as large as six feet in aperture have been made, but the best work has

been done by those about two feet in diameter. The mirror is of glass, upon wh
thin film of silver has been deposited.

11. Determination of Temperature

The International Hydrogen Scale adopted in 1887 by the Internati Committee on Weights and Measures is the standard thruout the worl designating temperature. The temperature of melting ice is designate 0° C. and that of the saturated vapor of distilled water boiling at stan atmospheric pressure is 100° C. Other temperatures are defined as pro tional to the increments of pressure exerted by any fixt mass of hydr confined at constant volume, the pressure when at 0° C. to be that due t weight of a column of mercury one meter high; so that when the gas e a pressure p, its temperature will be designated by as many degrees c grade as 1/100 of the increase of pressure on warming from 0° to 10 contained in the amount p exceeds algebraically the pressure when at 0°

Between 100° and 1500° C. nitrogen is used instead of hydrogen, as the latter c be employed at high temperatures because of its great chemical activity and the rea with which it permeates the walls of containing vessels. Temperatures beyon range of the nitrogen thermometer are specified by radiation methods. Within the for which it is adapted, each of these scales agrees with Kelvin's thermodynamic as closely as it is possible to determine temperatures at the present time (1919), an be regarded as representing thermodynamic temperature within its own interval.

Temperatures used in specifying scientific data are almost unive exprest in degrees of the International Centigrade Scale, except by English and American engineers, who use the designation of Fahre If the same temperature is designated by C.° Centigrade (or Celsius Fahrenheit, and R.° Reamur, then

$$C/100 = (F - 32)/180 = R/80$$

The Absolute Zero, often used for convenience in making thermody computations, is about −273° C. or −459°.6 F. Temperatures specified this zero are called Absolute Temperatures (C. or F.), and on the cent scale are sometimes indicated by the letter K following the number of de

A Thermometer, or instrument to indicate the temperature of a b constructed by using any physical property whatever that varies wi temperature, provided that this property always has the same value same temperature, and that there is not more than one temperature the range thru which the thermometer is to be employed at which this erty has any one particular value. Convenience, sensitiveness, reliabi indications, and other considerations dictate the type of thermomete suited for a particular purpose. The graduations of a thermomete indicate degrees directly, or they may require translation by means of a Instruments, even when apparently alike, often differ considerably in th dications when at the same temperature. For all work where it is im to know temperatures accurately, an instrument should be employed th been calibrated (better both before and after use) by the Bureau of Sta at Washington, or by one of the other national physical laboratories, a vided with a statement of the conditions to be observed in its use as with a certified table of corrections.

Standard Temperatures of Reference for checking the accuracy o mometers are generally the freezing or the boiling points of certain sub easily obtainable in the pure state, which have been accurately dete in degrees of the standard scale. Standard boiling points under pres 76.0 cm mercury are as follows, the quantity following the + sign be increase for each cm of pressure:

Water .... 100.0° C. + 0.4°	Benzophenone 305.9° C. + 0.75°
Aniline ...... 184.1° C. + 0.5°	Sulfur......... 444.9° C. + 0.90°
Naphthalene .. 218.0° C. + 0.6°	Zinc........ 920° C. + 1.5°

A Pyrometer is a thermometer intended for use near and above the temperature at which heated bodies begin to glow. Various devices for determining temperature are on the market or used in scientific investigations; but most of those not enumerated below are either too crude and unreliable, or too complicated in construction or manipulation, to be comparable with them for engineering and industrial purposes.

An Ordinary Mercurial Thermometer is usable from about −39° C. to about 300° C. The upper limit can be extended to 550° C. by filling the capillary above the mercury with nitrogen or carbon dioxid under high pressure. For low temperatures alcohol (−70° C. to +50° C.), toluene (−90° to +20°), pentane or petroleum ether (−200° to +20°), etc., are used in place of mercury. Between 0° and 100° the indications of the best mercurial thermometers should differ from those of the standard hydrogen thermometer by less than 0.1°, but the ordinary commercial instruments may be out several degrees.

The Joly Meldometer determines the fusion points of solids very rapidly and very accurately. A minute specimen is placed on a slightly stretched strip of platinum gradually heated by a regulated electric current. The length of the strip at the instant of melting indicates the temperature. The meldometer is also useful for identifying substances of known melting points. Temperatures in the neighborhood of the fusion point of gold (1063° C.) are easily determined within a few degrees by means of this instrument; but great care is required to prevent injury to the platinum strip either thru melting, overstretching, or contamination with fused metals. The necessity of recalibration every time a strip is injured is avoided by the method of Burgess (Bull. Bureau of Standards, vol. 3, p. 346, 1906), in which observing with an optical pyrometer replaces measuring the length of the strip.

In several commercial thermometers the difference in the expansions of two solids, or the expansion of air in a bulb, operates a pointer moving over a dial graduated in degrees. The upper limit of these instruments is about 800° C. (1500° F.), and they deteriorate rapidly when used at the higher temperatures.

The Electrical Resistance of a coil of wire may be made a very sensitive and very reliable indicator of temperature. Platinum is usable from the lowest obtainable temperatures to 1000° C. Other metals, such as nickel, are suitable for lower temperatures.

A Thermoelement indicates temperature by the e.m.f. set up in a closed electrical circuit of two wires of different materials in series when the two junctions are at different temperatures. One junction is exposed to the temperature to be determined, while the other is kept at constant temperature. The particular combination of metals best adapted to any given case will depend on the range of temperature to be indicated. An element composed of one wire of pure platinum and the other of platinum alloyed with 10 % of rhodium is best for temperatures above 300° C., and can be used up to 1600° C. Constantan with copper or iron is more suitable under 300° C. Other combinations are found in commercial instruments.

Radiation Pyrometers are the only ones usable at temperatures high enough to melt or to change permanently any thermometric substance subjected to them, and in other cases where the hot body cannot be touched with the instrument. They are merely pointed at the body from a distance. They are useful from dull red to the highest temperatures obtainable, and are capable of considerable precision (about 1 %). Optical Pyrometers depend on the fact that the intensity of the light of any given color emitted by a hot body is a definite function of the temperature. They are essentially pho-

tometers graduated to indicate temperatures instead of brightness of illumination. Le Chatelier, Féry, Wanner, Holborn and Kurlbaum, and Mo have devised very satisfactory instruments of this type. The Féry THERMOELECTRIC TELESCOPE represents a second class, and is based on the f that the total energy of the radiation emitted per unit area of a body is a defin function of the temperature. In this instrument the radiation from a limi area of the hot body is focused by means of a concave mirror (or by a fluo or glass lens) upon a small thermoelement in series with a portable gal nometer, whose scale is graduated to indicate temperatures directly. F has also devised a simpler instrument in which the thermoelement is repla by a thin coiled strip composed of two differently expanding metals t causes a pointer to move over a graduated dial.

The Color of Glowing Bodies affords a very crude means of estimating temperat Approximate values are

First visible red	525° C.	Dull orange	1100° C
Dull red	700	Bright orange	1200
Turning to cherry	800	White	1300
Cherry proper	900	Brilliant white	1400
Bright cherry	1000	Dazzling white	1500

Workmen can sometimes guess to better than 25° C. up to 800° C. At 1200° erro over 100° will be made.

Seger's Pyrometric Cones are often used for indicating the maximum temperat reached in pottery kilns. They are merely little pyramids of clay whose pointed soften and curl over at fairly definite temperatures determined by their composi They are on the market with softening temperatures ranging by steps of about 2 from 590° to 1850° C.

The Calorimetric Method of observing temperature determines the given up to a mass of water when a piece of metal is suddenly transferre it after heating in the furnace or other region whose temperature is requ If a mass m_2 of water is warmed from $t_2°$ to $t_3°$ by dropping into it a mas of metal with an initial temperature $t_1°$ and a mean specific heat c_{13} betw $t_1°$ and $t_3°$, then t_1 may be found from the relation $m_1c_{13}(t_1 - t_3) = m_2(t_3$ Platinum and nickel are about the only metals suitable for high temperat iron, tho frequently used, is too readily changed by oxidation. The me is too crude and too time-consuming to be recommended except for occas rough determinations.

Thermometers for Recording and Use at a Distance. All the thermon described above except the optical and the fusion-point ones may be made to recor indications automatically, either autographically or photographically; but those l themselves most readily to this use are the electrical thermometers and the Féry th electric telescope. These have the further advantage that any number of thermo can be connected by a switchboard with one recording or indicating instrument, may be placed at any convenient distance from the body whose temperature is indicated.

12. Quantities of Heat

The 15° Gram Calorie (gm-cal) is the unit for measuring quantity o most frequently used in scientific work, and is the heat necessary to rai temperature of 1 gm of water from 14.5° C. to 15.5° C. Q gm-cal is the qu of heat necessary to raise Q gm of water thru the same interval, not the tity necessary to raise 1 gm of water thru Q degrees. The KILOGRAM CA (kg-cal), or large calorie, is 1000 gm-cal, and is the common unit for eng ing purposes in countries where the metric system is in use. In the c water, it happens that the quantity of heat necessary to raise a given m is very nearly the same at all temperatures between 0° and 100° C.

experiments of Barnes in 1902 indicate that this is a minimum in the neighborhood of 37.5° C. and a maximum at 0°; but the extreme variation found amounted to scarcely more than 1 %. The BRITISH THERMAL UNIT, often abbreviated Btu, is the heat required to raise 1 lb of water 1° F. The temperature does not need to be specified for the accuracy necessary in most engineering computations. 1 Btu = 0.252 kg-cal.

Mechanical Equivalent of Heat. When heat has to be compared quantitatively with energy in some other form, it is usually most convenient to measure all the quantities in terms of some unit of work. A 15° gm-cal is very nearly equivalent to 4.19 joules or 0.427 m-kg, and a Btu is nearly equivalent to 778.4 ft-lb. This mechanical equivalent of heat is usually represented by the symbol J (in honor of Joule), so that if W units of work is equivalent to Q units of heat, then $W = JQ$.

Thermal Capacity and Specific Heat. If ΔQ represents the heat added to a body and $\Delta T = T' - T$ the change in the body's temperature, then $\Delta Q / \Delta T$ is called the mean thermal capacity of the body between the temperatures T and T'; while the limit that this approaches as ΔT approaches zero is called the true thermal capacity of the body at the temperature T.

The Specific Heat of a homogeneous substance is its thermal capacity per unit mass. This may have any value whatever from $-\infty$ to $+\infty$ and is not determinate till it is specified how the volume of and pressure on the substance shall vary during the process of heating or cooling; because the heat transferred to a body during any given temperature change will depend not only on the temperature interval, but also on how much work is done by or on the body at the same time. This specification is especially necessary in the case of a gas or a vapor, where it usually suffices to distinguish between the specific heats c_p, at constant pressure, and c_v, at constant volume, tho it is sometimes desirable to know the specific heat of a vapor maintained in the condition of saturation during change of temperature.

Because of the way in which the unit of heat has been defined, it follows that the thermal capacity of a body is often exprest by almost the same number as what is known as the WATER EQUIVALENT of the body, that is, the mass of water whose temperature would be raised the same number of degrees by the addition of the same quantity of heat. Also, the mean specific heat of the body is often nearly the same as the ratio of the quantity of heat necessary to effect a given change in the body's temperature to the quantity of heat necessary to effect the same change in the temperature of an equal mass of water; but it may be far from this.

The Specific Heat of a solid or of a liquid is in nearly all cases practically independent of the manner in which heating takes place; because the external work involved in its thermal change of volume is negligible. While the specific heat of water is the same within about 1% at all temperatures between 0° and 100° C., that of most solids and liquids increases slowly with the temperature, tho in some instances, such as iron and diamond, the change is rapid. A marked change in specific heat also accompanies change in state of aggregation.

An Abnormal Specific Heat occurs during the more or less rapid softening that usually precedes the complete liquefaction of a solid as it is heated; and it becomes infinite when the change in state of aggregation occurs abruptly without change of temperature until the process is completed, as during fusion of some chemically simple crystalline substances, such as ice, tin, zinc, copper, silver, and gold, or during boiling and sublimation. When the transition is gradual, it is impossible to state what part of the heat absorbed is to be attributed to the change in state of aggregation and what merely to the accompanying change in temperature. The term LATENT HEAT is in use to designate the number of heat units absorbed or liberated per unit mass of the substance during any of those special changes of state that occur

without change in temperature, since the specific heat becomes unmanageab when it assumes an infinite value. Altho the term is usually restricted such very marked transitions as changes of state of aggregation, it is equal applicable to any isothermal change: for example, to the isothermal expansi of a gas against outside pressure. As special instances it is convenient distinguish heat of fusion, heat of vaporization, heat of sublimation, heat solution, heat of chemical reaction (with heat of combustion as a special cas heat of strain, and heat of recalescence.

Cooling and Heating Curves are obtained by plotting as coordinates t time a body had been cooling or heating under uniform external conditio and the instantaneous value of its temperature. They afford a convenie means of determining TRANSITION REGIONS, or temperature intervals with which internal physical or chemical changes take place, since the rapid absor tion of heat during rise, or liberation during fall, of temperature is indicat by a more or less sudden decrease in the angle the curve makes with the ti axis, followed by a return to a greater slope when the change is complete Such transformations are very common in solids far below their melti points, occurring commonly in alloys, and particularly in steels. They a accompanied and made evident by changes in physical properties such hardness, density, resistivity, or permeability. The recalescence point of ir is a familiar example. As such changes are generally slow, they may be o scured by being spread over too great a temperature interval if the cooli or heating is too rapid.

13. Transference of Heat

Radiation. All bodies, whatever their temperatures may be, are cont ually radiating energy which is propagated thru space with the speed light. This energy appears to be transferred by some sort of periodic d turbances, or wave-trains, of various frequencies. The greater the temp ature of a body the greater both the total quantity of this RADIANT ENER and the relative intensity of the waves of short period. Unless the body is least almost as hot as the sun, the most energetic of the waves that radi from it are of somewhat longer period than those that affect the eye with sensation of light. During the time that the body loses energy by transforn tion of some of its heat into the radiation it emits, its temperature must crease unless the supply of heat is replenished either by energy transformati going on within or by energy received from without. When radiant ene falls upon a body, that part which is neither reflected nor transmitted is sorbed by the body, and some or all of it is transformed into heat. Thus effect, the process of radiation transfers heat almost instantaneously from body to another at a lower temperature not visibly connected with it, and e at a considerable distance: the warmer radiates more energy than it recei from the colder, and the colder receives more than it radiates to the hot When, in this way, radiant energy causes the transference of heat, it is u ally misnamed RADIANT HEAT; but it should be remembered that the ene while traveling from one body to the other is not in the form of heat at and does not heat the bodies into which it passes except in so far as t absorb and transform some of it into heat. The behavior of all these wa is described by exactly the same general laws as those that describe the havior of that limited portion of them that has such periods as to be capa not only of heating bodies but also of producing the sensation of light, o exciting chemical activity.

The fraction of the radiant energy absorbed, the fraction transmitted, and the frac reflected by a given body will depend upon the periods of the incident waves, as

s upon the nature, surface, thickness, temperature, etc., of the body, and the angle at which the radiation is incident. Bodies that either reflect or transmit readily are poor radiators; and vice versa, opaque bodies if good absorbers are good radiators. Emission, absorption, and transmission of radiation are always most intense in a direction perpendicular to the radiating surface, while reflection increases with the obliquity of incidence; but the influence of direction is less the greater the absorptivity of the body; and it has no influence whatever in the case of a perfect absorber, or theoretically black body, that is, one that completely absorbs all the waves incident upon it regardless of their periods. Such a body is almost perfectly realized experimentally by a small hole leading into a relatively large cavity bounded by opaque walls of uniform temperature, no matter what their nature may be, as practically none of the radiation entering the hole would ever succeed in getting out again.

The transparency and also the reflectivity of a substance for those vibrations ordinarily called light afford no criteria whatever for predicting the behavior of the substance toward waves of longer or of shorter period. Thus, hard rubber, while completely opaque to visible radiations even in extremely thin layers, is fairly transparent to the waves of longer period; colorless glass and water, on the other hand, absorb strongly most of the invisible heating radiations; while rock-salt is very transparent to both visible and invisible. Polished metals are excellent reflectors of nearly all waves of longer period than those of the visible spectrum, and many of them, notably silver, have a high reflecting power in the visible as well.

Convection usually plays the most important part in the transference of heat from one portion of a fluid to another and in equalizing the temperature of the whole. After the particles adjacent to the sources of heat become warmed, they are carried away bodily by convection currents and distributed more or less uniformly thruout the entire extent of the fluid. These currents may be caused by changes in buoyancy following expansion or contraction, by the slow process of diffusion, or by mechanical stirring.

Conduction. All bodies transmit some heat from their warmer to their colder portions by what is called conduction. The number of heat units that will pass per unit time thru a plane section of area A within a substance when the temperature T is uniform over the section and falls along the normal N to it at the rate $-dT/dN$ is $dQ/dt = -kA\,dT/dN$, where k is called the THERMAL CONDUCTIVITY of the substance. The rate $-dT/dN$ is called the TEMPERATURE GRADIENT normal to the section. The conductivity k is a function of the temperature, but varies so little that in most problems it may be treated as constant unless very large temperature intervals are involved.

The thermal conductivities of different substances differ widely, being greatest in metals, especially silver. Non-metallic liquids, gases, and many solids are very poor conductors; but no substance is a complete insulator. The thermal conductivities of the different pure metals are to one another roughly as their electrical conductivities. (Law of Wiedemann and Franz.) Alloys, however, show large deviations from this relation. Bodies having finely porous structures such as powders, wood, wool, cloth, and paper are as a rule poor conductors. (See tables of Physical Properties of Substances.)

The Problem of Thermal Insulation is essentially the same whether it be desired to keep a hot body from losing heat or a cold body from gaining it. In the former case, however, the choice of insulating materials may be seriously limited by the temperatures they are capable of withstanding without troublesome deterioration. Whenever possible, insulating jackets should be enclosed between metallic walls highly polished on their outside surfaces to prevent radiation and absorption; the space between should be filled with a sufficiently thick layer of the poorest conducting substance that will stand the highest temperature to which it may be subjected; and this substance should be of a finely porous nature. The jacketing for a very highly heated body such as a furnace is best made in layers, some excellent insulator such as infusorial earth (diatomaceous earth, Kieselguhr) or light calcined magnesia being used for the outside and extending as far in as it can stand the temperature without shrinkage or fusion. Such heat-resisting materials as carborundum fire-sand or powdered charcoal may have to be used for the most highly heated layers; but they should in general be avoided when the temperature

is low enough to permit the employment of better insulators. The corrosive action o furnace gases is often the most important factor in determining the selection of the linin exposed to them. The best of all thermal insulation for low and moderate temperature is a very high vacuum between thinly silvered walls, as illustrated by the well-know Dewar vessels for containing liquid air, etc. In a good Dewar flask half a gallon o liquid air will take a week to evaporate, altho separated from the atmosphere of the roor by only ½ to ¾ in. With rising temperature, however, radiation plays an increasingl important part, until at furnace heats and above it becomes the principal means of effec ing heat-transfer; and radiation takes place most readily of all thru a vacuum. A shee of bright tin plate with free air circulation behind it is frequently a better protection to wooden wall than asbestos applied directly to the wood unless the asbestos is very thic In engineering practice much heat is continually wasted because of insufficient attentio to thermal insulation.

14. Changes Due to Heating

Heat and Expansion. Altho most substances expand as they are warmed or if hindered from expanding freely will exert pressure upon their container water between 0° and 4° C., quartz-glass below −84° C., and some other sub stances are exceptions to the general rule. When heating causes a body t change its state of aggregation (melt, vaporize, etc.) there is also change i volume. This may be either an expansion or a contraction, and may b accompanied by little or no change of temperature until after the process completed.

Thermal Hysteresis. When a solid has its temperature changed, e pecially by rapid cooling, slow changes in its dimensions continue long aft it has attained the same temperature thruout its entire extent. These chang are often so minute as to require extremely delicate means for detection; b in such cases as glass they are very marked. The gradual contraction thermometer bulbs has been observed to continue for over a quarter of century, causing the zero reading to rise. The zero point of even a goo thermometer may be shifted many degrees in a few minutes by heating several hundred degrees. (Bul. Bureau Standards, vol. 2, 1906, p. 18 Most of this after-effect disappears in a few hours or days, and the process considerably accelerated by prolonged heating at a high temperature follow by slow annealing.

Laws of Change. As long as a physically homogeneous body is n subjected to treatment that causes more or less permanent alterations in structure, its volume appears to be a definite function of its temperature a pressure, when these are uniform thruout its entire extent. The amou of expansion under constant pressure caused by a given change of temperatu depends upon the material of the body. Solids and liquids differ conside ably among themselves and follow no regular law. Gases, on the other han show remarkable uniformity, all expanding about $100/273 = 0.367$ of th volumes at 0° C. when warmed from this temperature to 100° C. (Law Gay-Lussac.) Besides, all gases expand very nearly alike thruout gre ranges of temperature; and the particular pressure under which a gas warmed makes very little difference.

Coefficients of Expansion. If the volume at $t°$ is V and at 0° is then the rate at which unit volume changes under constant pressure w change of temperature is $(dV/dt)/V$, which is called the true coeffici of cubical expansion at $t°$; while $(V-V_0)/V_0t = \alpha$ is called the mean-ze coefficient from 0° to $t°$. Similarly, if L represents the length of a solid, th $(L-L_0)/L_0t = \beta$ is the mean-zero coefficient of linear expansion from 0° to These definitions give $V = V_0(1+\alpha t)$ and $L = L_0(1+\beta t)$. Usually α and are so small that one may assume $\alpha = 3\beta$.

Values of the coefficient of cubical expansion for solids are given above in Art. 7. The coefficient of linear expansion is one-third of the cubical. Art. 7 gives values for the Centigrade degree. To find coefficients of linear expansion for the Fahrenheit degree, multiply tabular values by 0.185. Thus, for steel, the table gives coefficients of cubical expansion ranging from 0.000030 to 0.000041, hence coefficient of linear expansion for the Fahrenheit degree ranges from 0.0000055 to 0.000076, while mean value given for steel on p. 404 is 0.0000065.

Dalton's Law. In a mixture of several gases or vapors that do not react upon each other chemically the pressure exerted is approximately the same as if each constituent exerted the full pressure it would exert if it alone filled the entire volume; that is to say, if volumes V_1, V_2, V_3, . . . , of different gases and vapors, all under the same pressure p and at the same temperature, when mixt fill a volume V, then $p=p_1+p_2+p_3+\ldots$, approximately, where $p_1=pV_1/V$; $p_2=pV_2/V$; etc. This relation is more accurately fulfilled the farther all the vapors are from the conditions under which they liquefy and the less their liquids dissolve one another. p_1, p_2, etc., are spoken of as the partial pressures exerted by the different components.

15. Sound

Velocity of Sound in air at 0° F is 1050 ft per sec, and it increases 1.1 ft per sec for each 1° F rise in temperature. A few values are

Temperature F,	−10°	+10°	+30°	+50°	+70°	+90°
Velocity, ft per sec,	1039	1061	1083	1105	1127	1149

At 0° C the velocity of sound in dry air is 331 meters per sec and it increases 0.609 meters per sec for a rise of each degree of the Centigrade scale. At + 30° C the velocity is about 349 meters per sec.

The velocity of sound in air is independent of the barometric pressure, and hence is the same on high mountains as at sea level, the temperature being the same in both cases. It is said to be little influenced by fog or rain but materially altered by aqueous vapor and also by wind.

A formula for velocity of sound in any solid or liquid is $v=\sqrt{Eg/w}$, where $E=$ modulus of elasticity, $w=$weight per cubic unit of the substance, and $g=$acceleration of gravity. Mean values of v are as follows in ft per sec:

Fresh water	4 700	Copper	11 700
Salt water	4 765	Cast iron	12 400
Timber	13 260	Wrought iron	15 500
Silver	8 550	Steel	17 200

Stress is transmitted thru a solid with the same velocity as sound.

The velocities of sound in different gases at the same pressure and temperature vary inversely as the square roots of their densities. Thus, using densities of air and hydrogen as given on p. 1526, the velocity in hydrogen at 0° F is 3980 ft per sec.

In open air the intensity of sound varies inversely as the square of the distance of the source from the ear. For air in a pipe this law does not hold, but the intensity remains the same for considerable distances, it being diminished only by internal frictional resistances. The intensity also depends on the medium; the ticking of a watch is heard 2½ times as far under water as in air. It also depends on the volume of sound produced by the sonorous body; the explosion of a volcano has been heard at a distance of 300 miles.

When a sonorous body approaches the ear the tone perceived is higher than the true, and when it recedes the tone is lower. This is because high tones are produced by short waves, and in the case of approach to the ear, the sound waves are crowded together or shortened.

METEOROLOGY

16. Signals of United States Weather Bureau

Flag Signals for ordinary weather predictions are shown in Fig. 8.

No. 1. Fair weather. No. 2. Rain or snow. No. 3. Local rain or snow. No. 4. Temperature. No. 5. Cold wave. Col key

Fig. 8. Flags for Weather Predictions

No. 1, alone, indicates fair weather, stationary temperature.
No. 2, alone, indicates rain or snow, stationary temperature.
No. 3, alone, indicates local rain or snow, stationary temperature.
No. 1, with No. 4 above it, indicates fair weather, warmer.
No. 1, with No. 4 below it, indicates fair weather, colder.
No. 2, with No. 4 above it, indicates rain or snow, warmer.
No. 2, with No. 4 below it, indicates rain or snow, colder.
No. 3, with No. 4 above it indicates local rain or snow, warmer.
No. 3, with No. 4 below it, indicates local rain or snow, colder.

Whistle Signals. A warning blast of from fifteen to twenty seconds c tion is sounded to attract attention. After this warning the longer b (of from four to six seconds duration) refer to weather, and shorter blast from one to three seconds duration) refer to temperature; those for we are sounded first.

Blasts	Indicate	Blasts	Indicate
One long	Fair weather	One short	Lower temperat
Two long	Rain or snow	Two short	Higher tempera
Three long	Local rain or snow	Three short	Cold wave.

Storm and Hurricane Warnings are given by the flags in Fig. 9.

N. E. Winds. S. E. Winds. N. W. Winds. S. W. Winds. Hurricane Color K

Fig. 7. Storm and Hurricane Flags

A red flag with a black center indicates that a storm of marked violence is exp The pennants displayed with the flags indicate the direction of the wind; red, ea (from northeast to south); white, westerly (from southwest to north). The pennant the flag indicates that the wind is expected to blow from the northerly quadrants; from the southerly quadrants. By night a red light indicates easterly winds, and a light below a red light, westerly winds.

Two red flags with black centers, displayed one above the other, indicate the ex approach of a tropical hurricane, or one of those extremely severe and dangerous which occasionally move across the Lakes and northern Atlantic coast. No nigh ricane warnings are displayed.

Wind Pressure on Flags. Tests at the U. S. Navy Yard, Washington, D. C. the largest flags that could be handled in the wind tunnel, form the basis for an em formula for determining the pressure of wind on flags, for use in designing flagpoles. sizes of flags were used—one $3 \times 5\frac{1}{2}$ ft, and the other $2\frac{1}{2} \times 4\frac{1}{4}$ ft—and velocities v from 20 to 60 miles per hour were applied. The following formula was found o rep the results, the constant varying but slightly with size of flags, being less for the large

$$R = 0.0003\, A V^{1.9}$$

which R is the resistance in pounds, A is the area of flag in square feet, and V is the elocity of wind in miles per hour. This formula is for steady wind pressure. It was ot found practicable to measure the forces produced by wind gusts.

17. Local Weather Predictions

The wind and barometer indications for the United States are generally ımmarized in the following table (E. B. Garriott, U. S. Dept. Agriculture).

Wind direction	Barometer reduced to sea level	Character of weather indicated
SW. to NW.	30.10 to 30.20 and steady	Fair, with slight temperature changes, for 1 to 2 days.
SW. to NW.	30.10 to 30.20 and rising rapidly	Fair, followed within 2 days by rain.
SW. to NW.	30.10 to 30.20 and falling slowly	Warmer, with rain within 24 to 36 hours.
SW. to NW.	30.10 to 30.20 and falling rapidly	Warmer, with rain within 18 to 24 hours.
SW. to NW.	30.20 and above and stationary	Continued fair, with no decided temperature change.
SW. to NW.	30.20 and above and falling slowly	Slowly rising temperature and fair for 2 days.
. to SE.	30.10 to 30.20 and falling slowly	Rain within 24 hours.
. to SE.	30.10 to 30.20 and falling rapidly	Wind increasing in force, with rain within 12 to 24 hours.
SE. to NE.	30.10 to 30.20 and falling slowly	Rain in 12 to 18 hours.
SE. to NE.	30.10 to 30.20 and falling rapidly	Increasing wind, and rain within 12 hours.
E. to NE.	30.10 and above and falling slowly.	In summer, with light winds, rain may not fall for several days. In winter, rain within 24 hours.
E. to NE.	30.10 and above and falling rapidly.	In summer, rain probable within 12 to 24 hours. In winter, rain or snow, with increasing winds, will often set in when the barometer begins to fall and the wind sets in from the NE.
SE. to NE.	30.00 or below and falling slowly	Rain will continue 1 to 2 days.
SE. to NE.	30.00 or below and falling rapidly	Rain, with high winds, followed, within 36 hours, by clearing, and in winter by colder.
S. to SW.	30.00 or below and rising slowly.	Clearing within a few hours, and fair for several days.
S. to E.	29.80 or below and falling rapidly	Severe storm imminent, followed, within 24 hours, by clearing, and in winter by colder.
E. to N.	29.80 or below and falling rapidly	Severe northeast gale and heavy precipitation; in winter, heavy snow, followed by a cold wave.
Going to W.	29.80 or below and rising rapidly	Clearing and colder.

As a rule winds from the east quadrants and falling barometer indicate oul weather; and winds shifting to the west quadrants indicate clearing and air weather. The rapidity of the storm's approach and its intensity are ndicated by the rate and the amount in the fall of the barometer.

The indications afforded by the wind and the barometer are the best guides or determining future weather conditions. As low barometer readings sually attend stormy weather, and high barometer readings are generally ssociated with clearing or fair weather, it follows that falling barometer ndicates precipitation and wind, and rising barometer, fair weather or the pproach of fair weather. As atmospheric waves or crests (areas of high arometer) and troughs or depressions (areas of low barometer) are, by

natural laws, caused to assume circular or oval forms, the wind direc with reference to areas of low barometer are spirally and contraclocl inward toward the region of lowest atmospheric pressure, as indicate readings of the barometer. Areas of low barometric pressure are, in whirlwinds of greater or less magnitude and intensity, depending upo steepness of the barometric gradient. The atmospheric crests, or are high barometer, on the contrary, show winds flowing spirally clockwise ward from the region of highest barometric pressure.

The wind directions thus produced give rise to, and are responsible for, all local w signs. The south winds bring warmth, the north winds cold, the east winds, in the latitudes, indicate the approach from the westward of a low barometer, or storm and the west winds show that the storm area has past to the eastward. The indi of the barometer generally forerun the shifts of the wind. This much is shown b observations.

During the colder months, when the land temperatures are below the water t atures of the ocean, precipitation will begin along the seaboards when the winc and blows steadily from the water over the land without regard to the height of the eter. In such cases the moisture in the warm ocean winds is condensed by the the continental area. During the summer months, on the contrary, the onshore are not necessarily rain winds. for the reason that they are cooler than the land s and their capacity for moisture is increased by the warmth that is communicated t by the land surface. In such cases thunderstorms commonly occur when the ocea are intercepted by mountain ranges or peaks. If, however, the easterly winds of s increase in force, with falling barometer, the approach of an area of low bar pressure from the west is indicated and rain will follow within a day or two.

From the Mississippi and Missouri valleys to the Atlantic coast, and on the coast, rain generally begins on a falling barometer, while in the Rocky Mount Plateau districts, and on the eastern Rocky Mountain slope, precipitation seldom until the barometer begins to rise, after a fall. This is true as regards the eastern the country, however, only during the colder months, and in the presence of storms that may occur at other seasons. In the warmer months summer show thunderstorms usually come about the time the barometer turns from falling to The fact that during practically the entire year precipitation on the great wester and in the mountain regions that lie between the plains and the Pacific coast does not begin until the center of the low barometer area has past to the eastward o ward, and the wind has shifted to the north quadrants, with rising barometer, is portant one to note.

18. Weather Observations

Mean Temperature. When maximum and minimum readings of t ature are taken, the mean of the two is the mean temperature of th The mean of all the daily means in a month is the mean temperature month. When a recording thermometer is used the area between th and an axis of abscissas is to be divided by the length of that axis in to obtain the mean temperature for the elapsed time.

Rainfall. The rain gage used by voluntary observers consists of a drical receiver 8 inches in diameter which has a funnel-shaped botto discharges into a tube 2.53 inches in diameter. The cross section is one-tenth that of the receiver, and hence height of water in tube is te as great as actual rainfall. The depth in the tube is measured by which is so graduated as to read the true rainfall in inches. The 20 inches long so that a precipitation of 2 inches or less can be measure out emptying it.

Self-registering rain gages catch the water and weigh it, these being used at main of U. S. Weather Bureau. Snowfall is caught, melted, and then measured; rou inches of snow make one inch of water. A rain-gage at the top of a building giv rainfall than one on the ground.

Voluntary observers of the Weather Bureau record maximum and minimum

ature, precipitation, wind direction, general character of day, and miscellaneous phenomena such as halos, dates of frost, hail, sleet, auroras, and tornadoes. The general character of the day is recorded "clear" when the sky is $^3/_{10}$ or less obscured, "partly cloudy" when from $^4/_{10}$ to $^7/_{10}$ is obscured, and "cloudy" when more than $^7/_{10}$ is obscured.

19. Rainfall and Evaporation

Mean Annual and Monthly rainfall at many stations are given in Sect. 9, Art. 40. The term Rainfall includes both rain and melted snow.

Measurements of Evaporation are made by placing water-tight pans at the level of the ground and noting daily the variations in depth, together with the rainfall. On a water surface similar measurements may be made by floating boxes. It is found that the evaporation from water surfaces is greater than that from land, that it is greater in dry and desert regions than in cultivated ones, that it is less in low lands than on mountains, that it decreases as the humidity of the air increases, and that it increases with the temperature of the air and the velocity of the wind. In the North Atlantic states the annual evaporation from land surfaces is, on the average, about 40 percent, while that from water surfaces is about 60 percent of the annual rainfall. In low and level localities these percentages are decreased, while for high regions and steep slopes they are increased. In some arid localities west of the Rocky Mountains nearly all the rainfall evaporates from land surfaces, while the evaporation from water surfaces may be several times as great as the rainfall.

Experiments made in 1909–10 by the U. S. Department of Agriculture gave the following figures for the annual evaporation at twenty places in the United States, the evaporating pan being at or very near the surface of the ground or water.

Place	Position of pan	Diameter of pan, feet	Annual evaporation, inches
Salton Sea, Cal.	1500 ft inland	2	164.50
Salton Sea, Cal.	500 ft at sea	4	108.65
Salton Sea, Cal.	7500 ft at sea	4	106.45
Indio, Cal.	15 miles from Salton Sea	6	119.33
Mecca, Cal	½ mile from Salton Sea	6	107.81
Brawley, Cal.	20 miles from Salton Sea	6	103.55
Mammoth, Cal.	40 miles from Salton Sea	6	125.53
N. Yakima, Wash.	½ mile west of city	4	67.96
Hermiston, Ore.	On raft in reservoir	4	68.05
	On ground	3	97.29
Granite Reef, Ariz.	Floating in Salt River	4	97.74
	On ground	4	115.18
California, O.	Floating in reservoir	4	45.99
Birmingham, Ala.	Floating in reservoir	4	51.74
Dutch Flats, Neb.	A few miles from Mitchell	4	65.67
Deer Flat, Id.	On raft near water edge	4	77.43
	On ground of embankment	3	79.00
Ady, Ore.	Floating in borrow pit	4	53.45
Fallon, Nev.	Floating in canal	4	53.65
Lake Tahoe, Cal.	2 ft above water	4	42.21
Elephant Butte, N. Mex.	Near Rio Grande River	4	86.95
Carlsbad, N. Mex.	In the city	4	107.25
	In an alfalfa field	4	94.35
Lake Avalon, N. Mex	A few miles from Carlsbad	4	94.51

The evaporation from a pan 2 feet in diameter is about 75 percent, that from a pan 4 feet in diameter is about 50 per cent, and that from a pan 6 feet in diameter is about 30 percent greater than the evaporation from a large pond or lake. The above figures may be roughly corrected by using these percentages; thus, at Birmingham, Ala., the true annual evaporation is 34.50 inches.

The U. S. Weather Bureau maintains at selected locations hook gauge measurements of evaporation losses from cylindrical pans 10 in deep and 4 ft diameter, exposed on wood frames, bottom of pans 1 in above the ground, generally on level ground, and in full sunshine. Detailed description published in Monthly Weather Review, December, 1916, or in Circular L, Instrument Division, Weather Bureau No. 559. From comparisons available, it appears that losses from bodies of water of considerable area are 50 to 60 percent as great as from pans exposed as above. The records are published in detail in the reports issued by the state section directors of the U. S. Weather Bureau.

Maximum Intensity of Rainfall

The Beaufort Scale is used by seamen. In following table the corresponding velocity per hour in statute miles and in nautical miles is added.

Intensity or force of wind. Beaufort's scale	Velocity	
	Statute miles per hour	Nautical miles per hour
0. Calm. Full-rigged ship, all sail set, no headway	0 to 3	0 to 2.6
1. Light Air. Just sufficient to give steerageway..	8	6.9
2. Light Breeze. Speed of 1 or 2 knots, "full and by"	13	11.3
3. Gentle Breeze. Speed of 3 or 4 knots, "full and by"	18	15.6
4. Moderate Breeze. Speed of 5 or 6 knots, "full and by"	23	20.0
5. Fresh Breeze. All plain sail, "full and by"..	28	24.3
6. Strong Breeze. Topgallant sails over single-reefed topsails	34	29.5
7. Moderate Gale. Double-reefed topsails......	40	34.7
8. Fresh Gale. Treble-reefed topsails (or reefed upper topsails and courses)................	48	41.6
9. Strong Gale. Close-reefed topsails and courses (or lower topsails and courses)............	56	48.6
10. Whole Gale. Close-reefed main topsail and reefed foresail (or lower main topsail and reefed foresail)................................	65	56.4
11. Storm. Storm staysails......................	75	65.1
12. Hurricane. Under bare poles	90 and over	78.1 and over

The words "intensity" and "force," used in connection with this scale, have no direc relation to pressure, but refer to speed or velocity.

The Pressure exerted by the wind against a plane area normal to its direction varies closely with the square of the velocity; thus, $p = av^2$. When v i in meters per second and p is in kilograms per square meter, $a = 0.075$ when v is in statute miles per hour and p is in pounds per square foot, $a = 0.00$

21. Barometric Observations

Whenever pressure is specified in terms of the height of a column of mercury, it is always tacitly understood that it is the height the column balancing the pressure would have under "standard conditions," that is, at 0° C. and where g has the standard value $g_0 = 980.665$ cm per sec per sec adopted by the International Committee of Weights and Measures. In all cases where the mercury column (if of average barometric height and at ordinary atmospheric temperatures) is to be read closer than 2 or 3 mm (0.1 in) one or more of the corrections described below must be made or the accuracy of the reading will be imaginary.

Corrections. Let l be the height of the mercury column as read at t° C. with a scale correct at t_0° C. whose coefficient of linear expansion is β. Let ϕ be the latitude and H the elevation in meters above sea level.

(1) Temperature of the Mercury. Subtract $0.000182\, lt$.

(2) Temperature of the Measuring Scale. Add $\beta\,(t-t_0)\,l$. For brass $\beta=0.000019$; for glass $\beta=0.000008$. If, as is usual, the scale is correct at 0° C., the complete correction, (1) and (2), for the expansion of both the mercury and the scale may be made by subtracting from the observed reading $(0.000182-\beta)\,lt$, which gives

$0.000163\, lt$ for a brass scale, and
$0.000174\, lt$ for a glass scale.

Under ordinary conditions the correction may amount to as much as 4 mm.

(3) Capillary Depression in a Cistern Barometer. Add to the reading of the top of the meniscus the amount given in the table below corresponding to the internal diameter of the tube and the height of the meniscus. This somewhat uncertain correction can be avoided by using a tube at least 25 mm in diameter.

Capillary Depression of Mercury

(After Mendeléeff and Gutkowsky. Kohlrausch, 1910)

Diameter	Height of the meniscus in mm							
	0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8
mm	mm	mm	mm	mm	mm	mm	mm	mm
4	0.83	1.22	1.54	1.98	2.37	......	......	......
5	0.47	0.65	0.86	1.19	1.45	1.80	......	......
6	0.27	0.41	0.56	0.78	0.98	1.21	1.43	......
7	0.18	0.28	0.40	0.53	0.67	0.82	0.97	1.13
8	......	0.20	0.29	0.38	0.46	0.56	0.65	0.77
9	......	0.15	0.21	0.28	0.33	0.40	0.46	0.52
10	......	......	0.15	0.20	0.25	0.29	0.33	0.37
11	......	......	0.10	0.14	0.18	0.21	0.24	0.27
12	......	......	0.07	0.10	0.13	0.15	0.18	0.19
13	......	......	0.04	0.07	0.10	0.12	0.13	0.14

(4) Pressure of the Mercury Vapor. This causes a slight depression at high temperatures, but is less than 0.01 mm under 40° C.

(5) Variation of Weight with Latitude and Elevation. Multiply by $g/g_0 = (1-0.0026 \cos 2\phi - 0.000\,000\,2\,H)$, the local height obtained by applying the above corrections to the reading. The correction for elevation is only 0.1 mm at 700 m, but the correction for latitude may amount to as much as 2 mm.

Mean Barometer-Height b at an Elevation of H Meters above Sea Level
(Kohlrausch)
Air at 10° C. (50° F.) $b_0=760$ mm.

$H=$	0	100	200	300	400	500	600	700	800	900	1000 m
$b=$	760	751	742	733	724	716	707	699	690	682	674 mm
$H=$	1000	1100	1200	1300	1400	1500	1600	1700	1800	1900	2000 m
$b=$	674	666	658	650	642	635	627	620	612	605	598 mm

The international meteorological formula for reducing height b of mercurial barometer at t° C. and latitude ϕ to height b_0 at 0° C. and latitude 45° is

$$\log_e b_0=\log_e b+\frac{H(1-3/8\ \epsilon/b)}{(18\,429+67.5\,t+0.003\,H)(1+0.0026\cos 2\,\phi)}$$

22. Laws of Flight of an Aeroplane

Abstract from The Present Status of Military Aeronautics,
by General Geo. O. Squier, Signal Corps, U. S. A.

Support. In this class of flying machines, since the buoyancy is practically insignificant, support must be obtained from the dynamic reaction of the atmosphere itself. In its simplest form, an aeroplane may be considered as a single plane surface moving thru the air. The law of pressure on such a surface may be exprest by $L=2\,k\delta A V^2 \sin\alpha$ (1)

in which L is the lift (vertical force) acting upon the plane, k is the lift coefficient involving also the effect of aspect ratio (i.e., the ratio of length of plane to breadth), δ the density of the air, A the area of the plane, V the relative velocity of translation of the plane with respect to the air, and α the angle of attack; that is, the angle made by the plane with the direction of flight or translation.

This is the form taken by Duechemin's formula for small angles of attack such as are usually employed in practise. The equation shows that the upward pressure on the plane varies directly with the area of the plane, with the sine of the angle of attack, with the density of the air, and also with the square of the relative velocity of translation.

It is evident that the total upward force developed must be at least equal to the weight of the plane and its load, in order to support the system. If L is greater than the weight the machine will ascend; if less, it will descend.

The constant k depends upon the shape and aspect of the plane and should be determined by experiment. It approximates a constant value for small values of α; for example, with a plane 1 ft square $k\delta=0.00167$ as determined by Langley, when L is exprest in pounds per square foot and V in feet per second.

Equation (1) may be written: $AV^2=L/2k\delta\sin\alpha$.

If L and α are kept constant, then the equation has the form

$$AV^2=\text{constant}.$$

An interpretation of (2) shows that the supporting area varies inversely as the square of the velocity. In the Wright aeroplane, the supporting area at 40 miles per hour is 500 sq ft, while if the speed is increased to 60 miles per hour this area need be only $500/2.25=222$ sq ft, or less than one-half of its present size. At 80 miles per hour the area would be reduced to 125 sq ft, and at 100 miles per hour only 80 sq ft of supporting area is required. It thus appears that if the angle of attack be kept constant while the speed is increased to one hundred miles per hour, the total supporting area may be reduced to 80 sq ft, or two surfaces each measuring about 2.5 by 16 ft, or 4 by 10 ft if preferred.

In the case of a bird's flight, its wing surface is "reefed" as its velocity is increased, which action serves to reduce its head resistance and skin-frictional area, and the consequent power required for a particular speed.

Determination of k for Arched Surfaces. Since arched surfaces are commonly used in aeroplane construction, and as the above equation (1) applies to plane surfaces only, it is important to determine experimentally the value of the coefficient of figure k, for each type of arched surface employed, especially

as k is shown in some cases to vary with the angle of attack, that is, with the inclination of the chord of the surface to the line of translation.

Assuming α constant, the lift of any particular arched surface with a plane surface of the same projected plan and angle of attack may be compared. To illustrate, in the case of the Wright aeroplane, assume $L = 1000$ lb = total weight = W, $A = 500$ sq ft, $V = 40$ miles per hour = 60 ft per second, and $\alpha = 7°$ approximately. Whence

$$k = \frac{L}{2\,A V^2 \sin\alpha} = \frac{1000}{2 \times 500 \times 60^2 \times \frac{1}{8}} = 0.0022\ (V = \text{ft per sec}) = 0.005\ (V = \text{mi per hr}).$$

Comparing this value of k with Langley's value 0.004 for a plane surface, V being in miles per hour, the lift for the arched surface is 25 per cent greater than for a plane surface of the same projected plan. That is, the arched surface is dynamically equivalent to a plane surface of 25 per cent greater than the projected plan. Such a plane surface may be defined as the "equivalent plane."

Resistance and Propulsion. The resistance of the air to the motion of an aeroplane is composed of two parts: (*a*) the resistance due to the framing and load; (*b*) the necessary resistance of the sustaining surfaces, that is, the drag, or horizontal component of pressure, and the unavoidable skin friction. Disregarding the frame, and considering the aeroplane as a simple plane surface, we may express the resistance by the equation

$$R = W \tan\alpha + 2\,fA \qquad (3)$$

in which R is the total resistance, W the gross weight sustained, α the angle of attack, f the friction per square unit of area of the plane, A the area of the plane. The first term of the second member gives the drag, the second term the skin friction. The power required to propel the aeroplane is $H = RV$, in which H is the power, V the velocity. Now W varies as the second power of the velocity, as shown by equation (1), and f varies as the power 1.85, as will be shown later. Hence the total resistance R of the air to the aeroplane varies approximately as the square of its speed, and the propulsive power practically as the cube of speed.

Most Advantageous Speed and Angle of Attack. Again regarding W and A as constant, α may, by equation (1), be computed for various values of V, and f be found for those velocities from the skin-friction table given on page 1548. Thus δ, R and H may be found for various velocities of flight, and their magnitudes compared. In this way, the values in the following were computed for a soaring plane 1 foot square weighing 1 lb, assuming $k\delta = 0.004$, which is approximately Langley's value when V is in miles per hour.

Computed Power Required to Tow a Plane One Foot Square, Weighing One Pound, Horizontally thru the Air

Velocity miles per hour	Angle of attack degrees	Computed resistance in pounds			Tow-line power ft-lb per sec	Lift per tow-line horse-power, lb
		Drag	Friction	Total		
30	8.25	0.145	0.0170	0.162	7.13	77.1
35	5.94	0.104	0.0226	0.1266	6.51	84.3
40	4.52	0.0790	0.0289	0.1079	6.32	86.7
45	3.55	0.0621	0.0360	0.0981	6.39	86.1
50	2.88	0.0500	0.0439	0.0939	6.89	80.2
60	2.03	0.0354	0.0614	0.0968	8.50	64.7
70	1.47	0.0257	0.0814	0.1071	11.00	50.0
80	1.12	0.0195	0.1045	0.1240	14.56	35.8
90	0.88	0.0154	0.1300	0.1454	19.17	28.7
100	0.71	0.0124	0.1584	0.1708	25.00	22.0

Column two, giving values of α for various speeds, is computed from equation (1). Thus, at 30 miles per hour,

$$\sin\alpha = \frac{W}{2\,k\delta A V^2} = \frac{1}{2 \times 0.004 \times 1 \times 30^2}$$

whence $\alpha = 8°.25$. Column three is computed from the term $W \tan \alpha$ in equation (3), thus, Drag $= W \tan \alpha = 1 \times \tan 8°.25 = 0.145$. Column four is computed from the term $2fA$ in equation (3), f being taken from the skin-friction table given below.

The table shows that if a thin plane 1 ft square, weighing 1 lb, be towed thru the air so as just to float horizontally at various velocities and angles of attack, the total resistance becomes a minimum at an angle of slightly less than 3°, and at a velocity of about 50 miles per hour; also that the skin friction approximately equals the drag at this angle. The table also shows that the propulsive power for the given plane is a minimum at a speed of between 40 and 45 miles per hour, the angle of attack then being approximately 4.5°.

The last column of the table shows that the maximum weight carried per horse-power is less than 90 lb. This horse-power may be increased by changing the foot-square plane to a rectangular plane and towing it long-side foremost; also by lightening the load, and letting the plane glide at a lower speed; but, best of all, perhaps, by arching it like a vulture's wing and also towing it long-side foremost, as in the prevailing practise with aeroplanes.

Skin Friction in Air. Even as late as Langley's experiments, skin friction in air was regarded as a negligible quantity, but the extensive and reliable experiments of Zahm in air showed that it was appreciable. As a result of his research on atmospheric friction the following equations are deduced:

$$f = 0.00000778\, l^{-0.07} v^{1.85} \; (v = \text{ft per sec})$$

$$f = 0.0000158\, l^{-0.07} v^{1.85} \; (v = \text{mi per hr})$$

in which f is the average skin friction per square foot and l the length of surface. From this equation the accompanying table of frictions was computed.

Friction per Square Foot for Various Speeds and Lengths of Surface

Wind speed, miles per hour	Average friction in pounds per square foot					
	1-ft plane	2-ft plane	4-ft plane	8-ft plane	16-ft plane	32-ft plane
5	0.000303	0.000289	0.000275	0.000262	0.000250	0.000238
10	0.00112	0.00105	0.00101	0.000967	0.000922	0.000878
15	0.00237	0.00226	0.00215	0.00205	0.00195	0.00186
20	0.00402	0.00384	0.00365	0.00349	0.00332	0.00317
25	0.00606	0.00579	0.00551	0.00527	0.00501	0.00478
30	0.00850	0.00810	0.00772	0.00736	0.00701	0.00668
35	0.01130	0.0108	0.0103	0.0098	0.00932	0.00888
40	0.0145	0.0138	0.0132	0.0125	0.0125	0.0114
50	0.0219	0.0209	0.0199	0.0190	0.0181	0.0172
60	0.0307	0.0293	0.0279	0.0265	0.0253	0.0242
70	0.0407	0.0390	0.0370	0.0353	0.0337	0.0321
80	0.0522	0.0500	0.0474	0.0452	0.0431	0.0411
90	0.0650	0.0621	0.0590	0.0563	0.0536	0.0511
100	0.0792	0.0755	0.0719	0.0685	0.0652	0.0622

The numbers within the rules represent data coming within the range of observation. These observations show that "the frictional resistance is at least as great for air as water, in proportion to their densities. In aeronautics it is one of the chief elements of resistance both to hull-shaped bodies and to aero-surfaces gliding at small angles of flight."

WEIGHTS AND MEASURES

23. The Metric System

The Unit of Length in the metric system is the meter, a length very nearly equal to the one ten-millionth of the distance between the equator and the pole. The original meter was a platinum bar constructed and deposited in the Archives of the French Republic in 1799. At the same time a platinum

weight was constructed which was made as nearly as possible equal to the mass of a cube of pure water at 4° C., the sides of the cube being one tenth the length of the meter. This weight, which is equal to one thousand units in the metric system, is called the kilogram.

The use of the meter as the basis of geodetic surveys had become so general thruout Europe that a conference was called in Paris, France, in 1870, for the purpose of establishing a central bureau where the standards of the different countries could be intercompared. As a result of this conference an International Bureau of Weights and Measures was established near Paris, France, in 1875, by the concurrent action of the principal nations of the world. One of the first tasks undertaken by the Bureau was the construction of exact copies of the meter and kilogram deposited in the Archives. Thirty-one standard meters of iridio-platinum and forty kilograms of the same alloy were constructed and carefully compared with the standards of the Archives and with one another. This great work was completed in 1889, and the meter and kilogram which agreed most nearly with the original standards were called international prototypes, and were deposited at the International Bureau, where they are maintained to-day subject to the authority of the International Committee on Weights and Measures. The remaining meters and kilograms were distributed by lot to the different nations which contributed to the support of the Bureau. The United States secured two copies of the meter and two copies of the kilogram, which are in the custody of the Bureau of Standards at Washington. One of the meters, known as No. 27, and one kilogram, No. 20, were selected as the United States standards, while the other meter and kilogram are used as working standards. It was the declared intention of the International Committee that the various national prototypes should be returned to the International Bureau at regular intervals for the purpose of recomparing them with the international standards and with one another. In this way all measurements based upon metric standards thruout the world are ultimately referred to the international meter and kilogram.

The Unit of Capacity in the metric system is the liter, which is defined as the volume of one kilogram of pure water at the temperature of maximum density (4° C.) under a pressure of 76 cm of mercury. For all practical purposes the cubic decimeter and the kilogram of water may be regarded as identical, the difference between them being less than three parts in one hundred thousand, the kilogram of water having the larger volume.

24. The English System

Units of Length and Mass. While it is the common impression that the customary system of weights and measures in use in the United States is identical with the system in everyday use in Great Britain, there are important differences in some of the units. For all practical purposes the units of length and mass are the same, altho the fundamental standards are quite different in the two countries. In Great Britain the standard yard is a bronze bar in the custody of the Board of Trade and preserved in the Standards Office, Westminster. In terms of the International meter, in England, one yard equals 36/39.370113 meters. In the United States the yard is defined as 3600/3937 meters. The difference amounts to only a little more than one part in 400 000 which is about the difference found in comparing the Imperial yard with its authentic copies at different periods.

It is therefore doubtful whether there is a real difference between the English and United States yards. The difference is merely one of standards, the standard of Great Britain being the bronze bar previously referrred to, while in the United States the fundamental standard is the International meter, of which the U. S. yard is a certain definite fraction, easily measured with the proper apparatus. A similar condition exists with respect to the avoirdupois pound; in England a certain platinum cylinder deposited in the Standards Office is regarded as the standard pound, while in the United States the pound is defined as 453.5924277 grams of which the International kilogram contains 1000. This is the same as the legal value in Great Britain, so that the only difference between the British system in the two countries is one of fundamental standards.

The Capacity Measures of the two countries are, however, quite different. The United States gallon of 231 cubic inches and the Winchester bushel of

2150.42 cubic inches have not been legal measures in Great Britain since 1825, having been superseded by the present Imperial gallon, which is defined as the volume of 10 lbs of pure water at 62° Fahrenheit, weighed against brass weights in air at the same temperature as the water, and with the barometer at 30 in. The Imperial bushel is defined as the volume of 80 lbs of water weighed under the same conditions as the gallon. The bushel of Great Britain is, therefore, exactly equal to eight gallons. The volume of the Imperial gallon, according to the most reliable data available at this time, is 277,420 cubic inches and the bushel 2219.36 cubic inches, the first being larger than the United States gallon by approximately 20% and the latter larger than the United States bushel by 3.2%.

25. Chinese Measures

The following gives the new system of weights and measures adopted by China in pursuance of the imperial rescript of August 28, 1908.

Measures of Length

Chinese		Metric	
1 Hao	equals	0.0032	Centimeter
1 Li	"	0.032	"
1 Fen	"	0.32	"
1 Ts'un	"	3.2	Centimeters
1 Ch'ih	"	0.32	Meter
1 Pu	"	1.6	Meters
1 Chang	"	3.2	"
1 Li	"	576.	"

Measures of Surface

Chinese		Metric	
1 Hao	equals	0.006144	Are
1 Li	"	0.06144	"
1 Fen	"	0.6144	"
1 Fang pu	"	0.0256	"
1 Mu	"	6.144	Ares
1 Ch'ing	"	614.4	"

Measures of Capacity

Chinese		Metric	
1 Shao	equals	0.0104	Liter
1 Ko	"	0.1035	"
1 Sheng	"	1.0355	Liters
1 Tou	"	10.355	"
1 Hu	"	51.7734	"
1 Tan or Picul	"	103.5469	"

Measures of Weight

Chinese		Metric	
1 Hao	equals	0.0037301	Gram
1 Li	"	0.037301	"
1 Fen	"	0.37301	"
1 Ch'ien	"	3.7301	Grams
1 Liang	"	37.301	"
1 Chin or catty	"	596.816	"

26. Japanese Measures

The Kwan, equal to 3.75 kg or 8.267 pounds avoirdupois, is the unit of mass. It is divided into 1000 mommes, the momme into 10 funs and the fun into 10 rins, the rin into 10 mos, and the mo into 10 shis.

The Shaku is the unit of length, equal to $^{10}/_{33}$ (0.30303) meter, or 0.994 U. S. ft. The shaku is decimally divided into sun, bu, rin, mo, shi. Multiples of the shaku are the ken, equal to 6 shaku; the cho equal to 60 ken, and the ri, equal to 36 cho, or 12 960 shaku.

The shaku (land measure) is equal to 0.00033 are, or 0.9884 sq ft, ten shaku equal one go and ten gos equal one bu or tsubo, thirty bu equal one sé, ten sé one tan, and ten tan one cho.

The shaku (capacity measure) equals 0.01804 liter, or 0.0187 U. S. liquid quart, ten shakus equal one go, ten gos one sho, ten shos one to, and ten tos one koku. The metric weights and measures are recognized as legal in accordance with the above equivalents.

27. Russian Measures

The Funt, equal to 0.4095 kilogram, or 0.9028 lb avoirdupois, is the basis of Russian weights. The funt is divided into 96 zolotniks or 32 loths, and the zolotnik is divided into 96 dolias; 40 funts equal one pood.

The Archine, equal to 28 inches or 0.71120 meter, is the basis of the length measure. The archine contains 16 verskops; three archines equal one sagene and 500 sagenes equal one verst.

The dessiatine, equal to 2400 square saganes or 2.6997 acres, is the unit for land measure.

The tchetvert, equal to 2.099 hectoliters, or 5.9567 U. S. bushels, is the unit for dry measure. The tchetvert is divided into 8 tchetveriks, and the tchetverik into 8 garnetz. Twelve tchetverts equal one last.

The vedro, equal to 12.2993 liters, or 3.2491 U. S. gallons, is used for liquids.

28. Special Commercial Units

For Logs the Doyle rule, known in some sections as the Connecticut River Rule, the St. Croix Rule, the Thurber Rule, the Moore and Beeman Rule, and the Scribner Rule, is more generally employed than any other: Deduct 4 inches from the diameter of the log, as an allowance for slab; square one-quarter of the remainder and multiply the result by the length of the log in feet. It is the usual custom to measure the diameter inside the bark at the small end.

The Miner's Inch is defined as the quantity of water that will pass thru an orifice one square inch in cross-section under a given head. The head has been fixt in various localities as from four to six and one-half inches to the center of the orifice.

Bushel (dry measure) = 4 pecks = 8 gallons = 32 quarts, 1 struck bushel = 1.24445 cu ft = 2150.4 cu in.

Barrel. The crude oil barrel is 42 gallons, while the refined product is bought and sold on the basis of 50 gallons to the barrel. The large lime barrel contains 280 lb; the small one 180 lb. Legal net weight of a barrel of flour = 196 lbs. For natural cement barrels contain 282 lb, for portland cement 376 lb.

A legal standard barrel for fruits, vegetables and other dry commodities, except cranberries, contains 7056 cu in. Its outside dimensions are: Length of stave, 28½ in; distance between heads, 26 in; diameter of head, 17⅛ in; circumference of bulge, 64 in; outside measurement and thickness of staves not greater than 0.4 in. For cranberries the corresponding dimensions of the barrel are 28½ in, 25¼ in, 16¼ in, 58½ in.

Firewood is mostly sold by the cord of 128 cu ft.

Old Foreign Units, still sometimes used, with their U. S. equivalents, are as follows:

Central America: libra = 1.014 lb, arroba = 25.36 lb, quintal = 101.41 lb, vara = 32.87, 32.99, and 33 in.

Cuba: libra = 1.016 lb, arroba = 25.37 lb, vara = 33.38 in.

Danish West Indies: pund = 1.023 lb, fod = 1.029 ft, tõnde = 3.948 bu, pot = 0.2552 gal, mil = 4.68 miles.

Mexico: libra = 1.015 lb, arroba = 25.366 lb, vara = 32.992 in, frasco = 2.5 qt.

South Africa: leaguer = 153.64 gal, muid = 3.095 bu, morgen = 2.116 acres.

South America: libra = 1.014 lb, arroba = 25.36 and 25.40 lb, quintal = 100 and 101.42 lb, vara = 32.91 and 33.38 in.

Spain: libra = 1.0143 lb, arroba = 25.36 and 25.40 lb, vara = 32.913 in, butt = 140 gal.

Texas and States on Mexican border: vara = 33⅓ in = 2.778 ft, 5645.376 sq varas = 1 acre, labor = 1 000 000 sq varas = 177.136 acres, league = 25 000 000 sq varas = 4428.4 acres.

Turkey: oke = 2.819 lb, kilé = 1.1 bu, pic = about 27 in.

29. Equivalents of Units

In the following tables the quantities in the same line are equivalents. For example, 1 kilogram equals 2.20462 pounds or 0.980665 megadynes.

Numbers in **boldface** type are exact values by definition. The notation 0.(³)1259 indicates that the (³) is to be replaced by three ciphers.

30. Conversion Tables

The following tables give multiples for transferring English to metric measures or metric to English measures. For example, to reduce 39.37 inches to centimeters, take two numbers from the table at foot of page 1560 and add them together, thus 39 in = 99.06 cm, and 0.37 in = 0.94 cm; then 39.37 inches = 99.06 + 0.94 = 100.00 centimeters.

Venezuela	Bolivar	1.93

* Silver standard; other countries have the gold standard.

SECTION 14

STEAM AND ELECTRIC ENGINEERING

The following outlines of fundamental principles and facts have been prepared, not for mechanical and electrical engineers, but for civil engineers whose knowledge of the subjects is limited.—EDITOR-IN-CHIEF.

THERMODYNAMICS

ELECTRICITY

THERMODYNAMICS

1. Preliminary Statements and Definitions

Heat Energy. The mechanical theory of heat asserts that heat is a form of energy due to the motion or configuration of the molecules of a body. Like mechanical energy, heat energy may be of the kinetic or of the potential form. The summation $\Sigma \frac{1}{2} mv^2$ extended to the moving molecules of a system gives the thermal kinetic energy of the system. Considerations derived from the kinetic theory of gases show that the temperature of a body is a measure of its thermal kinetic energy. When the temperature rises, it is inferred that the thermal kinetic energy is increased, and vice versa. Thermal potential energy is due to the position or configuration of the molecules of a body. Thus when the volume of the body is increased, work is required to separate the molecules against their mutual attractions, and this work is stored as potential energy. Again, when the state of aggregation is changed, as in fusion or vaporization, work is required to break down the molecular structure, and this work is stored in the system as potential energy. In the case of gases, like air and nitrogen, the attractive forces between the molecules are so small that the thermal potential energy is practically zero. The internal energy of a gas is therefore assumed to be wholly of the kinetic form.

Units of Energy. The conventional units used in this chapter are (1) for mechanical energy, the foot-pound and the horsepower-hour (h p-hr), which is equal to 1 980 000 ft-lb; (2) for heat energy, the British thermal unit (B t u), which is defined as the heat required to raise the temperature of one pound of water from 63° to 64° F.

Mechanical Equivalent of Heat. The numerical relation between the unit of heat and the unit of work has been determined very accurately from experiments. The accepted relations are

$$1 \text{ B t u} = 777.64 \text{ ft-lb} \qquad 1 \text{ h p-hr} = 2546.2 \text{ B t u}$$

In ordinary calculations the integral values 778 and 2546 are sufficiently accurate. The mechanical equivalent is denoted by the symbol J, and the reciprocal of it by A; thus, $J = 778$, and $A = 1/J = 1/778$.

State of a System. A thermodynamic system is defined as a body or group of bodies capable of receiving and giving out heat or other forms of energy. Examples of such systems are the media used in heat engines, as water vapor, air, ammonia, etc. In order that a system may receive or give up energy, its state must change; hence the magnitudes that determine the state must change. It is assumed ordinarily that the system is homogeneous and of uniform density and temperature thruout; also that it is subjected to uniform pressure. Then the magnitudes that describe the state of a unit mass are: the pressure p, the temperature t, and the volume v. In the case of a homogeneous mixture of vapor and liquid, as wet steam, a fourth variable is required; this is the ratio x of the weight of vapor to the weight of the mixture. These magnitudes, p, v, t, and x, are called the coordinates of the system.

Absolute Temperature. Many of the equations of thermodynamics are simplified by taking the temperatures from absolute zero instead of from the zero of the F. or C. scale. The position of the absolute zero, as determined by experiments on actual gases, is about 273.1° below 0 C., or 459.6° below 0 F. Hence, denoting ordinary temperatures by t and absolute temperatures by T,

$$T = t + 273.1 \text{ for the C. scale,}$$
$$T = t + 459.6 \text{ for the F. scale.}$$

Characteristic Equations. Of the three coordinates, p, v, T, any two may be, in general, taken as independent and the third is then a function of these two.

Thus in the case of a confined gas, the pressure p may be kept at any desired value and by the addition of heat the temperature T may be raised to any predetermined point. The volume v must, however, depend upon the values given to p and T; that is, v is a function of p and T, as $v = f(p, T)$. Likewise, taking v and T as independent, a functional relation $p = \phi(v, T)$ must exist. For any substance there is such a functional relation between the coordinates, and this relation is called the characteristic equation of the substance. The simplest characteristic equation is that which applies to an ideal perfect gas, namely

$$pv = BT.$$

For certain imperfect gases van der Waal's equation

$$p = \frac{BT}{v-b} - \frac{a}{v^2}$$

represents the relation between p, v, and T. The behavior of superheated steam is, within certain limits, represented accurately by the empirical equation

$$p(v-c) = BT - p(1 + ap^{\frac{1}{2}})\frac{m}{T^n}.$$

The characteristic equation $\phi(p, v, T) = 0$ having three variables may be represented geometrically by a surface. Any possible state of the substance is represented by a point on the surface and a change of state is represented by a path lying in the surface. In the case of a mixture of liquid and vapor (as wet steam), the pressure is a function of the temperature only, and the volume depends upon the temperature and the ratio x. The characteristic surface of such a mixture is a cylindrical surface cutting the pt-plane in the curve $p = f(t)$.

Changes of State. Certain changes of state of a thermodynamic system are of special importance.

1. Constant volume. The volume remaining constant, the pressure varies with the temperature and, in general, heat is absorbed or rejected by the system.
2. Constant pressure. A change of volume involves a change of temperature. Heat is absorbed or rejected.
3. Isothermal. If the temperature remains constant during a change of state, the change is said to be isothermal. In general, heat is absorbed or rejected.
4. Adiabatic. An adiabatic change is one in which the system neither receives nor gives out heat.
5. Isodynamic. In an isodynamic change of state the internal energy of the system remains constant.

Specific Heat. The heat required to raise the temperature of a unit weight of a body one degree under given external conditions is called the thermal capacity of the body. The ratio of the thermal capacity of a substance at the temperature t to the thermal capacity of water at a chosen standard temperature (17.5° C. or 63.5° F.) is the specific heat of the substance. Since at 63.5° F. the thermal capacity of water is 1 B t u, it follows that the specific heat of a substance at temperature t is numerically equal to the thermal capacity at the same temperature. In the case of gaseous substances two specific heats are of special importance: the specific heat at constant volume denoted by c_v, and that at constant pressure denoted by c_p. For solids and liquids, these specific heats are practically identical, but for gases they are considerably different; thus in the case of air, $c_p = 1.4\, c_v$.

Latent Heat. During a change of state of aggregation the heat added to a substance is expended in performing work of disgregation, and none of it is used in raising temperature; that is, the heat absorbed goes to increase the potential energy of the system. Heat thus absorbed during fusion or vaporization is

called latent heat. The heat required to vaporize a unit weight of a liquid depends upon the pressure under which the vapor is formed. The following are latent heats of fusion for various substances in British thermal units per pound:

Ice	144	Cast iron, grey	41.4
Lead	9.66	Cast iron, white	59.4
Tin	25.65	Zinc	50.6
Silver	37.93	Sulfur	16.86

2. Fundamental Laws of Thermodynamics

Transformations of Energy. All transformations of energy are subject to two far-reaching general laws: (1) The law of CONSERVATION OF ENERGY, of which the following is a statement: The total energy of an isolated system remains constant and cannot be increased or diminished by any physical process whatever. (2) The law of DEGRADATION OF ENERGY. According to this law, the result of any transformation of energy is to reduce the quantity of energy that may be usefully transformed into mechanical work.

Examples of the law of degradation are abundant. Work is transformed into heat thru friction and only a small part can be recovered; electrical energy is rendered unavailable when transformed into heat in the conducting system; heat flows from a body of higher temperature to one of lower temperature and as a result a smaller fraction of it becomes available for transformation into work; in the transformation of work into electrical energy or of electrical energy into work, some of the high-grade energy is transformed into heat and is rendered unavailable. The term thermodynamic degeneration is sometimes applied to the inevitable loss of available energy in any transformation of energy; and the law of degradation may be stated as follows: Every natural process is accompanied by thermodynamic degeneration.

The First Law of Thermodynamics is merely the law of conservation applied to the transformation of heat into work. It may be stated as follows:

> When work is expended in producing heat the quantity of heat generated is equivalent to the work done; and conversely, when heat is employed to do work, a quantity of heat precisely equivalent to the work done disappears.

Denoting by Q the heat converted into work, and by W the work thus obtained, the first law is exprest symbolically by the equations $W = JQ$ and $Q = AW$.

The Energy Equation. Let heat be absorbed by a body, as a given mass of air or a saturated vapor. If the volume of the body remains constant, the energy absorbed must be added to the intrinsic energy of the system, and as a result the temperature will rise, or, in the case of a liquid, vaporization will ensue. If, however, the volume of the system changes, external work will be done, and the heat absorbed will in part be used in doing this work, while the remainder will increase the intrinsic energy. In general, therefore,

$$\text{heat absorbed} = \text{increase of energy} + \text{external work.}$$

The change of energy depends upon the initial and final states of the system only. The external work depends, however, on the relation between p and v during the change of state, that is, upon the path; hence the heat absorbed also depends upon the path.

If a system passes thru a closed cycle of processes and returns to its initial state, the change of energy for the cycle is zero; hence for a closed cycle the heat absorbed by the system is the equivalent of the external work. If the change of state is adiabatic, the heat absorbed is zero and the external work is gained at the expense of the intrinsic energy of the system.

The Second Law of Thermodynamics is essentially the law of degradation of energy. While the first law gives a relation that must be satisfied in any

transformation of energy, it is the second law that gives information regarding the possibility of transformation and the availability of a given form of energy for transformation into work. A general statement of the second law is

> No change in a system of bodies that takes place of itself can increase the available energy of the system.

A more concrete statement is that of Kelvin, namely: It is impossible by means of inanimate material agency to derive mechanical effect from any portion of matter by cooling it below the temperature of surrounding objects. In effect, Kelvin's statement denies the possibility of deriving work directly from the heat contained in the atmosphere.

Carnot's Cycle. The availability of a given quantity of heat energy for transformation into work is given by the efficiency of the ideal Carnot engine. In the ideal cycle described by Carnot, the medium is subjected to four processes: (1) It is placed in contact with a source of heat at a higher temperature T_1 and expands isothermally while absorbing heat Q_1 from the source. (2) It is removed from the source and expands adiabatically until the temperature reaches the lower value T_2. (3) It is placed in contact with a refrigerator at temperature T_2, is compresst isothermally and rejects to the refrigerator the heat Q_2. (4) It is compresst adiabatically and arrives at the initial state. The heat $Q_1 - Q_2$ is transformed into work, and the efficiency of the cycle is therefore the fraction $e = (Q_1 - Q_2)/Q_1$. According to Carnot's principle, which may be proved by the second law, all ideal reversible engines working between the same temperature limits T_1 and T_2 have the same efficiency; that is, the efficiency is independent of the working medium and depends upon T_1 and T_2 only. Hence $e = f(T_1, T_2)$. Kelvin proposed as a definition of temperature the relation $Q_2/Q_1 = T_2/T_1$. From this definition, $e = (T_1 - T_2)/T_1 = 1 - T_2/T_1$. Given a quantity of heat Q in a body having the temperature T, and let T_0 denote the lowest available temperature (e.g., the temperature of the atmosphere). No device can transform a greater part of Q into work than the ideal Carnot engine; hence the available part of Q is $Q(1 - T_0/T)$ and the remainder QT_0/T must inevitably be wasted. For example, if the absolute temperature of the source is 900° and that of the atmosphere is 540°, the available energy is $1 - 540/900 = 0.4$ of the total energy; therefore of 1000 B t u taken from the source not more than 400 B t u can by any possible means be transformed into work and at least 600 B t u is unavailable.

Entropy. Experience shows that any actual physical process, as the change of state of a system, is irreversible and is accompanied by frictional effects. A strictly reversible frictionless process is an ideal that may be approched but never attained. In the case of the ideal reversible process, there is no change in the quantity of available energy; but an actual irreversible process is always accompanied by a decrease of the amount of energy available for transformation, or, what is the same thing, an increase of unavailable energy. An investigation of special cases shows that the increase of unavailable energy is the product of two factors: one is T_0, the lowest absolute temperature available in a refrigerator, the other is a term of the form Q/T or $\int T^{-1}\,dQ$. This second factor is called the increase of entropy of the system under consideration.

When the conception of increase of entropy is applied to the system composed of all the bodies involved in a change, that is, to an isolated system, it appears that the increase of entropy is a measure of the thermodynamic degeneration produced by the change. According to the law of degradation every natural change is accompanied by thermodynamic degeneration, therefore it is accompanied by an increase of entropy. The following important principle is evident: The direction of a process, physical or chemical,

that occurs of itself is such as will bring about an increase of entropy of the system. This principle is the foundation of the application of thermodynamics to chemistry.

The Change of Entropy of a body which is in thermal communication with other bodies (as a pound of air, or the steam in an engine cylinder) is illustrated as follows: Let the ordinate A_2A (Fig. 1) represent the absolute temperature T_1 of the body in its initial state. Suppose the body to receive heat from external sources while its state changes reversibly; and let the ordinate A_1A increase in length so as to represent the successive values of T during the heating and at the same time move horizontally in such a way that the area swept over represents the heat absorbed. The end of the ordinate must move in a definite path, as AB. The horizontal distance A_1B_1 thru which the ordinate moves represents the increase of entropy. If OA_1 is chosen arbitrarily to represent the entropy S_1 of the body in the initial state, then OB_1 represents the entropy S_2 in the final state. The area A_1ABB_1 represents the heat Q absorbed (provided the process is reversible), and the following relations between Q and the change of entropy exist:

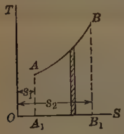

Fig. 1

$$Q = \int_{S_1}^{S_2} T\,dS, \quad S_2 - S_1 = \int_{T_1}^{T_2} \frac{dQ}{T}.$$

The entropy of a system, as thus defined, depends upon the state only; hence S may be used with p, v, and T as a coordinate. Graphical representations on the TS-plane are specially advantageous, as the areas involved represent heat entering or leaving the system. If the process in question is not reversible (for example, as in the case of the flow of steam in a nozzle), this graphical representation fails. The area in this case does not represent the heat entering the system.

An isothermal process is represented on the TS-plane by a straight line parallel to the S-axis, as AB and CD, Fig. 2; reversible adiabatic processes by lines parallel to the T-axis, as BC and DA. The closed cycle $ABCD$ is the ideal Carnot cycle. Area A_1ABB_1 represents the heat Q_1 absorbed from the source during the isothermal expansion AB, area B_1CDA_1 represents the heat Q_2 rejected to the refrigerator during the isothermal compression CD, and the cycle area $ABCD$ represents the heat $Q_1 - Q_2$ transformed into work. The expression for efficiency $e = (Q_1 - Q_2)/Q_1 = (T_1 - T_2)/T_1$ follows from the geometry of the figure. When the order of events in the cycle of Fig. 2 is reversed, the cycle represents the operation of a refrigerating machine under ideal conditions. During the isothermal expansion DC heat Q_2 is absorbed from the cold body, and during the isothermal compression heat Q_1 is rejected to a body at temperature T_1. The cycle area represents the equivalent of the work W that must be furnished from external sources; and $Q_1 = Q_2 + AW$.

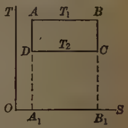

Fig. 2

Heat Content. The functions $u + pv$ plays an important part in many technical applications of thermodynamics. The energy u is measured in mechanical units (foot-pounds) and the product pv has necessarily the same unit. The heat equivalent $A(u + pv)$ is denoted by i and is called the heat content of the system (per unit weight). Evidently i, like u and s, is a function of the state only. The heat absorbed by a unit weight of a substance at constant pressure is the change in heat content $i_2 - i_1$. It is frequently convenient to represent changes of state on a plane having i and s as coordinates. In this scheme of representation, quantities of heat are represented by segments of lines instead of by areas.

3. Properties of Gases

Experimental Laws. The so-called permanent gases obey quite closely the laws of Boyle, Charles, and Joule, namely:

BOYLE'S LAW. At constant temperature, the volume of a given mass of gas varies inversely as the pressure. That is, the product pv is constant when T is constant.

CHARLES'S LAW. At constant pressure, the change of volume of a gas is proportional to the change of temperature. That is, $(\Delta v/\Delta t)p$ = constant.

JOULE'S LAW. The intrinsic energy of a gas is independent of the volume of the gas and depends upon the temperature only. Denoting the energy of unit weight of gas by u, Joule's law is exprest symbolically by the relations: $u = f(t)$, $\partial u/\partial v = 0$.

Characteristic Equation. By a combination of the laws of Boyle and Charles the relation $pv = BT$ is obtained as the characteristic equation of a gas that strictly obeys those laws. Here v denotes the volume of unit weight. If V is used to denote the volume of M lb of gas, the equation takes the useful form $pV = MBT$. The homogeneous form $p_1V_1/T_1 = p_2V_2/T_2$ is advantageous in the solution of problems that involve two states of the gas. The numerical value of the constant B is determined from the equation by inserting known values of p, v, and T corresponding to some assumed standard state. The following are the values of B for certain gases (English units):

Air	53.34	Hydrogen	765.86
Oxygen	48.25	Carbon dioxide	35.09
Nitrogen	54.99	Carbon monoxide	55.14

The gas equation may be written in the form $p = B\gamma T$, where $\gamma = 1/v$ denotes the weight of unit volume. For a chosen pressure and temperature, the product $B\gamma$ is the same for all gases to which the equation applies; and since γ is directly proportional to the molecular weight m, the product Bm is likewise the same for such gases. This product is denoted by R and it is called the universal gas constant. For English units the numerical value of $R = 1544$; hence the gas equation may be written in the form $pv = (1544/m)T$.

It is frequently desirable to refer the specific volume or the specific weight of a gas to a standard state, namely, atmospheric pressure and a temperature of 32° C. In this state v and γ are exprest in terms of the molecular weight m of the gas by the relations $v_0 = 358.65/m$ and $\gamma_0 = 0.002788\ m$.

Specific Heat of Gases. The specific heat of a gas that obeys the law $pv = BT$ must be independent of the volume and also of the pressure, but it may vary with the temperature. For moderate ranges of temperature the specific heats c_p and c_v may be assumed constant without serious error. The following are mean values for the range 0° to 200° C. (32° to 392° F.):

	c_p	c_v	$k = c_p/c_v$
Air	0.240	0.171	1.4
Hydrogen	3.424	2.446	1.4
Nitrogen	0.2438	0.174	1.4
Oxygen	0.2175	0.155	1.4
Carbon monoxide	0.2426	0.162	1.3
Ammonia	0.5106	0.387	1.32

When the temperature range is large, as exemplified in the internal combustion engine, the assumption of constant specific heat is no longer justified. The experiments of Mallard and Le Chatelier, Langen, and others, show that both c_p and c_v increase with the temperature according to a law that is exprest sufficiently well by the linear relation $c = a + bt$. According to Langen's experiments the variation of specific heat with temperature is represented by the following equations, temperatures being Fahrenheit and m being the molecular weight of the gas:

1. For simple gases, as air, nitrogen, hydrogen, etc.:

$$c_v = \frac{1}{m}(4.77 + 0.000667\,t) = \frac{1}{m}(4.48 + 0.000667\,T),$$

$$c_p = \frac{1}{m}(6.75 + 0.000667\,t) = \frac{1}{m}(6.46 + 0.000667\,T).$$

2. For carbon dioxide:

$$c_v = 0.15 + 0.000066\,t = 0.12 + 0.000066\,T,$$
$$c_p = 0.195 + 0.000066\,t = 0.165 + 0.000066\,T.$$

3. For superheated water vapor:

$$c_v = 0.324 + 0.000133\,t = 0.263 + 0.000133\,T,$$
$$c_p = 0.435 + 0.000133\,t = 0.374 + 0.000133\,T.$$

Changes of State. For any change of state of a permanent gas the following relations hold. Denoting by M the weight of gas under consideration, the change of energy is

$$U_2 - U_1 = JMc_v(T_2 - T_1) = (p_2V_2 - p_1V_1)/(k - 1),$$

the change of heat content is

$$I_2 - I_1 = Mc_p(T_2 - T_1) = A\,(p_2V_2 - p_1V_1)k/(k - 1),$$

and the change of entropy per unit weight is

$$s_2 - s_1 = c_p \log_\epsilon \frac{v_2}{v_1} + c_v \log_\epsilon \frac{p_2}{p_1}.$$

For certain important special changes of state the following relations exist: ($W =$ external work, $Q =$ heat absorbed.)

(a) Constant volume:

$p_2/p_1 = T_2/T_1$. $W = 0$. $Q = Mc_v(T_2 - T_1) = (U_2 - U_1)A$.

$$S_2 - S_1 = Mc_v \log_\epsilon \frac{T_2}{T_1}.$$

(b) Constant pressure:

$V_2/V_1 = T_2/T_1$. $W = p(V_2 - V_1) = MB(T_2 - T_1)$.

$$U_2 - U_1 = \frac{p(V_2 - V_1)}{k - 1} = \frac{W}{k - 1}. \quad Q = Mc_p(T_2 - T_1) = I_2 - I_1.$$

$$S_2 - S_1 = Mc_p \log_\epsilon \frac{T_2}{T_1}.$$

(c) Isothermal change of state:

$$p_1V_1 = p_2V_2. \quad U_2 - U_1 = 0. \quad W = MBT \log_\epsilon \frac{V_2}{V_1} = p_1V_1 \log_\epsilon \frac{V_2}{V_1}.$$

$$Q = AW. \quad S_2 - S_1 = \frac{Q}{T} = ABM \log_\epsilon \frac{V_2}{V_1}.$$

(d) Adiabatic change of state: In the adiabatic change, the equation of the expansion curve is $pv^k =$ const. Combining this with the equation $pv = BT$,

$$Tv^{k-1} = \text{const., or } \left(\frac{V_2}{V_1}\right)^{k-1} = \frac{T_1}{T_2}; \quad \frac{p^{\frac{k-1}{k}}}{T} = \text{const., or } \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} = \frac{T_2}{T_1}.$$

$$Q = 0. \quad W = U_1 - U_2 = JMc_v(T_1 - T_2) = \frac{p_1V_1 - p_2V_2}{k - 1}. \quad S = \text{const.}$$

(e) Polytropic change of state: This change is defined by the relation $pV^n =$ const., in which n is a constant.

$$(V_2/V_1)^{n-1} = T_1/T_2. \quad (p_2/p_1)^{\frac{n-1}{n}} = T_2/T_1$$

$$W = \int_{v_1}^{v_2} p\,dV = p_1V_1^n \int_{v_1}^{v_2} V^{-n}dV = \frac{p_2V_2 - p_1V_1}{1-n}. \quad U_2 - U_1 = \frac{p_2V_2 - p_1V_1}{k-1}.$$

$$JQ = U_2 - U_1 + W = \frac{k-n}{(k-1)(1-n)}(p_2V_2 - p_1V_1).$$

$$W : U_2 - U_1 : JQ = k - 1 : 1 - n : k - n.$$

For example, let air be compress according to the law $pV^{1.3} =$ const. Taking $k = 1.4$, $W : U_2 - U_1 : JQ = 0.4 : -0.3 : 0.1$. That is, three-fourths of the work of compression is stored in the air and is manifested by a rise of temperature and one-fourth of it is taken away by the water jacket.

The specific heat corresponding to the polytropic change is constant and is given by the relation $c_n = c_v(k-n)/(1-n)$. For values of n lying between 1 and k, c_n is negative. The work W and heat absorbed may be exprest in terms of c_n; thus

$$W = JM(c_n - c_v)(T_2 - T_1) = \frac{MB}{n-1}(T_2 - T_1). \quad Q = Mc_n(T_2 - T_1).$$

Also $$S_2 - S_1 = Mc_n \log_e \frac{T_2}{T_1}.$$

To determine the value of n for an experimental curve, which is assumed to follow the law $pV^n =$ const., measure to any convenient scale p_1, V_1 and p_2, V_2 at two assumed points A and B. Then compute $n = (\log p_2 - \log p_1)/(\log V_1 - \log V_2)$.

Air Compression. The ideal indicator diagram of an air compressor without clearance is shown in Fig. 3. The curve AB represents the change of state of the air during compression. Without a water jacket, curve AB may be taken as an adiabatic. If a water jacket is used, AB is represented by an equation $pV^n =$ const., and the value of n lies between 1.4 and 1.0. In practice, n is usually about 1.3.

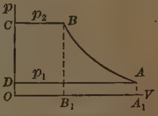

Fig. 3

The work represented by area $ABCD$ is given by the expression $W = n(p_1V_1 - p_2V_2)/(n-1)$, in which V_1 and V_2 denote the volumes at points A_1 and B_1 respectively. The heat absorbed by the water in the jacket during the compression AB is given by $Q = AW(k-n)/(k-1)$. The work of compression is reduced: (a) by water-jacketing; (b) by compression in two or more stages with cooling between the stages.

4. Saturated and Superheated Vapors

Characteristics of Vapors. When sufficient heat is applied to a liquid the state of aggregation is changed from the liquid to the gaseous. The process is called vaporization, and the resulting gaseous product is called a vapor. As long as the vapor is in contact with the liquid from which it is formed it is said to be saturated. The leading characteristic of a saturated vapor is that its temperature depends upon the pressure only, that is, $t = f(p)$. If the vapor is removed from the liquid and is further heated at constant pressure, the temperature rises above the saturation temperature given by $t = f(p)$, and the specific volume increases. The vapor is then said to be superheated, and the difference between the temperature of the vapor and the saturation temperature is the degree of superheat. In the case of saturated vapor, the volume of one pound is a function of the pressure only ($v = \phi(p)$), while in the case of a superheated

vapor the volume is a function of pressure and temperature ($v = F(p, t)$). The so-called permanent gases, air, nitrogen, etc., are in reality superheated vapors far removed from the saturation state.

Vapor and Liquid Mixtures. The process of vaporization and superheating is shown graphically on the TS-plane in Fig. 4. Liquid at 32° F. represented by point A (OA = 491.6) is heated under constant pressure. The process is represented by AB. At B the saturation temperature is reached, vaporization begins and proceeds till all the liquid is changed to vapor, as indicated by point C. Further application of heat superheats the vapor, as indicated by CD. Point B represents liquid at the boiling temperature, point C, saturated vapor, and point D, superheated vapor. For different pressures, points B and C will move along curves s' and s'', called the liquid and saturation curves, respectively. In raising the temperature from 32° to the boiling point, heat represented by area $OABB_1$ is absorbed; this is the heat of the liquid (q'). To vaporize the liquid, heat represented by area B_1BCC_1 is required; this is the heat of vaporization (r). The sum of these is the total heat of the vapor (q''). The area C_1CDD_1 represents the heat absorbed during the superheating. OB_1 represents the increase of entropy (s') during the heating of the liquid, and B_1C_1 the further increase of entropy during vaporization. A point M between B and C represents a mixture of vapor and liquid, the ratio BM/BC being the ratio of the weight of vapor to the weight of the mixture. This ratio is denoted by x and is called the quality of the mixture.

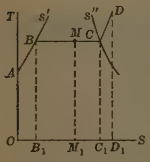

Fig. 4

The latent heat of vaporization r is separable into two parts: (1) the external latent heat, that is, the heat equivalent of the work done during the vaporization process; (2) the internal latent heat ρ, which is the heat required to break up the molecular structure and is stored in the steam in the form of potential energy. The total heat of steam q'' is practically equal to the heat content i'', and in recent steam tables i'' rather than q'' is given.

For a mixture having the quality x (as indicated by point M, Fig. 4) the total heat is $q' + xr$ B t u per lb, and the energy above that of water at 32° is $q' + x\rho$ B t u per lb. The entropy of the mixture per pound is $s' + xr/T$.

Thermal Properties of Saturated and Superheated Steam. The magnitudes i', i'', r, ρ, v'', s', and s'', defined in the preceding articles, are dependent on the temperature of vaporization. For several vapors of technical importance these properties have been determined experimentally with more or less accuracy, and empirical formulæ have been deduced by means of which the properties are exprest as functions of the temperature. In the case of water vapor, the older tables based on Regnault's experiments are now known to be inaccurate.

The relation between pressure and temperature of saturated steam is given very accurately by the formula

$$\log p = 10.5688080 - \frac{4876.643}{T} - 0.0155 \log T - 0.00406258\,T$$
$$+ 0.00000140055\,T^2 - 0.00002\left[10 - 10\left(\frac{t-370}{100}\right)^2 + \left(\frac{t-370}{100}\right)^4\right]$$

The relation between the volume, pressure and temperature of superheated steam is given by the equation

$$v - 0.017 = 0.59495\frac{T}{p} - (1 + 0.05129\,p^{\frac{1}{2}})\frac{66834 \times 10^6}{T^4}$$

in which p is in lb per sq in.

The following formulas give the heat content and entropy of superheated steam.

$$i = 0.320\,T + 0.000063\,T^2 - \frac{23583}{T} - p(1 + 0.0342\,p^{\frac{1}{2}})\frac{6188 \times 10^7}{T^4} + 948.5,$$

$$s = 0.73683 \log T + 0.000126\,T - \frac{11792}{T^2}$$

$$-0.254 \log p - (1 + 0.03420\,p^{\frac{1}{2}})\frac{49504 \times 10^6}{T^5} - 0.0811.$$

With p in lb per sq in the energy u is obtained from the relation

$$u = i - 0.1852\,pv.$$

If in the preceding formulas corresponding values of p and T at the saturation state are inserted, the volume, heat content, and entropy (v'', i'', s'') of saturated steam are obtained.

* The number in brackets is the saturation temperature corresponding to the pressure.

Example 1. Let a mixture of steam and water having a quality $x = 0.96$ expand adiabatically from a pressure of 120 lb per sq in absolute to atmospheric pressure. Required the properties of the mixture in the initial and final states and the work of expansion.

In the initial state the heat content is $i_1' + x_1 r = 311.9 + 0.96 \times 879.5 = 1156.2$ B t u, and the energy of the mixture is $i_1' + x_1 \rho_1 = 311.9 + 0.96 \times 796.9 = 1076.8$ B t u. The entropy is $s_1' + x_1 r_1/T_1 = 0.4911 + 0.96 \times 1.0982 = 1.5454$. The volume of 1 lb of dry steam at 120 lb pressure is 3.735 cu ft, and the volume of a pound of the mixture is $3.735 \times 0.96 = 3.586$ cu ft.

In the adiabatic expansion the entropy remains constant, and in the final state, therefore, $s_2' + x_2 r_2/T_2 = 1.5454$, whence $x_2 = 0.852$; that is, at the end of the expansion the mixture contains nearly 15% water. The heat content in the second state is $180 + 0.852 \times 971.7 = 1007.9$ B t u, the energy is $180 + 0.852 \times 898.9 = 945.9$ B t u, and the volume of 1 lb is $26.81 \times 0.852 = 22.84$ cu ft. The external work is the equivalent of the decrease in energy, or $778\ (1076.8 - 945.9) = 101\ 840$ ft-lb per pound of mixture. The difference $i_1 - i_2 = 1156.2 - 1007.9 = 148.3$ B t u, is the available heat, that is, the heat that may be transformed into work in an ideal engine working between the pressure limits under consideration. It is also the equivalent of the kinetic energy $w^2/2g$ of a jet flowing from a region of 120 lb pressure into a region of atmospheric pressure.

Example 2. Let steam at 200 lb per sq in absolute pressure superheated to 560° expand adiabatically to a pressure of 3 in of mercury. Required the final quality, the change in heat content, and the change of energy.

By interpolation the following values are obtained for the steam in the initial state: $i = 1300.9$, $s = 1.6562$, $v = 2.95$. Consequently the energy per pound is $1300.9 - 0.1852 \times 200 \times 2.95 = 1191.6$ B t u $\quad s_2 = 1.6562 = s_2' + x_2 r_2/T_2 = 0.1561 + 1.7893 x_2$, whence $x_2 = 0.838$, the final quality. $i_2 = 83 + 0.838 \times 1028.3 = 945.1$, $u_2 = 83 + 0.838 \times 965.2 = 892.2$ B t u. The change in energy is therefore $1191.6 - 892.2 = 299.4$ B t u, and the change in heat content is $1300.9 - 945.1 = 355.8$ B t u.

Adiabatic Changes. An adiabatic expansion of a saturated or superheated vapor may be represented approximately by the equation $pv^m = \text{const.}$ For saturated steam m depends upon the initial quality and pressure and is given by the equation $m = 1.059 + 0.000315\,p + o(0.0706 + 0.000376\,p)x$. For superheated steam m may be taken as 1.31, for superheated ammonia at 1.333, and for superheated sulfur dioxide as 1.282. The final volume V_2 is given by the relation $V_2 = V_1(p_1/p_2)^{\frac{1}{m}}$ and the external work is then approximately $W = (p_1 V_1 - p_2 V_2)/(m - 1)$.

5. Flow of Elastic Fluids

General Equation of Flow. Let an elastic fluid, as air or steam, flow along a horizontal tube, Fig. 5. At an assumed cross-section F_1 the pressure of the fluid is p_1 and the mean velocity is w_1; at a second section F_2 the pressure is p_2 and the velocity is w_2. The principal equation of flow is $(w_2^2 - w_1^2)/2g = J(i_1 - i_2)$, in which i_1 and i_2 denote, respectively, the heat content per pound of fluid at sections F_1 and F_2. If section F_1 be taken in the boiler or reservoir from which the fluid is flowing, then $w_1 = 0$, and the equation becomes

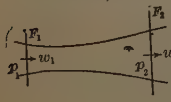

Fig. 5

$$w^2/2g = J(i_1 - i_2); \quad \text{or} \quad w_2 = 223.7\sqrt{i_1 - i_2}.$$

In the flow of elastic fluids, the heat content i plays the same part as the head h in the flow of liquids.

Example. Steam at 120 lb per sq in, quality 0.96. flows into the atmosphere thru a properly proportioned nozzle. Required the velocity of flow. The heat content i_1 is 1156.2 B t u per lb, and if the flow is adiabatic and frictionless the final heat content i_2 is 1007.9 B t u. Hence $w = 223.7\sqrt{1156.2 - 1007.9} = 2724$ ft per sec.

Formulas of Discharge. The weight M of fluid flowing past a cross-section per second is given by the equation of continuity $Fw = Mv$, in which

F denotes the area of the section and v the specific volume of the fluid at this section. If the flow is thru an orifice or short tube, it is found that the pressure in the plane of the orifice never falls below a certain value p_m called the critical pressure. The ratio p_m/p_1 (p_1 being the pressure in the boiler or reservoir) is called the critical ratio. For air its value is about 0.53; for saturated steam, about 0.57. If the pressure p_2 of the region into which the fluid is flowing is greater than p_m, the pressure at the orifice is p_2; but if p_2 is less than p_m, then the pressure at the orifice is p_m and the discharge M is the same whatever the value of p_2. The following formulas for discharge are in current use:

(a) Fliegner's equations for air.

When $\quad p_2 < 0.53\,p_1, \qquad M = 0.53\,F\dfrac{p_1}{\sqrt{T_1}}.$

When $\quad p_2 > 0.53\,p_1, \qquad M = 1.06\,F\sqrt{\dfrac{p_2(p_1 - p_2)}{T_1}}.$

(b) Grashof's equation for steam. Taking the area of the orifice in square inches and the pressure p_1 in lb per sq in,

$$M = 0.0165\,Fp_1^{0.97}. \qquad p_2 < 0.57\,p_1.$$

(c) Rateau's equation. This equation is empirical and is based on experimental data.

$$M = \frac{Fp_1}{1000}(16.367 - 0.96\log p_1). \qquad p_2 < 0.57\,p_1.$$

(d) Napier's equations. These are also empirical and rather inaccurate.

When $\quad p_1 > \frac{5}{3}p_2, \quad M = \dfrac{Fp_1}{70}.$

When $\quad p_1 < \frac{5}{3}p_2, \quad M = \dfrac{Fp_2}{42}\sqrt{\dfrac{3(p_1 - p_2)}{2\,p_2}}.$

Example. Required the discharge in pounds per minute of saturated steam at 100 lb pressure (absolute) thru an orifice having an area of 0.4 sq in. The back pressure is less than the critical pressure, 57 lb per sq in.

By Grashof's formula:

$$M = 60 \times 0.0165 \times 0.4 \times 100^{0.97} = 34.493 \text{ lb}.$$

By Rateau's formula:

$$M = \frac{60 \times 0.4 \times 100}{1000}(16.367 - 0.96 \times 2) = 34.673 \text{ lb}.$$

By Napier's formula:

$$M = \frac{0.4 \times 100}{70} \times 60 = 34.286 \text{ lb}.$$

The discharge may be found from the two fundamental formulas:

$$w = 223.7\sqrt{i_1 - i_2}, \quad \text{and} \quad M = Fw/v.$$

The critical pressure p_m is 57 lb per sq in. From the steam table, i_1 (for 100 lb) = 1188.4 B t u; i_m (for 57 lb) = 1144.1 B t u; $x_m = 0.963$; $v_m = 7.26$ cu ft.

Then $w = 223.7\sqrt{1188.4 - 1144.1} = 1490$ ft per sec. and $M = 60 \times \dfrac{0.4}{144} \times \dfrac{1490}{7.26} =$ 34.18 lb.

Flow in Nozzles. When the pressure p_2 of the region into which a jet is flowing is less than the critical pressure p_m, which is the pressure existing in the emerging fluid, the difference $p_m - p_2$ gives rise to a lateral spreading of the jet. This spreading may be prevented by the addition of a properly proportioned tube (Fig. 6). The tube must diverge so as to permit the expansion of the fluid required by the drop in pressure from p_m at the smallest section a to the

external pressure p_2 at the end section b. The effect of the diverging nozzle is to cause a solid jet to emerge with a velocity w_2 given by the fundamental relation $w_2 = \sqrt{2\,gJ(i_1 - i_2)} = 223.7\sqrt{i_1 - i_2}$. If the external pressure p_2 is greater than p_m, the diverging tube is unnecessary and a simple orifice is used. In the Rateau turbine, for example, the drop in pressure from cell to cell is so arranged that $p_2/p_1 > 0.57$, and the steam flows thru orifices rather than nozzles.

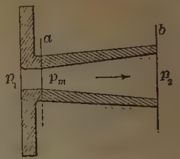

Fig. 6

On account of the length of a nozzle there is necessarily some loss of energy due to frictional resistances. The work of friction is converted into heat, which enters the flowing fluid and increases the final heat content i_2 to a larger value i_2'. It is customary to take as a friction coefficient the ratio of the loss of energy to the kinetic energy of the jet without friction. Denoting the coefficient by y, its formula is

$$y = (i_2' - i_2)/(i_1 - i_2)$$

and the actual velocity of exit w_2' is given by the relation

$$w_2' = \sqrt{2\,gJ(1 - y)\,(i_1 - i_2)} = 223.7\sqrt{(1 - y)\,(i_1 - i_2)}.$$

The quality of the steam at exit is increased by the heat generated thru friction and is given by the equation

$$x_2' = x_2 + (i_1 - i_2)y/r_2,$$

in which x_2 denotes the quality on the assumption of frictionless adiabatic expansion and is given by $s_1' + x_1r_1/T_1 = s_2' + x_2r_2/T_2$. Experiments indicate that y may vary from 0.08 to 0.20, depending on the size of nozzle.

Throttling. The throttling or wiredrawing of a fluid is merely a special case of flow, in which the loss by friction is excessive. The fluid in the region of higher pressure p_1 passes thru a valve or constricted passage into a region of lower pressure p_2. The velocity is increased from w_1 to w_2, but the increased kinetic energy is dissipated as the fluid passing the orifice enters and mixes with the fluid in the second region. Ultimately the velocity w_2 is sensibly equal to the original velocity w_1, and therefore $i_2 = i_1$. For a mixture of saturated vapor and liquid, the equation of throttling is $i_1' + x_1r_1 = i_2' + x_2r_2$. From this equation the value of x_2 is found, and having x_2, the increase of entropy is determined; and the increase of entropy multiplied by T_0 gives the loss of available energy resulting from the throttling.

If steam at the higher pressure p_1 is nearly dry, it becomes superheated when throttled to a much lower pressure. The equation, in this case, becomes $i_1' + x_1r_1 = i_2'' + c_p(t_2' - t_2)$, in which t_2 denotes the saturation temperature for the pressure p_2, t_2' the temperature of the superheated steam, and c_p the mean specific heat for the range $t_2' - t_2$. By means of this equation the initial quality x_1 may be determined from observed values of p_2 and t_2'.

6. Steam Boilers

Types of Boilers. Steam boilers may be divided into two general classes: (1) fire-tube boilers, in which the hot gases from the furnace pass thru the tubes and the water surrounds the tubes; (2) water-tube boilers, in which the water flows thru the tubes. A second classification takes account of the location of the furnace. In an externally fired boiler, the furnace is placed in a brick chamber external to the boiler. The internally fired boiler has its furnace enclosed in the steel shell of the boiler itself. Marine and locomotive boilers are examples of the latter type.

Horse-power Rating. The capacity of a boiler for the generation of steam is measured in terms of an arbitrary unit called horse-power. As defined b

the American Society of Mechanical Engineers, a "boiler horse-power" is equivalent to the evaporation of 34.5 lb of water per hour from and at 212° F. Taking 970.4 B t u as the latent heat of steam at 212°, a horse-power is thus equivalent to the development of 33 480 B t u per hour.

In the original report of the committee, the unit was given as the evaporation of 30 lb of water per hour from feed water at 100° F. into dry steam at a pressure of 70 lb per sq in gage. With the older values of the latent heat of steam, this unit was equivalent to 33 305 B t u per hour, and practically equivalent to the evaporation of 34.5 lb of water from and at 212° F.

Heating and Grate Area. The heating surface of a boiler includes all parts of the boiler that have water on one side and hot gases on the other. In the fire-tube boiler, this includes about two-thirds of the shell and tube sheets, and the external surface of all the tubes. It is customary to allow 10 to 12 sq ft of heating surface per boiler horse-power; hence with 34.5 lb of water evaporated per horse-power, 1 sq ft of heating surface gives an evaporation of about 3 lb of water from and at 212°. It is possible by increasing the speed of the hot gases along the tubes to increase considerably the rate of absorption of heat and thereby increase the capacity of the boiler at some sacrifice of economy.

The grate area required depends upon the character of the fuel used and the draft. With ordinary chimney draft, the grate area should be ⅓ sq ft per horse-power, or more. With forced draft, the area may be considerably smaller. The rate of combustion is ordinarily 10 to 15 lb of coal per hour per sq ft of grate for anthracite coal, and 15 to 20 lb for bituminous coal. With forced draft, these rates may be largely exceeded.

Boiler Economy. The measure of the economic performance of a steam boiler is the weight of water evaporated per pound of coal. In order that boilers working under different conditions may be compared, it is customary to reduce the actual evaporation to equivalent evaporation from and at 212°. If under actual conditions the feed water enters the boiler at temperature t_2 and steam of quality x is generated at pressure p_1, the heat required per pound is $q_1' + xr_1 - q_2'$, where q_2' is the heat of the liquid corresponding to the temperature t_2. To evaporate 1 lb from and at 212° requires 971.7 B t u; hence if M is the actual evaporation and M_e is the equivalent evaporation from and at 212°, $971.7\ M_e = M(q_1' + xr_1 - q_2')$, or $M_e = M(q_1' + xr_1 - q_2')/971.7$. The weight of water evaporated per pound of coal depends (1) upon the efficiency of the boiler and (2) upon the quality of coal used. With high grade bituminous coal having a heating value of 15 000 B t u per lb, the maximum evaporation from and at 212° is 15 000 ÷ 971.7 = 15.44 lb per lb of coal, and the actual evaporation will vary from 9 to 12 lb. With a low-grade coal having a heating value of 10 000 to 11 000 B t u per lb, the actual evaporation from and at 212° may fall as low as 5 or 6 lb.

Losses in Boilers. Coal always contains a certain amount of moisture and ash; and the term combustible is used to denote coal without these incombustible constituents. In tests of boilers the performance is based upon the combustible rather than upon the coal as fired. The total weight of combustible fired multiplied by the heating value of 1 lb of combustible gives the maximum amount of heat that can be produced in the furnace. The heat actually produced is less than this maximum because of incomplete combustion: (1) Part of the carbon may burn to CO instead of to CO_2. (2) With bituminous coal, some of the volatile hydrocarbons may escape unburned. These furnace losses may be reduced to a minimum by proper design of the furnace and by the use of suitable mechanical stokers.

Of the heat actually generated in the furnace, only a part is absorbed by the water in the boiler. The following are the losses of heat: (1) Loss due to moisture in coal

(2) Loss due to moisture formed by burning hydrogen. (3) Loss due to heat carried away by chimney gases. (4) Loss due to radiation. The data required for the determination of these losses are an analysis of the coal with the determination of its heating value, an analysis of the chimney gases, and the temperatures of the outside air and of the chimney gases, respectively.

The composition of the chimney gases furnishes an indication of the conditions as regards economy under which the boiler operates. The CO_2 content of the gas is of special significance. Under proper conditions of operation, the CO_2 may lie between 9 and 12%. A lower value of the CO_2 content indicates either excessive air supply to the furnace or leakage of air thru the brick setting. Many large boiler plants are provided with autographic CO_2 recorders for the continuous recording of the percentage of CO_2 in the gases.

Efficiencies. The efficiency of the furnace is the ratio of the heat actually generated in the furnace to heating value of the combustible fired. The efficiency of the boiler is the ratio of the heat absorbed by the boiler and carried away in steam to the heat actually generated in the furnace. The product of these two efficiencies is the over-all efficiency, that is, the efficiency of the boiler and furnace combined; it may be defined as the ratio of the heat absorbed by the water in the boiler to the heating value of the combustible. The over-all efficiency in ordinary practices is 0.65 to 0.72, tho values as high as 0.80 have been reached.

Boiler Tests. The object of a boiler test is to determine the efficiency and capacity of the boiler. The test consists essentially in measuring accurately the coal consumed and the water evaporated, and in observing the conditions under which the steam is generated. A standard code of rules for conducting boiler tests has been published by the Amer. Soc. of M. E. The following is a brief outline:

I. Determine at the outset the specific object of the trial.

II, III. Examine the boiler, ascertain important dimensions, notice the general condition of boiler and equipment.

IV. Determine the character of the coal to be used.

V. Establish the correctness of all apparatus used in the test; as scales, tanks, water-meters, thermometers, pyrometers, gages.

VI. See that the boiler is thoroly heated before the trial.

VII. The boiler and connections should be proved to be free from leaks before beginning the test, and all water connections except the pipe thru which the water is fed shoulc be disconnected.

VIII. The duration of the test should be ten hours of continuous running.

IX–XIII. These rules refer to methods of starting and stopping the test, uniformit of conditions, and the keeping of records.

XIV. The percentage of moisture in the steam should be determined by the use of a calorimeter.

XV–XVII. A fair sample of the coal should be obtained. The percent of moistur should be determined by air drying and weighing. The quality of the coal should b determined either by heat test, by analysis, or both. The ashes and refuse are to b weighed in the dry state. For elaborate trials a complete analysis of the refuse and as should be made.

XVIII. The analysis of the flue gases is especially desirable. Care should be taken t procure average samples.

XXII. An approximate "heat balance" may be included in the report of the test i the following form:

Total Heat Value of 1 lb of Combustible

	Btu	Per cent
1. Heat absorbed by boiler		
2. Loss due to moisture in coal		
3. Loss due to moisture formed by burning of hydrogen		
4. Loss due to heat carried away by dry chimney gases		
5. Loss due to incomplete combustion of carbon		
6. Loss due to unconsumed hydrogen and hydrocarbons, to heating the moisture in the air, to radiation, and unaccounted for		

7. Steam Engines

Types of Steam Engines. Reciprocating steam engines may be grouped in classes in several ways. The type of valve gear furnishes one basis of division; thus engines may be classed as slide-valve, Corliss, four-valve, etc. Slide-valve engines may be either throttling or automatic, according as the governor regulates the work in the cylinder by throttling the steam or by changing the point of cut-off. Engines in which the complete expansion of steam takes place in one cylinder are simple engines; if the expansion requires two, three, or four cylinders, the engines are termed compound, triple, and quadruple, respectively. Engines are condensing when the exhaust steam passes into a condenser, non-condensing when it passes directly into the atmosphere. Most steam engines are double-acting, that is, work is done during both strokes of the piston.

Ideal Cycle. The ideal cycle of a steam engine without clearance may be represented most advantageously on the temperature-entropy plane. The point A (Fig. 7) represents the state of one pound of water entering the boiler; curve AB represents the heating of the water to the boiling temperature T_1, BC represents vaporization, CD adiabatic expansion in the engine cylinder, and DA condensation of the exhaust steam. The cycle area $ABCD$ represents the available heat, that is, the part of the total heat supplied that may be transformed into work. Denoting by i_1 the heat content of the steam in state C and by i_2 the heat content after adiabatic expansion to D, the available heat is the difference $i_1 - i_2$. The weight of steam consumed per h p-hr is $2546/(i_1 - i_2)$.

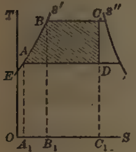

Fig. 7

Example. Referring to the examples on p. 1586, it was shown that in the case of an engine using steam at 120-lb pressure, quality 0.96, and exhausting at atmospheric pressure, the available heat was 148.3 B t u per lb. For an engine using steam at 200-lb pressure superheated to 560° and with a condenser pressure of 3 in of mercury, the available heat was 355.8 B t u per lb. In the first case the ideal steam consumption is $2546/148.3 = 17.2$ lb and in the second case it is $2546/355.8 = 7.16$ lb per hp-hr.

This ideal cycle is called the Rankine cycle and is used as a standard by which to measure engine performance. With given limiting pressures p_1 and p_2 and initial quality x_c, the available heat is the maximum amount of heat that can be transformed into work under these conditions, and the ratio of the heat actually transformed to the available heat indicates the real efficiency of the engine from the point of view of thermodynamics.

Indicator Diagram. The actual cycle of the steam engine differs from the ideal Rankine cycle in several particulars: (1) The metal of the cylinder walls and piston conduct heat, and there is thus an active interchange of heat between the metal and steam, thus making adiabatic expansion impossible. (2) The valves do not act instantly and there is wiredrawing of steam in passing thru the ports. (3) The cylinder must have clearance. The result of these modifications is a cycle having a smaller area than the ideal Rankine cycle.

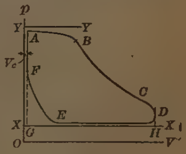

Fig. 8

On the pv-plane the actual cycle of the engine is the diagram drawn by the indicator (Fig. 8). In this diagram, OV represents the line of zero pressure, XX the atmospheric line, OX representing atmospheric pressure, and YY the line of boiler pressure. The length GH represents the volume swept thru by the piston, and XG the clearance volume V_c. AB is the steam line, B the point of cut-off, BC the expansion curve, C the point of release, CD the exhaust line, DE the back-pressure line, E the point of exhaust closure, EF the compression curve, and FA the admission line.

A single indicator diagram shows graphically the pressures exerted by the steam on one side of the piston during two strokes. To determine the net steam pressure transmitted to the piston rod, diagrams taken simultaneously from opposite ends of the cylinder must be superimposed.

The expansion curve BC of the actual diagram may be represented by an equation of the form $pV^n =$ const. The usual statement that the curve is an equilateral hyperbola, in other words, that $n = 1$, has no foundation. Experiments show that the value of n depends upon the quality of the mixture in the cylinder at cut-off; if there is a large per cent of water in the mixture, n falls as low as 0.85 or 0.9, while if there is little or no water present, due to use of superheated steam, n may rise to 1.2.

The indicator diagram has two principal uses: (1) It shows the distribution of the steam to the cylinder, and reveals errors in the setting of the valves. (2) It gives the horse-power developed in the cylinder, the so-called indicated horse-power (i h p).

Indicated Horse-power. The area of the indicator diagram is the integral $\int p\,dV$ taken around the closed cycle; hence it represents the work of the cycle. The mean ordinate of the diagram (see Fig. 8) is found by any convenient method. Ordinarily the area is determined by a planimeter, and this area divided by the length GH gives the mean ordinate. Multiplying by the scale of the indicator spring (30, 40, or 60 lb per sq in), the resulting product is the mean effective pressure (m e p) in lb per sq in.

Let p denote the mean effective pressure, a the area of piston in sq in, l the length of stroke in feet, and n the revolutions per minute. Then the indicated horse-power is

$$\text{i h p} = 2\,plan/33\,000.$$

For a single-acting engine, the factor 2 is dropped. For accurate calculations, the area a should be reduced by one-half of the cross-section area of the piston rod if the rod passes thru one head and by the whole area if the rod passes thru two heads. The piston speed is given by $2\,ln$; hence i h p $= paS/33\,000$.

Brake Horse-power is the horse-power of the engine delivered at the flywheel. The difference between the i h p and b h p is the friction horse-power, and the ratio b h p/i h p is the mechanical efficiency of the engine. The brake horse-power is determined experimentally by the use of a band brake or an absorption dynamometer.

Losses in the Steam Engine. The following are the principal sources of loss of available heat in the operation of the engine: (1) Wiredrawing in ports and valves, and friction in pipes. (2) Leakage past the piston and valves. (3) Loss due to clearance. (4) Radiation and conduction from the cylinder. (5) Initial condensation.

The losses indicated in the first four items may be reduced to a minimum by careful design and construction. The most serious loss is due to the interchange of heat between steam and metal, resulting in initial condensation and subsequent evaporation. The magnitude of this loss depends upon the conditions of operation. It is greater the slower the rotative speed of the engine, the earlier the cut-off, the greater the temperature range in the cylinder, and the greater the ratio of cylinder-wall surface to cylinder volume. The following are the means used to reduce the loss due to initial condensation.

(a) Steam Jackets. The cylinder is surrounded by an annular space containing steam at boiler pressure. The condensation takes place in this jacket instead of in the cylinder. The jacket is most effective in slow-speed engines having large ratios of expansion.

(b) Compounding. The large temperature range that accompanies a large ratio of expansion may be divided between 2, 3, or 4 cylinders, thus giving a relatively small range in each cylinder. The total loss from condensation in all the cylinders is less than the loss would be if the steam were expanded in a single cylinder. The use of two or more cylinders is also advantageous mechanically; the pressures on cranks, shafts, etc., are reduced, and by setting the cranks at proper angles a more uniform turning moment on the shaft is obtained.

(c) Superheating. The most effective means of reducing initial condensation is the use of steam initially superheated. By a sufficient degree of superheat dry steam at cut-off may be insured, and as the rate of absorption of heat by a gas is small, the activity of heat interchange between steam and metal is greatly reduced.

Efficiency Standards. The term efficiency when applied to the steam engine may mean any one of several ratios. Let q = heat supplied to an engine per lb of steam, q_a = available heat, the maximum quantity of heat that can be transformed into work in the ideal Rankine cycle, q_e = heat transformed into work in actual engine, $W_e = Jq_e$ the indicated work per lb of steam, W_b = the work obtained at the brake per lb of steam. Then $e_a = q_a/q$ = thermal efficiency of Rankine engine, $e_e = q_e/q$ = thermal efficiency of actual engine, $e_i = e_e/e_a = q_e/q_a$ = efficiency ratio (sometimes called potential efficiency), $e_b = W_b/Jq_e$ = brake efficiency ratio (based on work at brake), $e_m = W_b/W_a$ = mechanical efficiency. Two other standards are coming into use. These are: B t u consumed per i h p-hour, and B t u per b h p-hour. Since 1 h p-hr = 2546 B t u, the first ratio is equal to 2546 divided by the indicated thermal efficiency; thus if the thermal efficiency is 0.20, the engine consumes 2546/0.20 = 12 730 B t u per hour per i h p.

The really useful criterion of engine performance is the ratio e_b which is equal to the product $e_i \times e_m$. The ratio e_i is a measure of the extent to which the engine transforms into work the heat q_a that is available for transformation, and the ratio e_m measures the mechanical perfection of the engine. The product $e_i \times e_m$, therefore, is an indication of the quality of the engine both thermodynamically and mechanically.

The Rankine efficiency e_a depends upon the pressure limits used and may vary from 0.08 to 0.30. The thermal efficiency of the actual engine varies from 0.03 to as high as 0.25. The efficiency ratio e_e usually lies between 0.60 and 0.75, but in exceptional cases the extremely high value 0 88 has been attained. At full load the mechanical efficiency e_m should lie between 0.80 and 0 90. Since the engine friction remains nearly constant at all loads, e_m may fall as low as 0.50 at light loads.

Performance of Steam Engines. The following gives approximate values of steam consumption of various classes of steam engines (Allen and Bursley's Heat Engines, p. 160):

Steam Consumption.	Pounds per i h p-hr.
Simple throttling engine, non-condensing	44–45
Simple automatic engine, non-condensing	30–35
Simple Corliss engine, non-condensing	26–28
Simple automatic engine, condensing	22–26
Simple Corliss engine, condensing	22–24
Compound automatic engine, non-condensing	25–30
Compound automatic engine, condensing	18–20
Compound Corliss engine, condensing	14–16
Triple Corliss engine, condensing	12¼–13

The Economy of Pumping Engines is usually exprest in terms of duty, which is defined as follows: The duty is the number of foot-pounds of work obtained from the pump cylinders per million B t u furnished to the engine by the boilers. The duty that may be expected of various forms of pumping engines is as follows (Allen and Bursley's Heat Engines, p. 163):

Small duplex non-condensing pumps	10 000 000
Large duplex non-condensing pumps	25 000 000
Small simple flywheel pumps, condensing	50 000 000
Large simple flywheel pumps, condensing	65 000 000
Small compound flywheel pumps, condensing	85 000 000
Large compound flywheel pumps, condensing	120 000 000
Large triple-expansion flywheel pumps, condensing	150 000 000
Large triple-expansion flywheel pumps, condensing, of exceptional economy	165 000 000

At the Deer Island sewage pumping station, Boston, Mass., a 45 000 000-gallon centri ugal pump showed upon test a duty of nearly 96 000 000.

A table by C. V. Kerr (Trans. A. S. M. E., vol. 25, 1904) gives the results of a numbe of tests on various types of steam engines. It appears from these results that the efficienc ratio of a good steam engine should lie between 0.62 and 0.75. Under exceptional con ditions it may rise to 0.80. In general, the steam consumption per h p-hr and the efficienc ratio vary with the load. At light loads the efficiency decreases rapidly as the load decreased; for loads in excess of the engine's rating, the efficiency also decreases but a slower rate.

Steam-engine Testing. The object of the test is to determine the stea consumption of the engine and the efficiency ratio. If a surface condenser used the steam consumption is determined by weighing the steam condense otherwise, the water fed to the boilers must be measured, care being taken th all the steam produced from the feed water goes to the engine. The length the engine test should be at least 5 hours, and if the test includes the boilers, should continue 24 hours. The indicated horse-power is determined from ind cator diagrams taken at intervals of 10 or 15 minutes; and the brake horse-pow is obtained by the use of a brake or dynamometer. The weight of water reduc to pounds per hour is divided by the average i h p and the quotient is the stea consumption in lb per i h p-hr. The steam consumption for the ideal Rankin engine is readily found for the same conditions and the ratio of these gives t efficiency ratio.

A code of rules for conducting steam-engine tests is contained in the Transactions of t A. S. M. E., vol. xxiv. The following are extracts from the report of the committee.

From Introduction to Report: The heat consumption of a steam-engine pla is ascertained by measuring the quantity of steam consumed by the plant, calculati the total heat of the entire quantity, and crediting this total with that portion of the he rejected by the plant which is utilized and returned to the boiler. The term engine pla as here used should include the entire equipment of the steam plant which is concern in the production of the power, embracing the main cylinder or cylinders; the jackets a reheaters; the air, circulating, and boiler-feed pumps, if steam driven; and any other stea driven mechanism or auxiliaries necessary to the working of the engine.

X. Measurement of Feed Water. The method of determining the steam co sumption applicable to all plants is to measure all the feed water supplied to the boile and deduct therefrom the water discharged by separators and drips, as also the water a steam which escape on account of leakage of the steam main and branches connecti the boiler and engine. In plants where the engine exhausts into a surface condenser steam consumption can be measured by determining the quantity of water discharged the air pump, corrected for any leakage of the condenser, and adding thereto the ste used by jackets, reheaters, and auxiliaries as determined independently.

XIII. Indicated Horse-power. The indicated horse-power should be determi from the average m e p of diagrams taken at intervals of 20 minutes, and at more frequ intervals if the nature of the test makes this necessary, for each end of the cylinder.

XXI. Standards of Economy and Efficiency. The hourly consumption of h . . . divided by the indicated and brake horse-power, that is, the number of heat u consumed per i h p and per b h p per hour, are the standards of engine efficiency rec mended by the committee.

XXIV. Ratio of Economy of an Engine to That of an Ideal Engine. The i engine recommended for obtaining this ratio is . . . one which follows the Ran cycle, where steam at constant pressure is admitted into the cylinder with no cleara

d after the point of cut-off is expanded adiabatically to the back pressure. In obtain-g the economy of this engine the feed water is assumed to be returned to the boiler exhaust temperature.

8. Steam Turbines

Types of Steam Turbines. Steam turbines may be divided into two general asses: (1) The impulse or velocity turbine, which is analogous to the Pelton ater wheel. Steam expands in a nozzle until the pressure drops to the essure in the region in which the turbine wheel rotates, and the jet issuing ith relatively high velocity is directed against the blades of the wheel. (2) The action or pressure turbine, which is analogous to the water turbine. In this pe of turbine the steam flows thru alternate guide blades and moving blades d the pressure gradually falls thru both sets of blades. The essential differ-ces between the two types are shown by the following comparison:

Impulse or Velocity	Reaction or Pressure
1. Drop of pressure in nozzles only.	1. Drop of pressure continuous in guides and moving blades.
2. Jet fills only part of wheel circumference.	2. Turbine runs full.
3. Blades usually symmetrical.	3. Blades necessarily unsymmetrical.
4. Jet velocity high, 1000 to 3500 ft per sec.	4. Steam velocities low, 300 to 900 ft per sec.
5. Speed of blade nearly one-half of jet velocity for highest efficiency.	5. Speed of blade nearly equal to velocity of steam.

Compounding. The high velocity of the steam jet resulting from a consider-le drop of pressure renders desirable some method of compounding in order at the peripheral speed of the turbine wheels may be kept within reasonable nits. In most turbines pressure compounding is used. The total drop of essure $p_1 - p_2$ is divided among several wheels, thus reducing the velocity the jet at each wheel. The arrangement is shown in Fig. 9. Steam passes ru orifices m_1, m_2, etc., in the partitions which divide the interior of the turbine to wheel chambers. The pressure drops from p_1 to p_2 in passing thru the st orifices, then from p_2 to p_3, etc. The curves p and w show roughly the essure and velocity changes. The principle of velocity compounding is shown Fig. 10. The steam is expanded in a nozzle to the back pressure p_2, thus ving a jet of relatively high velocity. The jet passes into the first moving heel, then thru a fixt guide, where its direction is reversed, then into a second oving wheel. A second guide and a third wheel are sometimes added. The rves p and w show the changes of pressure and velocity.

Leading Commercial Turbines. The De Laval turbine is a velocity rbine having a single stage. The steam expands in a diverging nozzle to the al pressure and the jet passes thru a single wheel.

The Rateau turbine is a velocity turbine with pressure compounding, g. 9. The ratio of pressures between successive stages is kept above the itical ratio, so that diverging nozzles are not necessary. The number of essure stages is relatively large.

The Zoelly turbine differs from the Rateau turbine only in constructive tails and in having a smaller number stages.

The Parsons turbine is a reaction or pressure turbine. The moving blades e mounted on a drum or rotor and the rows of moving blades alternate with ws of stationary blades attached to the casing. The entire annular space tween rotor and casing is filled with steam and the pressure drops continuously the steam passes thru the stages. The radial length of the blades is increased om stage to stage to provide for the increasing specific volume of the steam.

The Parsons turbine is made in the United States by the Westinghouse Company and by the Allis-Chalmers Company.

The WESTINGHOUSE DOUBLE-FLOW TURBINE is a combination of a velocity and pressure turbine. The steam at boiler pressure is expanded in a nozzle to a much lower pressure and the jet at high velocity is past thru two sets of moving blades with intermediate guide blades (see Fig. 10). The steam is then led to two rotors on opposite ends of the shaft, and the remainder of the expansion is the same as in the Parsons turbine.

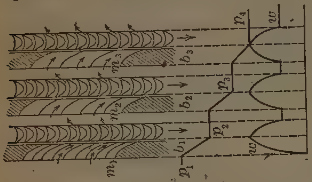

Fig. 9

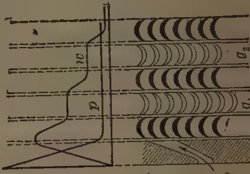

Fig. 10

The CURTIS TURBINE has from 4 to 6 pressure stages, with 2 velocity stage in each pressure stage. That is, there are 4 to 6 wheels, each in a chamber, an each wheel carries 2 rows of blades, with an intermediate row of stationar blades (Fig. 10) attached to the casing. The larger Curtis turbines have ver tical shafts. The shaft is supported by a step bearing which is supplied wit oil under a pressure sufficient to support the weight of the shaft and rotatin parts.

Performance of Steam Turbines. The economy of a steam turbine mea ured in steam consumption per h p-hr is not much different from the econom of a reciprocating engine under the same conditions. With a good vacuum (2 to 29 in of mercury) and with superheated steam the consumption per b h p-h should lie between 10.5 and 14 lb. The efficiency ratios shown by numerou tests lie between 0.60 and 0.72.

Low-pressure Steam Turbines. Because of the limitation of cylind volume, the reciprocating engine is unable to make effective use of an extreme high vacuum. No such restriction applies to the steam turbine, as the blades the final stages may be made long enough to pass the required volume of stea at the lowest pressures obtainable. In general, the reciprocating engine is mo economical than the turbine at high pressures, but the reverse is true at lo pressures; hence a combination of reciprocating engine, to work between boil pressure and atmospheric pressure, and a turbine to take steam from the engi and expand it to condenser pressure, is more efficient than the engine alone turbine alone. Such combinations have found favor in marine engineering. many cases low-pressure turbines have been installed with excellent results existing reciprocating engine plants (see paper by Stott and Pigott, Tra A. S. M. E., 1910). Rateau has applied the low-pressure turbine in cases whe the steam supply is intermittent, as in rolling mills, mine hoists, etc. The engi exhausts at about atmospheric pressure into a heat accumulator, which simply a tank partly filled with water, and the turbine is supplied from th accumulator (see paper by Rateau, Trans. A. S. M. E., vol. 25.).

Relative Fields of Engines and Turbines. The reciprocating engine is most eff tive in any service of an irregular character, where varying speed is required, or where t direction of rotation must be reversed. The moderate rotative speed of the engine is a a decided advantage in many classes of service. The field in which the turbine is preë nent is in central power-station service. The high rotative speed of the turbine facilita

direct connection to electric generators. The turbine can be closely regulated, its efficiency is nearly constant under widely varying loads, it requires small floor space and comparatively inexpensive foundations. For these reasons the turbine has practically displaced the reciproacting engine in central-station service. The turbine has also been applied successfully to marine service both alone and in combination with reciprocating engines. Rateau has been successful in applying the turbine to centrifugal pumps and air compressors; and an extension of this field may be expected.

9. The Internal Combustion Engine

Heating by Internal Combustion. An air engine is one that uses air as the working fluid. The term hot-air engine is usually applied, however, to an engine in which the air is separated from the furnace by a metal wall. Such engines have been failures for the reason that the air absorbs heat slowly and it is impossible to maintain a high temperature in the working fluid. By the method of heating by internal combustion the rapid chemical action supported by the medium itself permits the rapid heating of large quantities of air to a very high temperature. The medium and the furnace being within the cylinder, the metal walls can be kept at a sufficiently low temperature by a water jacket, and the inner surface may be exposed to high temperature without danger of destruction. Engines that make use of the principle of internal combustion are in reality air engines, since the working medium is principally air, but they are generally known as gas engines and oil engines.

Types of Gas Engines. Internal combustion engines fall under two chief classes: (1) The explosion type, in which the mixture of fuel and air is drawn into the cylinder and ignited, thus producing an explosion and a sudden rise of pressure at nearly constant volume. (2) The slow burning type, in which the fuel is introduced gradually and burned quietly without increase of pressure. The Otto engine is a representative of the first type, the Diesel engine of the second type.

Another classification is based on the number of strokes of the piston required for the completion of the cycle. In the four-cycle engine four strokes are required, in the two-cycle engine, two strokes. Engines of small power are usually single-acting; large engines, are, however, usually double-acting. The Nürnberg, Westinghouse, and Snow engines are examples of double-acting four-cycle engines; the Koerting and Oechelhaeuser engines are examples of double-acting two-cycle engines. (For descriptions of various types of gas engines, see Levin's Modern Gas Engine, chap. xiv.)

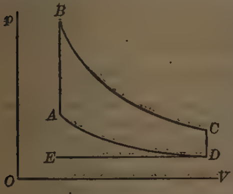

Fig. 11

The Otto Cycle. In Fig. 11 is shown the ideal indicator diagram of the four-cycle Otto engine. The operations are as follows: The explosive mixture is drawn into the cylinder, as represented by ED, and comprest adiabatically (DA). The mixture is ignited, causing a rise of pressure, as shown by AB. The gases in the cylinder, which are products of combustion with an excess of air, expand adiabatically, as shown by BC. Finally, the burned gases are in part expelled from the cylinder, as indicated by DE. As a first approximation it is assumed that the medium thruout the cycle has the properties of air, that the specific heat is constant, and that the medium during the process AB receives a quantity of heat equal to that developed by the combustion of the fuel in the actual cycle. With this assumption, the ideal efficiency of the engine is

$$e = 1 - \frac{T_d}{T_a} = 1 - \left(\frac{V_a}{V_d}\right)^{k-1} = 1 - \left(\frac{p_d}{p_a}\right)^{\frac{k-1}{k}}.$$

It is seen that the higher the compression pressure p_a, the greater the ideal efficiency.

For the ideal case the temperature and pressure at the point B are determined as follows: If q_1 is the heat absorbed per pound of air during the process AB,

$$q_1 = c_v(T_b - T_a), \quad \text{whence} \quad \frac{T_b}{T_a} = \frac{q_1}{C_v T_a} + 1; \quad \text{and since } V_a = V_b,$$

$$\frac{p_b}{p_a} = \frac{T_b}{T_a}, \quad \text{or} \quad p_b = p_a\left(\frac{q_1}{C_v T_a} + 1\right).$$

The temperature and pressure as thus calculated are never realized in practice. In the first place, part of the heat q_1 is absorbed by the water jacket; secondly, the properties of the actual fluid in the cylinder are not the same as the properties of air, and the specific heat of the fluid is not constant but increases with the temperature. The efficiency of the cycle when the calculation is made with the actual contents of the cylinder taken into consideration is not more than 0.8 of the efficiency deduced for the cycle with air as the medium; and the efficiency of the actual engine is still smaller.

Diesel Cycle. In the Diesel oil engine, air without fuel is comprest to a pressure of about 500 lb per sq in. The fuel is introduced into this air by the aid of a separate small air compressor, and burns without explosion. No igniting device is required, as the temperature of the air is raised by compression above the temperature of ignition. The fuel may be cut off early or late, depending on the load. The De La Vergne oil engine resembles the Diesel engine in its general features, but a lower compression pressure is employed.

Horse-power of Gas Engines. The indicated horse-power of a gas engine is given by the formula i h p = $plan/33\,000$, in which n denotes the number of explosions per minute. The mean effective pressure that may be obtained depends upon the kind of fuel. It may vary from 60 to 70 lb per sq in for producer and blast-furnace gas, 85 to 95 lb for natural gas and gasoline, and 95 to 110 lb for alcohol. The brake horse-power of automobile engines is given approximately by the rule of the Association of Automobile Manufacturers, namely: b h p = $d^2N/2.5$, in which d denotes the cylinder diameter in inches and N the number of cylinders.

Performance of Gas Engines. The internal combustion engine has intrinsically a higher thermal efficiency than the steam engine. Based on coal used, the consumption of a gas engine with producer gas is about 30% less than the consumption of a steam engine. This result is obtained under most favorable conditions for both engines.

A large number of tests of a gas engine and gas producer were made by the U. S. Geological Survey at the St. Louis exhibition. The producer was rated at 250 horse-power capacity and the engine at 235 h p at 200 r p m. Tests were made with a large number of coals. With high-grade bituminous coal the weight of coal consumed by the producer per brake horse-power delivered by the engine ranged from 0.95 lb to 1.32 lb. A steam engine of the same power would consume about double the weight of coal.

The following are the results of tests of gas and oil engines of the larger sizes:

Engine	Fuel	Brake h p	Thermal efficiency Per i h p	Thermal efficiency Per b h p
Westinghouse	Natural gas	606	28.6	25.5
Snow	Natural gas	595	29.4	23.7
Borsig-Oechelhaeuser	Coke-oven gas	628	33.0	27.5
Premier	Producer gas	368	33.7	25.6
Koerting	Producer gas	341	34.0	24.1
Westinghouse	Producer gas	500	30.1	25.2
Cockerill	Blast-furnace gas	725	31.5	26.0
Nürnberg	Blast-furnace gas	1186	33.9	28.2
Diesel	Oil	297	45.8	32.2

ELECTRICITY

10. Definitions, Units, Fundamental Laws

Systems of Units. There are two systems of electrical units, both of which are derived from the fundamental or centimeter-gram-second (C G S) system. The ELECTROSTATIC SYSTEM is based on the force exerted between two charges of electricity; the ELECTROMAGNETIC SYSTEM is based on the force exerted between a magnetic field and a conductor carrying a current placed in that field. Many of these units are inconvenient to use in practice, and certain modifications, known as practical units, have been adopted and legalized in a number of countries by international agreement. These practical units are used in all engineering work; C G S units are frequently used in physical and research work.

Electromotive force (symbols E, e, and e m f) is that which causes electricity to flow or tend to flow, and is analogous to hydrostatic head. The practical unit is the VOLT, that electromotive force which, when applied to a circuit of one ohm resistance, will cause a current of one ampere to flow. The standard volt is represented by the Clark and Weston standard cells. The legal value of the Clark cell, when made according to certain prescribed directions, is 1.434 volts at 15° C. The value of the Weston cell, adopted by the U. S. Bureau of Standards, Jan. 1, 1911, is 1.0183 volts at 20° C.

The Volt is equal to 10^8 C G S units. When very small electromotive forces or potentials are to be measured, the unit millivolt, one thousandth of a volt, is frequently used. High potentials are often exprest in kilovolts or thousands of volts. DIFFERENCE OF POTENTIAL is the difference in electrical pressure between two points in an electric circuit and is measured in volts. This term is often incorrectly used instead of electromotive force.

Current (I, i) is the rate of flow of electricity. The practical unit is the AMPERE, which is the current flowing in a circuit of one ohm resistance when an electromotive force of one volt is impressed on it. The legal standard ampere is that steady current which will deposit 0.001118 grams of silver per second when past thru a silver nitrate solution under certain prescribed conditions.

The Ampere is equal to 10^{-1} C G S units. A milliampere is one thousandth part of an ampere.

Resistance (R, r) is that property of a material that opposes the flow of electricity thru it. It varies directly with the length and inversely with the cross-sectional area. The practical unit is the OHM, which is the resistance of a circuit in which a current of one ampere flows when subjected to an electromotive force of one volt. The legal standard ohm is the resistance of a column of mercury 106.3 cm long and 14.4521 grams mass at 0° C. Working standard resistances are made of resistance wire or ribbon carefully adjusted and standardized by comparison with the legal standard. Manganin, a copper alloy, is most extensively used because of its permanency. The usual sizes range from 100 000 ohms to 0.00001 ohm, and always in powers of 10.

The Ohm is equal to 10^9 C G S units. Insulation resistances are usually exprest in terms of the megohm, or one million ohms, and very small resistances in microhms, or millionths of an ohm. RESISTIVITY (ρ) or specific resistance of a material is the resistance between opposite faces of a centimeter cube or an inch cube. CONDUCTANCE is the reciprocal of resistance, and CONDUCTIVITY (γ) is the reciprocal of resistivity. RELATIVE CONDUCTIVITY (usually incorrectly abbreviated to "conductivity") is the term most used in engineering. It is the percentage ratio of the true conductivity (i.e., reciprocal of resistivity) of the material to that of copper of a certain specific gravity and specific resistance known as the International Annealed Copper Standard. Materials are classed as conductors or insulators according as they are of low or high resistivity, respectively INSULATION RESISTANCE refers to the resistance of insulating material measured in

megohms. The DIELECTRIC STRENGTH of an insulating material is the high-potential voltage which ruptures that material and is usually express in volts per mil or per millimeter.

Quantity of Electricity (Q, q) is the product of current and time. The practical unit is the COULOMB, which is one ampere flowing in a circuit for one second.

The Coulomb is equal to 10^{-1} C G S units. The unit in more common use commercially is the ampere-hour, equal to 3600 ampere-seconds or coulombs.

Electrical Energy (W) is the work done in a circuit or an apparatus by current flowing thru it. The practical unit is the JOULE or WATT-SECOND, which is the work done when one ampere flows thru a resistance of one ohm for one second.

The commercial unit is the watt-hour, equal to 3600 joules; also the kilowatt-hour, equal to 1000 watt-hours.

Electrical Power (P) is the rate of expending electrical energy or the rate of doing work per unit of time. The practical unit is the WATT, which is the work done in one second when one ampere flows in a circuit under a pressure of one volt, or $P = I \times E = I^2R$.

The commercial unit is the kilowatt (one thousand watts). One horse-power is equal to 746 watts.

Capacitance or Electrostatic Capacity (C, c) of a circuit or apparatus is the property by virtue of which it can hold a charge of electricity. The practical unit is the FARAD, which is the capacity of a circuit or apparatus that will be charged to a potential of one volt by one coulomb of electricity.

The farad is so large a quantity that commercially the microfarad is generally used The farad is equal to 10^{-9} C G S units; the microfarad to 10^{-15} C G S units.

Self-induction of a circuit is that property which opposes any change in the value of the current flowing thru it. It is analogous to inertia and is due to the magnetic field which surrounds a conductor carrying current. When the current is established or changes, the field increases or decreases and the lines of force cut the conductor, inducing a counter e m f which opposes the change in the current.

Inductance (L, l.), or coefficient of self-induction, of a circuit is the constant by which the time rate of change of the current in the circuit must be multiplied to give the e m f induced in the circuit by such change. The practical unit is the HENRY, which is the inductance of a circuit where a change of one ampere per second will induce one volt e m f.

A henry is equal to 10^9 C G S units. The unit ordinarily used is the millihenry (one-thousandth of a henry).

Impedance (Z) of a circuit is the resistance offered to the passage of alternating current. It depends on the frequency of the current and the resistance, inductance, and capacity of the circuit. It is measured in ohms and is equal to $\sqrt{R^2 + X^2}$.

Reactance (X) of a circuit is that part of the resistance offered to the passage of alternating current which is due to the inductance and capacity of the circuit.

It is measured in ohms and is equal to $2\pi nL - \frac{1}{2\pi nC}$.

Frequency (n) of an alternating-current circuit is the number of complete reversals, or cycles, of the current per second. It is equal to the product of half

the number of poles on the generator and the revolutions per second. An alternation is half a cycle.

The standard frequencies in this country are 25 and 60 cycles, altho 40-cycle systems are in operation. A very few of the early 133-cycle systems are also to be found, and 15 cycles has been advocated for alternating current railways.

Phase refers to the time relation between the current and potential in an alternating-current circuit, or to the time relation between the potentials in two or more circuits.

Thus, if the current and potential in a circuit reverse at the same instant, they are in phase. When the current reverses after the potential, it is said to be out of phase. and a lagging current; when it reverses before the potential, it is out of phase, and a leading current. A two-phase generator has two circuits in its armature and the e m f's generated are ¼ cycle or 90 electrical degrees apart. Similarly, a three-phase generator has three circuits and the e m f's are ⅓ of a cycle or 120° apart.

Power Factor of a circuit is the ratio of the true power passing thru it to the product of the volts and amperes. It is equal to the cosine of the time angle at any instant between the potential and current.

When the time angle is zero, that is, when the potential and current are in phase, the power factor is 1.00 (cosine 0°), often exprest 100%. If they are out of phase by 90°, the power factor will be zero (cosine 90°).

Load Factor. The daily or yearly (or other period) load factor of a machine, plant or system is the ratio of the average power to the maximum power during the period indicated.

The **demand factor** of an installation is the ratio of the maximum load actually taken by the installation to the total connected load (that is the sum of the ratings of all apparatus in the installation).

The **diversity factor** of an installation is the ratio of the sum of the maximum demands of the various loads in the installation to the maximum demand of the whole installation.

Hysteresis is that property of magnetic material which causes the induction corresponding to a given magnetizing force to be greater when the latter is decreasing than when it is increasing.

Hysteresis loss is the energy expended in the material because of hysteresis when the magnetizing force is changed from one direction to the other and back again. It appears in the form of heat.

Eddy Currents are stray local currents induced in those metal parts of electrical apparatus which are in rapidly changing magnetic fields.

Eddy-current loss, which appears in the form of heat, is the power expended by eddy currents flowing in these metal parts, and is equal to the product of the square of the current and the resistance. It is one of the largest losses in alternating current apparatus, and therefore parts in which this loss occurs are laminated in order to reduce the length of the current paths, thereby increasing the resistance and decreasing the currents.

A Series Circuit is one in which the total current passes thru each part of the circuit. A PARALLEL OR MULTIPLE CIRCUIT is one in which the total current is divided among the various parts of the circuit.

Fundamental Laws. The following are the more important laws and principles of electricity and magnetism underlying the practical applications of electricity.

Ohm's Law. The current in a circuit containing no source of e m f is equal to the potential applied at the terminals of the circuit divided by the resistance, or $I = E/R$.

This law applies to alternating-current circuits only when they are non-inductive, that is, contain resistance only. Otherwise the current is equal to the potential divided by the impedance, or $I = E/Z$.

Laws of Series and Parallel Circuits Carrying Direct Current. In a series circuit the total resistance is equal to the sum of the resistances of its component parts. In a parallel circuit the current in each circuit is inversely proportional to the resistance of each branch of the circuit, and the reciprocal of the total resistance of the circuit is equal to the sum of the reciprocals of the branch resistances.

Capacitances. When two or more capacitances (condensers) are connected in series, the reciprocal of the total capacitance is equal to the sum of the reciprocals of the capacitances. If they are connected in parallel, the total capacitance is equal to the sum of the capacitances. It is to be noted that the law is just the reverse of that for resistances.

Conductor in a Magnetic Field. When a free conductor is placed in a magnetic field and current is passed thru it, the conductor will move. The force exerted will be proportional to the field strength and the current. This is the fundamental principle of MOTORS.

Electromagnetic Induction. When a conductor is moved thru a magnetic field or a magnetic field is moved thru a conductor, an e m f will be induced in it which will be proportional to the field strength, the rate of motion, and the length of conductor cutting the field. This is the fundamental principle of GENERATORS.

Fundamental Equation for the Generation of an EMF. The following is the equation for the e m f generated in (*a*) a coil rotating in a magnetic field at a uniform speed or (*b*) a coil which incloses an alternating magnetic flux varying in such a manner that a sine wave e m f is generated (see Art. 11).

$$E = 4.44\,\frac{n\phi f}{10^8}$$

where E = e m f, mean effective value (see Art. 11) in volts;

n = number of complete turns in coil;

ϕ = total magnetic flux (maximum instantaneous value if produced by alternating current) inclosed by the circuit. If the magnetic flux density is uniform (the usual case) throughout the space occupied by the coil, $\phi = BA$ where B = flux density in lines per square centimeter and A = area inclosed by coil in square centimeters.

f = revolutions of coil per second or frequency in cycles per second of magnetizing current.

Law of Magnetic Circuits. In a magnetic circuit the total magnetic flux is equal to the magnetomotive force divided by the reluctance of the circuit, the relation being similar to Ohm's law. The total magnetic flux (lines of force) corresponds to current (amperes), the magnetomotive force (gilberts) to electromotive force (volts), and magnetic reluctance (oersteds) to resistance (ohms). In practice it is customary to deal with the magnetizing force per unit length of magnetic circuit, which, when the magnetic circuit is of non-magnetic material, is equal to $H = 4\pi NI/10\,l$, where H = field strength (gausses), NI = ampere turns and l = length. When the material is magnetic, the magnetic induction (gausses) is $B = kH$, where k = permeability, a quantity which varies with the material and with B.

Galvanic Electricity. If two unlike metals are immersed in an acid or salt solution an electromotive force will be generated between them. The magnitude of the e m f will depend upon the metals and the solution used. This phenomenon is the basis of all electric batteries.

Electrolysis. When electric current (direct) is passed thru a solution (called electrolyte), it is decomposed. According to Faraday's law, the amount of decomposition is directly proportional to the quantity of electricity (product of current and time) passed thru the solution.

Thermoelectric Effect. When a circuit is made up of two dissimilar metals and the two junctions are maintained at different temperatures, an e m f will be established which will be very nearly proportional to the difference in temperature between the two junctions. Conversely if current is passed thru a circuit consisting of two dissimilar metals, heat will be developed at one junction and absorbed at the other junction. This is known as Peltier effect.

Heating Effect. When an electric current is passed thru a solid conductor, the electric energy expended in the conductor is entirely converted to heat energy. The amount of heat developed is proportional to the resistance, the square of the resistance and the time. (Joule's law). That is,

$$H = 0.2928\, I^2RT,$$

where H = heat in British thermal units;
I = current in amperes;
R = resistance in ohms;
T = time in hours.

11. Commercial Electrical Measurements

Commercial and Ordinary Engineering Measurements are made with various indicating instruments which are calibrated by various more or less direct methods against the primary standard or standards representing the quantity indicated by the instrument.

Direct current and potential are measured with ammeters and voltmeters respectively. They are almost universally of the D'Arsonval type, in which a small fine wire coil is free to move in the field of a permanent magnet. In ammeters this coil is connected to a specially made low resistance called a "shunt." Its deflections are proportional to the fall of potential across this shunt and therefore to the current flowing thru it. Voltmeters differ from ammeters only in that the moving coil is connected in series with a high resistance and across the circuit to be measured instead of in parallel to a low resistance which is in series with the circuit.

For moderate current (25 amperes and less) the shunt is contained in the instrument case, but for larger currents it is external to the instrument and connected to the latter by small flexible wires. Thus, shunts as high as 25 000 amperes capacity can be placed in the circuit at the most convenient point. Instruments permanently located on switchboards are called switchboard or station instruments, as distinguished from portable instruments used for testing purposes.

Alternating current is measured with ammeters of several types, the more usual being the iron-disk, inclined-coil dynamometer, and hot-wire types. The principle of iron-disk instruments is the repulsion between the eddy currents induced in a very small iron disk, and the field which produces them. The principle of the inclined-coil and dynamometer instruments is the attraction and repulsion between two coils carrying current. In hot-wire instruments the expansion of a taut wire, when heated by the passage of a current, is utilized to measure the current. Some of the types are made self-contained up to 300 amperes, but current transformers are usually used with larger currents. In all high-tension circuits (over 440 volts) current transformers are used irrespective of the size of the current in order to insulate the instrument from the circuit.

The several VALUES OF AN ALTERNATING CURRENT (and e m f) are (*a*) *instantaneous value* or value at any instant during a cycle, (*b*) *mean effective value* which is the square root of the sum of the squares of the instantaneous values during one cycle (also called effective value and root-mean-square value), (*c*) *average value* which is the arithmetical average of the instantaneous values during one alternation or half cycle, (*d*) *maximum value* which is the maximum of the instantaneous values during one cycle. When the wave form is a sine curve (that is, when the variation of the instantaneous values during one cycle with respect to time follows the sine law) the relations between these various values are as follows:

$$\text{Maximum value} = \sqrt{2} \times \text{effective value};$$

$$\text{Maximum value} = \frac{\pi}{2} \times \text{average value};$$

$$\text{Average value} = \frac{2\sqrt{2}}{\pi} \times \text{effective value};$$

$$\frac{\text{Effective value}}{\text{Average value}} = \frac{\pi}{2\sqrt{2}} \doteq 1.11 \ (= \text{form factor});$$

$$\frac{\text{Maximum value}}{\text{Effective value}} = \sqrt{2} = 1.414 \ (= \text{crest, peak or amplitude factor}).$$

All of these values are employed in electrical engineering but the *effective value* is the one ordinarily measured and used. This particular value is used because it is the value which will produce the same heating effect as a direct current of the same magnitude, and it is the value indicated by all alternating-current instruments used in all ordinary measurements.

Alternating Potentials are measured with voltmeters of the same types as the ammeters, being wound with many turns of small wire instead of a few turns of relatively large wire. Voltage transformers which step-down the voltage to the standard value of 110 volts are used when measuring high voltages.

The secondaries of current transformers are usually 5 amperes capacity, but the instrument scales are marked to read the primary current. Similarly, the scale of the voltmeter may be marked to indicate the line potential altho the voltage on the instrument is usually about 110 volts.

Power in direct current circuits is usually measured with an ammeter and a voltmeter, the power in watts being the product of the amperes and the volts. In alternating current circuits however, power is usually measured with a *wattmeter*. It is a two-circuit instrument, one circuit being a fixed coil of a relatively few turns of relatively large wire, connected in series with the circuit to be measured. The other circuit consists of a coil of many turns of fine wire so mounted as to be free to move within the magnetic field produced by the fixed coil. It is connected in series with a certain amount of resistance and across the circuit to be measured.

In a single-phase alternating-current circuit, having a power factor of 1.00 (which is practically the case where the load is incandescent lamps), the power may be measured with an ammeter and a voltmeter because in that case the power is equal to the product of the amperes and the volts. If, however, the power factor is less than 1.00 (which is always the case where the load is all or partially motors, arc lamps, etc.), the power is equal to the product of amperes, volts and power factor, and a wattmeter is used. (The power may be measured by the less convenient "three-ammeter" or "three-voltmeter" method indicated below.)

In polyphase alternating current circuits, wattmeters are always used because the condition where the power could be measured with a voltmeter and an ammeter, that is unity power factor, is practically never found.

Wattmeter Connections. The following paragraphs show the methods of connecting wattmeters in various kinds of alternating current circuits. Current and potential transformers are used with wattmeters where necessary, the same set of transformers being often used for all three instruments (wattmeter, ammeter and voltmeter) at the same time.

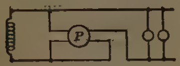

Fig. 12

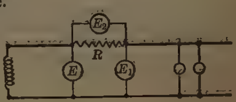

Fig. 13

Single-phase Circuit. One wattmeter connected as shown in Fig. 12 will read true watts. The power may also be measured with three voltmeters or three ammeters.

In the three-voltmeter method, a known non-inductive resistance, R, is connected in series with the load as shown in Fig. 13, where E, E_1, and E_2 are points where voltmeter readings are to be taken. The power in watts is

$$W = \frac{E^2 - E_1^2 - E_2^2}{2R} \qquad \text{(watts)}$$

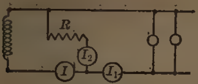

Fig. 14

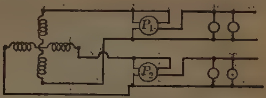

Fig. 15

Similarly, in the three-ammeter method, Fig. 14, the power in watts is

$$W = R\left(\frac{I^2 - I_1^2 - I_2^2}{2}\right) \qquad \text{(watts)}$$

Two-phase, Four-wire Circuit (not interconnected). Two wattmeters, connected as shown in Fig. 15 are sufficient, these conditions being equivalent to two single-phase circuits. The total power is obviously the arithmetical sum of the readings of the two instruments.

Two-phase, Three-wire Circuit. Two wattmeters should be connected as shown in Fig. 16, the total power being the algebraic sum of the two readings. This connection is

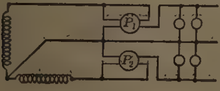

Fig. 16

Fig. 17

correct for all conditions of load, balance and power-factor. One wattmeter may be used as in Fig. 17, provided there is no load across the outer conductors and the phases are balanced as to load and power factor.

Two-phase, Four-wire, Interconnected Circuit. Three wattmeters should be used, connected as in Fig. 18, the total power being the algebraic sum of the three readings. This connection is correct for all conditions of load, balance and power-factor. Two wattmeters, one in each phase, will give the true power only when the load is balanced.

Three-phase, Three-wire Circuits. Two wattmeters should be used, connected as indicated in Fig. 19, the total power being the algebraic sum of the two readings. With

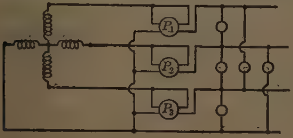

Fig. 18

Fig. 19

a balanced load, each instrument will indicate half the total power at unity power-factor, and at 50 per cent power-factor one instrument will indicate the total power, the other instrument indicating zero. At less than 50 per cent power-factor, one instrument will read negative.

Three-phase, Three-wire Circuits, Balanced Load. When the load is balanced, the power may be measured with one wattmeter by the following methods:

(*a*) With "star" box or artificial neutral as shown in Fig. 20. The total power is three times the reading of the wattmeter. The resistance in each leg of the star box should be non-inductive and small compared with that of the potential circuit of the wattmeter, so that the current taken by the latter will not disturb the potential at the neutral point.

(*b*) With "Y" box as shown in Fig. 21. The total power is three times the wattmeter reading. This arrangement is similar to (*a*), one leg of the star box being re-

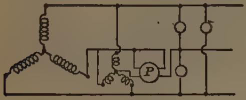

Fig. 20

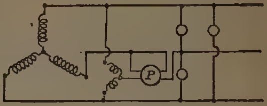

Fig. 21

placed with the potential circuit of the wattmeter itself. The other two legs have the same resistance as the potential circuit of the wattmeter.

(*c*) With a "T" reactance coil as shown in Fig. 22. The total power is twice the wattmeter reading. The impedance of the reactance coil must be small compared with that of the potential circuit of the wattmeter, so that the current taken by the potential circuit will not disturb the potential at *O*.

Three-phase, Four-wire Circuits. Three wattmeters are used as shown in Fig. 23. The total power is the algebraic sum of the three readings. This method is correct

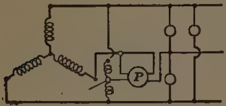

Fig. 22

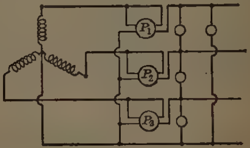

Fig. 23

for all conditions of load, balance and power-factor. A three-phase "star" system with a grounded neutral is virtually a four-wire system and the power should be measured with three wattmeters. Obviously, if the load is balanced, one wattmeter can be used, the total power being the indication of the wattmeter multiplied by three. In that case, the current coil should be connected in series with one conductor or phase wire and the potential coil between that conductor and the neutral.

The Power Factor of a single-phase circuit and of each phase of a two-phase circuit is the ratio of the watts, indicated by a wattmeter, to the product of the volts and amperes. In a three-phase circuit it is the ratio of the total watts to the product of the average volts across the three phases, the average current in the three conductors and 1.73 $(\sqrt{3})$.

Energy is measured with watt-hour meters. They are essentially small motors in which the speed is proportional to the power and the total revolutions is proportional to the energy being consumed. The moving element is geared to a suitable registering mechanism which indicates the kilowatt-hours of energy past thru the meter. On direct-current circuits the whole current must pass thru the instrument. Alternating current meters can be used with potential and current transformers, and in such cases the meter readings are multiplied by the product of the ratios of these transformers. Single-phase energy is measured with one meter, two-phase with one meter in each phase, or with a poly-

phase meter, and three-phase energy is measured either with two meters connected in the same manner as two indicating wattmeters or with a polyphase watt-hour meter which consists essentially of two single-phase meters with a common shaft.

Watt-hour meters are connected into the circuit just the same as watt meters as indicated in Figs. 12 to 23 inclusive. A polyphase meter has separate terminals for each element and is connected just as two wattmeters would be connected.

12. Conductors

Electrical Conductors are materials of comparatively low resistance, thru which electricity will flow in appreciable quantities, as distinguished from high-resistance materials called INSULATORS, thru which electricity will not pass except in minute quantities. There is no sharp distinction between the two, there being good and poor conductors, and good and poor insulators. Most metals are conductors, but only a few are used commercially. Silver is the best conductor, but copper is very nearly as good, and being comparatively plentiful, cheap, and otherwise very suitable, it is by far the most generally used metal for conductors. Aluminum, which has about 62% of the conductivity of copper, is being used to some extent in high-voltage transmission and on heavy current switchboards where minimum weight is desirable. Iron and steel have 10 to 20% of the conductivity of copper and are used in telephone and telegraph lines and in special cases where the current is small and low cost or greater strength is important. There has recently come into commercial use a bimetallic conductor consisting of steel wire with a shell of copper welded on the outside. This material has a conductivity of 30 to 40% of that of copper alone, and a much

* Down to and including No. 7 B & S is stranded; No. 8 B & S and smaller is solid. The mass and resistance of stranded wire is assumed to be 2 per cent greater than that of the equivalent solid wire.

These data apply to bare copper wire of 100% relative conductivity (International Annealed Copper Standard). The resistance of hard drawn wire may be considered as about 2.5% higher than these values. The corresponding data for aluminum wire of 61% conductivity may be obtained by multiplying weights by 0.304, feet per pound by 3.29 and resistance by 1.64.

The data for sizes larger than No. 0000 B & S refer to stranded cable and are approximate. They may be in error from 1% to 3%.

greater tensile strength. Poor conductors, such as nickel, nickel alloys of various kinds, and platinum, are used to a great extent where the comparatively high resistance is desirable, as in rheostats and heating devices. Wire made of these materials is known as resistance wire.

The cross-section of electrical conductors is usually measured in circular mils. A circular mil is the area of a circle 0.001 inch diameter. The specific resistance is often exprest in terms of a mil-foot, which is the resistance of a wire one circular mil in cross-section and one foot long. Telephone and telegraph engineers use the term pounds per mile-ohm, which is the weight in pounds of a conductor one mile long and having a resistance of one ohm. The resistance of conductors varies with the temperature, usually increasing in direct proportion to the temperature up to at least 100° C. The increase in resistance per ohm per degree increase in temperature above a given standard

(0° or 20° C.) is the resistance temperature coefficient. The preceding tables give data for the more common conductor materials and copper wire of standard sizes.

Resistance Wires. The following materials are representative of this class of conductors:

German Silver is one of the first materials used for resistance purposes. Alloy of copper, nickel, and zinc (the percentage in the table refers to percentage of nickel). Tends to become brittle if repeatedly heated and cooled and has comparatively high temperature coefficient (0.0002 to 0.0004 per degree C.). Resistance per mil-foot, 195 and 290 ohms, respectively.

Manganin. Alloy of copper, nickel, and manganese. Very low temperature coefficient (0.00001 per degree C.). Permanent if not heated excessively. Used extensively for standard resistances. Resistance per mil-foot, 250 ohms.

"Nichrome." Trade name for a nickel-chromium alloy. Practically non-corrosive and has extremely high melting point (2800 deg. F.). Used extensively in heating appliances and small electric furnaces. Resistance per mil-foot, 600 ohms.

"Advance." Trade name for a copper-nickel alloy. Temperature coefficient practically nil. Durable at moderate temperatures. Used extensively in electrical instruments. Resistance per mil-foot, 295 ohms.

"Therlo." Trade name for a copper-manganese-aluminum alloy. Temperature coefficient practically nil and has a very low thermal e m f against copper. Used in electrical instruments, particularly shunts of ammeters. Resistance per mil-foot, 280 ohms.

13. Direct-current Generators and Motors

Definitions. A GENERATOR is a machine for converting mechanical power into electrical power, and a MOTOR is a machine which converts electrical power into mechanical power. A direct-current generator can also be operated as a motor, but commercially it is not customary to make motors and generators interchangeable because there are minor differences in design.

When a loop of wire is revolved in a magnetic field, an electromotive force is induced, the value of which, at any instant, depends upon the speed of rotation, the strength of the magnetic field, and the size of the loop. The direction of the e m f in such a loop will reverse twice each revolution; hence to obtain direct current a COMMUTATOR is used to

reverse the connection between the external circuit and this coil at the proper moment, thus keeping the polarity of the potential at the terminals the same. A number of such loops wound on an iron or steel CORE together with a suitable commutator constitute the ARMATURE of a generator. The magnetic field is produced by two, or any multiple of two, electromagnets, called POLES, which surround the armature. These poles and the supporting frame which completes the magnetic circuit constitute the FIELD of the machine.

Types of Generators. The various types of direct-current generators may be classified according to the method of exciting the field. SERIES GENERATORS have the field windings connected in series with the armature, and hence the voltage depends upon the load. This type can be designed to give potentials of 2000 to 6000 volts, and a special form is used extensively for series arc-lighting systems. SHUNT GENERATORS have their field windings connected in parallel with the armature. The field contains many turns of relatively small wire and requires only a small current. The voltage is regulated independently of the load by increasing or decreasing the field current by means of a variable resistance (rheostat) which is in series with the field. This type is little used, the COMPOUND GENERATOR being the standard type. In this, both a shunt field and a series field are provided, one winding being placed over the other.

In the plain shunt generator the voltage decreases somewhat as the load increases unless the field current is increased. By winding a few turns of heavy conductor on the poles and passing the load current thru them, the field is automatically increased so that the voltage can not only be kept automatically constant, but even raised to compensate for the drop in voltage in the feeders and mains. This form of compound generator is said to be over-compounded. The compound generator is universally used for lighting and power at 125 and 250 volts, and for railway purposes at 550 to 1200 volts. Any number of compound generators can be operated in parallel, but a special connection between the series fields of the several machines, called an equalizer, is necessary to obtain satisfactory operation.

A Separately Excited Generator is a generator in which the field current is obtained from a source other than the generator itself. It is used only in special cases, such as low-voltage generators for electroplating and for storage-battery charging. BOOSTERS are separately excited low-voltage generators in which the armature is connected in series with a circuit in which it is desired to raise the voltage. They are frequently used on circuits where the voltage is below normal on account of the excessive drop due to heavy loads or long length. MAGNETO GENERATORS have permanent magnets and are only built in small sizes for telephone signals, gas-engine ignition, and similar purposes.

Types of Motors. There are three general classes of motors,—SERIES, SHUNT, and COMPOUND; like generators, they are distinguished by the method of exciting the field. The field of the SERIES MOTOR is in series with the armature and the characteristic feature is a large torque at low speed, which makes it particularly adapted for railways, hoists, and cranes where a high torque is required at starting. SHUNT MOTORS have the fields in parallel with the armature and are essentially shunt generators operated as motors. This is the type in most common use for general power purposes, as its speed decreases only a few per cent from no load to full load. Fig. 24 shows the characteristic relation between speed and torque, also between current and torque for both series and shunt motors. COMPOUND MOTORS have both shunt and series fields, and are either accumulative or differential, according as the series field strengthens or weakens the total field when the load increases. The accumulative form is ordinarily used, for it combines the high-starting-torque feature of the series motor with the constant-speed feature of the shunt motor. Where very uniform speed or an increase in speed is desired, the differential form is used. To prevent excessive sparking in motors subject to rapidly changing loads over wide

ranges, interpoles are provided. These are small poles placed between the regular poles and provided with a winding which is in series with the armature.

Speed Regulation can be effected by changing the voltage applied to the armature or the amount of magnetic flux passing thru it. The former is done either with a regulating rheostat in series with the armature or by having several different voltages available to which the armature can be connected. The usual method of changing the magnetic flux is to change the field current by means of a rheostat. There are also in commercial use, in small motors, methods in which the distance between the pole pieces and the armature can be readily changed with a hand wheel and thus alter the field strength.

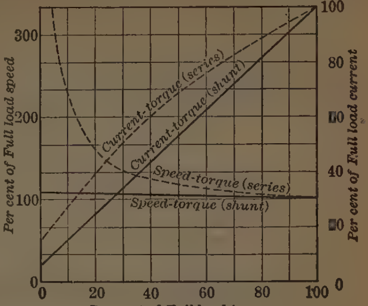

Fig. 24

Starting. Motors are not connected directly to the line when starting because the resistance is so low that an excessive current would flow which would injure the motor. When the motor is running, a generator or counter e m f is produced which opposes the line voltage, and limits the current to the amount required by the load. A motor is started by reducing the line voltage to a low value by inserting resistance (starting rheostat) in series with the armature, the resistance being gradually cut out as the motor comes up to speed. These rheostats are usually provided with attachments which automatically cause the lever to return to the starting position if the voltage is cut off the line.

The Capacity of generators and motors is determined by the temperature that their insulation will withstand continuously without injury. The rating of such machines is therefore more or less indefinite, but the Amer. Inst. Elec. Eng. prescribes in its Standardization Rules that, at rated load and with a room temperature not exceeding 40° C., the maximum rise in temperature above the room of any part of the insulation shall not exceed certain stipulated values for the various types of insulation in general use. These range from 55° to 85° C.

Specifications for generators should state the class of service on which the machine is to operate; type of machine; kind of prime mover; and whether direct-connected or belted; kilowatt capacity; voltage; speed; allowable temperature rise of commutator, field, and armature under continuous operation at full load and two hours at 25% overload; that no sparking should occur at any load from no load to full load with brushes stationary; that the machine should carry 50% overload one hour without injury or serious sparking; efficiency at 25, 50, 75, 100, and 125% loads; and change in voltage from no load to full load. Specifications for motors include similar clauses, except that speed regulation replaces voltage regulation.

Cost and Efficiency of generators and motors will vary with the conditions of use. In the table on p. 1612 are given figures for average, conservative conditions.

The cost of motors and generators varies greatly with the speed. Standard slow-speed machines are 30 or 40% more expensive than standard high-speed machines of the same capacity. The efficiency falls off, with decrease in load, about 1% at 75% load, 2 to 3% at 50% load, and 7 to 15% at 25% load.

14. Alternating-current Generators and Motors

Alternating-current Generators, frequently called alternators, are essentially direct-current machines without commutators, the armature circuit being con-

Average Efficiency and Cost of Direct-Current Generators and Motors

Generators			Motors		
Size, k w	Efficiency at full load, per cent	Cost, dollars per kw	Size, h p	Efficiency at full load, per cent	Cost, dollars per h p
5	87	70	1	75	70
10	88.5	50	2	80	65
25	90	40	3	83	60
50	91	35	5	85	50
100	92	30	7.5	87	42.5
200	93	25	10	88	35
500	94	22.5	15	89	30
1000	94.5	20	20	89	25
1500	95	19	50	90	20
2000	95	18	100	91	17.5

For a standard starting rheostat, add for example about 10% for a 1-h p motor and about 5% for a 100-h p motor.

nected directly to the outside circuit. The connection between the armature and the outside circuit is not reversed, every time the winding passes from a north pole to a south pole, and vice versa, as in a direct-current generator. Thus an e m f is produced at the machine terminals which rises from zero to a maximum value in one direction, decreases to zero, reverses, increases to a maximum in the other direction, and again decreases to zero in the time that the winding passes under one north pole and one south pole. Such a cyclic period is called a CYCLE and the FREQUENCY of the current is the number of cycles per second.

Types of Generators. The most common forms of alternating-current generators may be divided into two types. In the REVOLVING-ARMATURE type, the armature is the moving member and the field is stationary, current being delivered to the circuit by means of BRUSHES resting on the revolving collector rings. In the REVOLVING-FIELD type, the field is the moving member, while the armature is stationary. It is wound in the frame which surrounds the field.

The revolving-armature type is confined to generators of less than 200 or 300 kw capacity. The stationary-armature type permits the direct generation of potentials up to 15 000 volts and the economical construction and operation of large capacity generators for a wide range of speeds, from that of the low-head water wheel to that of the steam turbine.

Windings. There are three kinds of alternators, based on the number of circuits in the armature. A SINGLE-PHASE generator has only one circuit in its armature and two terminals. In a TWO-PHASE generator there are two circuits which generate e m f's 90 electrical degrees apart. When each circuit or phase is brought out separately there are four terminals, for connection to a two-phase four-wire circuit. Frequently, the two phases are connected to each other and to the middle one of three terminals, for connection to a two-phase three-wire circuit. In a THREE-PHASE generator there are three circuits or phases in which three e m f's 120 electrical degrees apart are generated. These circuits are interconnected with either a delta or a star connection requiring three or four terminals respectively.

The following diagrams indicate the relation between the currents and voltages in these various forms of generators and the circuits to which they are ordinarily connected. I and i are the amperes per phase, and E and e the volts per phase in armature and circuit respectively.

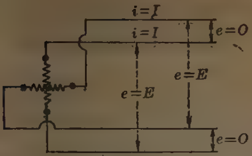

FIG. 25. Two-phase Four-wire Circuit

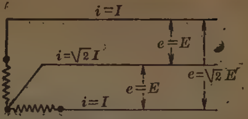

FIG. 26. Two-phase Three-wire Circuit

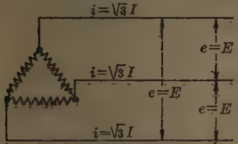

FIG. 27. Three-phase, Three-wire Circuit, Delta connected

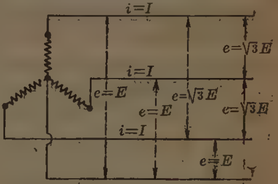

FIG. 28. Three-phase Four-wire Circuit, Star connected

Field Excitation. Alternators are usually separately excited. Small ma-:hines are sometimes provided with a commutator device by means of which ;ufficient current is rectified to excite the field. A common practice is to pro-vide a separate generator or exciter for each alternator. This machine is driven rom the alternator shaft by a belt or by direct mechanical connection. In large tations, a source of excitation common to all the generators is usually provided.

Efficiency and Cost. The following table gives average conservative figures for the fficiency and cost of polyphase alternators. The cost figures, in particular, are neces-arily approximate. Slow-speed machines cost more than high-speed machines, and high-oltage more than low-voltage machines. Hence there may be a difference of at least 5% in the cost of generators of the same capacity.

Efficiency and Cost of Polyphase Alternators

Size, kw	Efficiency			Cost, dollars per kw
	50% load	75% load	100% load	
50	81.0	83.0	86.0	18.00
75	82.5	84.5	87.5	15.00
100	84.5	86.5	89.0	13.00
200	85.5	87.5	90.0	11.00
300	87.0	89.0	91.0	10.00
500	88.0	90.5	92.0	9.50
750	89.0	91.5	93.0	9.25
1000	90.5	93.0	94.0	9.00
1500	91.0	93.5	94.5	8.00
2000	91.5	94.0	95.0	7.50
3000	92.0	94.5	95.5	6.50
5000	92.5	95.0	96.0	5.00

Motors. There are two general types of alternating-current motors,—the ynchronous and the induction. The SYNCHRONOUS MOTOR is essentially an

alternator operated as a motor. It has to be brought up to synchronous speed (the speed at which it would run if operated as a generator at the line frequency) by external means before it can be connected to the line. It will operate only at synchronous speed.

Synchronous motors are used as a rule only in large sizes (200 h p and over) and where it is not necessary to stop the machine frequently. Such cases are in substations where power is converted from one frequency to another or from alternating current to direct current, and in large factories.

Induction Motors are, theoretically, transformers in which the core and the secondary winding are free to move, and the force which the windings of a static transformer exert on each other is utilized to produce mechanical power. When the rotating member (rotor) runs at synchronous speed, no magnetic flux from the stationary member (stator), which is connected to the line, cuts the conductors, and hence no torque is exerted. When a load is applied to the motor, the speed falls below synchronism (called slip), and a current is induced in the rotor conductors which will produce the necessary torque to carry the load. Fig. 29 shows the characteristic relation between speed and torque, also between current and torque, of a polyphase induction motor.

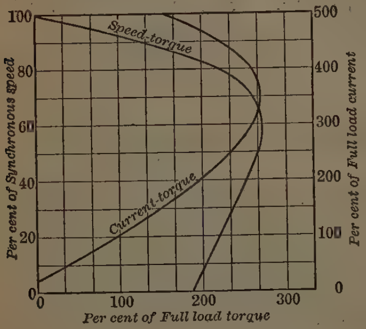

Fig. 29

Polyphase Induction Motors (both two and three phases) are the most commonly used type. Their characteristics are similar to those of the shunt motor, in that they have a comparatively low starting torque and operate at approximately constant speed. Polyphase motors are built in all sizes from fan motors to 1000 h p and over, and are used for all power purposes. There are two forms,—the SQUIRREL CAGE, in which the winding of the rotor consists of heavy copper bars short circuited on each other, and with no external connections; in the SLIP-RING form, the rotor has a regular polyphase distributed winding, into the phases of which an external variable resistance is connected thru collector rings on the shaft. The slip-ring form has a larger torque at starting than the squirrel-cage form, but its efficiency is somewhat lower. When induction motors are overloaded a certain definite amount they will stop. This load is called the maximum torque, or "stalling" load and is two or three times normal load.

Single-phase Motors are infrequently used because special devices are necessary to make them self-starting, and they are more expensive and less efficient than polyphase motors.

The Series Alternating-current Motor is essentially a direct-current series motor with certain modifications which are necessary for operation on alternating current. It is a single-phase motor and is used in traction work where variable speed and variable torque are required. The repulsion motor is one of several forms of the series alternating-current motor.

Operating Data and Cost. In the following table are given approximate average values for the slip, power factor, efficiency, and cost of standard 60-

cycle polyphase motors. The efficiency and cost of 25-cycle motors are slightly higher. As with all rotating electrical apparatus, the cost varies greatly with the speed—as much as 50% in some cases.

Polyphase Induction Motor Data

Standard sizes, h p	Slip, per cent	Power factor, per cent	Efficiency, per cent	Cost, dollars per h p
¼	20	70	65	90
½	15	75	70	80
1	10	75	75	70
2	8	78	78	60
3	7	80	80	55
5	6	82	82	45
7½	6	84	84	40
10	6	85	85	35
15	6	86	85.5	30
20	5.5	87	86	25
30	5	88	87	20
50	4.5	89	88	17.5
75	4.0	90	88.5	15
100	3.5	91	89	13
150	3.0	91	90	12.5
200	2.5	92	90	12
300	2.0	92	90.5	10.5
500	2.0	92	91	9

Starting. If an induction motor is connected directly to the line when starting it will take a current two to four times the normal full-load running current. To avoid the disturbance which this produces in the system, it is customary to start at a reduced voltage. This is obtained by means of a COMPENSATOR, a single-winding transformer with several taps on it to which the motor is successively connected. The slip-ring type is started with full-line voltage on the motor but with resistance in the rotor circuits. This resistance is gradually cut out as the motor speed increases.

Speed Variation. The inherent characteristics of induction motors are such that the speed is practically constant at a value depending on the frequency and the number of poles in the stator winding. Certain fixt changes in speed are sometimes obtained by providing a special winding by means of which the number of poles can be changed. Change in speed may also be obtained with a variable resistance in the rotor circuits of a slip-ring motor, but the efficiency is materially decreased.

Rating. Alternating-current apparatus, like direct-current apparatus, is rated on the basis of the load which it will carry without overheating. In alternators, this rating is the output in kilovolt-amperes, and in motors it is horse-power. The recommendations of Amer. Inst. Elec. Eng for the limiting temperature rise above a room temperature not exceeding 40° C., vary from 55° C. to 85° C, depending upon the class of insulation used.

Specifications for ALTERNATORS should include, in addition to a description of the type of machine desired and the class of service in which it is to be used, certain performance requirements as follows: Efficiency at various loads from 50% to 125% normal load; voltage regulation (per cent rise in voltage when the load is reduced from normal value to zero) at 100% and 80% power factor; maximum voltage required to excite the field with 125% normal load at 80% power factor; temperature rise of the various parts after continuous operation at full load and 25% overload; ability to withstand 50% overload for one hour without injury; and ability to withstand running at 100% overspeed without injury. Specifications for INDUCTION MOTORS should include: description of type of motor desired; purpose for which they are to be used; efficiency; power factor and slip at various

loads up to 25% overload; maximum torque at starting when connected directly to the line; maximum current required when starting; maximum torque and maximum load which motor will carry without stopping; temperature rise after continuous operation at full load and after two hours at 25% overload; and ability to carry 50% overload one hour without injury.

15. Power Plants

The term Central Station usually refers to a plant operating under a franchise, for the manufacture and sale of electricity to the general public. It is therefore a semipublic enterprise as distinguished from a private plant, in which electricity is generated for private purposes. Central stations vary in size from 50-kw plants in small villages to the large stations in New York and Chicago of over 100 000-kw capacity. Private plants range from single-unit plants for lighting buildings to the large traction plants of over 50 000 kw capacity.

Location. The location of HYDRAULIC PLANTS is obviously at the source of water power. Many conditions govern the location of a STEAM-DRIVEN central station. The more important are: kind of service to be rendered, whether alternating or direct current; concentrated or scattered area of distribution; size of plant; cost of real estate; and transportation facilities. Large steam plants are located on waterways wherever possible on account of cheap transportation and ample water supply for condensers and boilers. Where a waterway is not available, cheap land, railroad facilities, and water free from scale-forming impurities are the more important considerations. On the other hand, it might be more economical for a smaller plant to be located as near the center of distribution as possible, regardless of other disadvantages. GAS-DRIVEN plants are usually private plants, and hence are located on the same premises as the load. Private plants in buildings primarily used for other purposes should be located with due regard to the following points: effect of vibration and noise, ventilating facilities, facilities for handling coal and ashes; value of the space for other purposes, and coal storage facilities.

Prime Movers. The prime movers in common use for electric power generation are reciprocating steam engines, high- and low-pressure steam turbines, internal combustion engines, and hydraulic turbines.

The Reciprocating Steam Engine is the most commonly used steam-driven prime mover. The principal types used for electric power generation are the simple and compound high-speed engines in small sizes, the various forms of slow-speed horizontal Corliss engines in medium sizes, and the special vertical types which have been developed in 5000 to 10 000 h p sizes for large central stations. Small single-cylinder engines receive steam at 75 to 100 lb pressure per sq in, and exhaust it at about atmospheric pressure. Large engines receive steam at 100 to 200 lb pressure and discharge it into a vacuum at 2 to 4 lb absolute pressure.

In Steam Turbines the steam issues from nozzles at a high velocity and impinge on blades set in the periphery of a disk free to move. Turbines are rapidly supersedin reciprocating engines for power-station purposes because they are simpler, occupy muc less space, are more efficient, can be used with steam superheated to a much highe degree than is permissible with reciprocating engines, and can be built in much large units,—machines up to 70 000 kw capacity are now in daily operation. Furthermore high-speed generators, which are cheaper than low-speed generators, can be used.

Low-pressure turbines receive steam at about atmospheric pressure and discharge it int a vacuum. A much greater percentage of the energy in steam below atmospheric pressur can be utilized in a turbine than in the low-pressure cylinder of a reciprocating engine The capacity of existing plants using condensing engines can be increased 10 to 30% by exhausting from the engines at atmospheric pressure into low-pressure turbine This additional capacity is obtained without additional fuel consumption. At th

same time the range of loads at which maximum economy is obtained is greatly increased.

Internal Combustion Engines are operated with natural, illuminating, producer, and blast-furnace gases, with kerosene oil and with gasoline. Where liquid fuels are used, an auxiliary device vaporizes the liquid before it is admitted to the cylinders. This very efficient class of prime movers has been handicapped for electric power plant work because of non-uniform angular velocity, unreliability of operation, limited overload capacity, and high maintenance cost. These faults are rapidly being overcome and gas engines are being used quite extensively, particularly where very cheap fuel is available, such as the waste gases from blast furnaces. Engines of 2000-h p capacity are in successful operation on this fuel. The thermal efficiency of the gas engine is from 20 to 30% and is the highest of all heat engines. The cost of power is therefore very low even in small sizes, especially in connection with producer-gas plants, where cheap grades of coal can be utilized.

Hydraulic Turbines in power plants where the head is less than 150 ft are usually of the pressure type. The turbines in the older plants are of the vertical type, but the lower cost and more reliable operation of horizontal generators has led to the general use of horizontal turbines. Where the head is high the impulse type of turbine is used.

Approximate Steam and Fuel Consumption of Prime Movers

	Pounds of steam per kw-hr	Pounds of coal per kw-hr
Steam Reciprocating Engines:		
Simple, non-condensing, 25 to 200 h p	200 to 75	30 to 10
High-speed, automatic, compound, condensing, 200 to 1000 h p	75 to 50	10 to 6
Simple, Corliss, condensing, 150 to 500 h p	60 to 40	7 to 5
Compound, Corliss, condensing, 500 to 5000 h p	40 to 20	5 to 2.25
Compound and triple, four-cylinder, condensing, 2000 to 10 000 h p	22 to 17	2.2 to 1.7
Steam Turbines, high pressure:		
Non-condensing, 200 to 500 kw	60 to 40	10 to 5
Condensing, 500 to 3000 kw	25 to 18	3 to 1.8
Condensing, 5000 to 20 000 kw	17 to 13	1.7 to 1.3
Steam Turbines, low pressure, combined with reciprocating engines:		
One 1000-kw engine with one turbine	20	2.5
8000-kw engine plant with one turbine	14	1.5
One 7500-kw engine with one turbine	12	1.2
Gas Engines:		
Natural gas, 50 to 200 h p	....	25 to 15 cu ft
Producer gas, 50 to 200 h p*	....	3.0 to 2.0
Illuminating gas, 10 to 75 h p	....	35 to 25 cu ft
Gasoline, 10 to 75 h p	....	2.0 to 1.2 pints
Oil Engines:		
100 to 500 h p	....	1.5 to 1.0 lb oil

* Complete plant.

Boilers for the production of steam are built in several different types, the most commonly used for power-plant purposes being the water-tube and fire-tube. The WATER-TUBE BOILER is the safest, most efficient, and can be operated at the highest pressure. The small FIRE-TUBE BOILER is cheaper and easier to operate than the small water-tube boiler, and hence is preferable for small plants. Boilers are arranged to reduce the piping to a minimum and make firing as convenient as possible. They are usually placed side by side in one row or in two rows facing each other. All are piped to a common pipe or header, but in such a way that each boiler and group of boilers can be cut off by conveniently located valves.

Rating. Boilers are rated in horse-power, an arbitrary unit equal to the evaporation of 34.5 lb of water per hour from water at 212° F. to steam at 212°. Boilers properly rated should develop their rated horse-power when fired by an ordinary fireman and with ordinary steam coal. They should be capable of giving 30 to 50% over their rating when forced.

Steam Piping should be well lagged and free from pockets where condensed steam can collect. All valves should be easily accessible. The following table gives the approximate size of piping required to deliver any quantity of steam at any distance from the boiler. This table is based on Babcock's formula which is as follows:

$$p = 0.0001321\left(1 + \frac{3.6}{d}\right)\frac{M^2L}{Dd^5}$$

where p = difference in pressure between the two ends of the pipe, lb per sq in;
d = internal diameter of pipe, inches;
M = amount of steam, lb per min;
L = length of pipe, feet;
D = mean density of steam, lb per cu ft.

It is to be noted that authorities do not agree on what is the correct formula for steam flow so that for exact calculations reference should be made to the more extensive discussions of the subject in Lucke's "Engineering Thermodynamics," Marks' "Mechanical Engineer's Handbook" (p. 360), etc.

Flow of Steam through Pipes (Babcock)

Pounds per minute with 1 lb loss of pressure

Initial gage pressure, lb per sq in	Diameter of pipe, inches. Length, 240 diameters								
	1	1½	2	3	4	5	6	8	10
50	4.04	11.2	20.01	49.48	91.34	150.8	226.0	412.2	665.0
60	4.32	11.9	21.38	52.87	97.60	161.1	241.5	440.5	710.6
70	4.58	12.6	22.65	56.00	103.37	170.7	255.8	466.5	752.7
80	4.82	13.3	23.82	58.91	108.74	179.5	269.0	490.7	791.7
90	5.04	13.9	24.92	61.62	113.74	187.8	281.4	513.3	828.1
100	5.25	14.5	25.96	64.18	118.47	195.6	293.1	534.6	862.6
120	5.63	15.5	27.85	68.87	127.12	209.9	314.5	573.7	925.6
150	6.14	17.0	30.37	75.09	138.61	228.8	343.0	625.5	1009.2

For any other loss of pressure, multiply by the square root of the proposed loss. For any other length of pipe, divide 240 by the given length expresst in diameters, and multiply the table figures by the square root of this quotient to get the flow for one pound loss of pressure.

The resistance due to steam entering pipe = 60 diameters additional length; to a globe valve = 60; to an elbow = 40, or two-thirds of a globe valve.

Furnaces should be designed for the particular class of fuel to be used. The object of a furnace is to transfer the heat in the fuel to the water in the boiler with the least loss; hence there is a certain kind of grate and arrangement of fire-walls, baffles, plates, etc., best suited for each fuel. The average grate surface provided per boiler horse-power is about ¼ to ½ sq ft. Furnaces for oil or gas fuel are the same as coal-burning furnaces, except that special burners are substituted for grates.

Combustion. The sources of inefficiency in a furnace are, coal passing thru the grates unburnt and incomplete combustion. The unburnt coal in the ashes should not exceed 2 or 3%. Complete combustion means that the carbon — the source of heat in the fuel — is completely oxidized to carbon dioxide. If oxidized only to the monoxide, about two-thirds of the available heat is wasted. Incomplete combustion is usually caused by insufficient air supply. Too much air, on the other hand, not only lowers the temperature of the furnace but absorbs heat which is carried up the chimney. Frequent

analysis of the flue gases and ash is necessary to insure that the furnace is being properly operated.

Draft. Air is supplied to the furnaces by natural draft thru chimneys or by forced draft. NATURAL DRAFT is more commonly used and various formulæ have been developed to express the relation between the internal area and height of chimney required per horsepower of boilers. Kent's formula, based on the rather liberal allowance of 5 lb of coal per boiler h p, is $HP = 3.33\,(A - 0.6\sqrt{A})\,H$, where HP = horse-power of boiler plant, A = inside area in square feet and H = height in feet. Self-supporting steel chimneys cost about one-third as much as brick chimneys, and are therefore replacing brick for plants of 100-h p capacity and less. FORCED DRAFT, either by pressure in the ash pit made air-tight or by suction in the flues, is used to a considerable extent in large power plants. The maximum capacity of the plant can be greatly increased with forced draft, and greater economy, under fluctuating load conditions, is obtained.

Mechanical Stokers are devices for automatically carrying the coal under the boilers, properly burning it, and depositing the ashes in the ash pit. The principal forms are the rocking grate, endless chain grate, and the screw feed. They have many advantages when used in large plants, principal among which are economy in labor, economy in fuel because cheaper fuels may be used, and more uniform fires. Their use is not advisable in comparatively small plants where the total load varies thru wide ranges, hand firing under such conditions being more flexible and economical.

Approximate Cost and Heating Value of Fuels (1912)

Fuel	Cost, dollars	B t u	B t u per dollar
Anthracite	6.50 per ton	13 000 per lb	4 000 000
Bituminous	3.00 per ton	14 000 per lb	9 300 000
Coke	5.00 per ton	13 100 per lb	5 250 000
Wood, hard, dry	4.00 per cord	6 250 per lb	7 000 000
Crude petroleum	0.035 per gal	19 000 per lb	4 000 000
Kerosene	0.12 per gal	17 000 per lb	1 100 000
Illuminating gas	1.00 per M cu ft	750 per cu ft	750 000
Natural gas	0.25 per M cu ft	1 000 per cu ft	4 000 000
Gasoline	0.15 per gal	18 000 per lb	620 000

Generators. The type of generator used in a power plant varies with the conditions. Where the load is concentrated, near at hand, and mixt lighting and power, direct-current generators are used. Since, however, the cost of power production decreases with the size of the units and the size of the plant, the trend of modern engineering is toward the concentration of power production in large stations with large alternating-current generator units (single units of 70 000 kw capacity of the compound type are now in service), the power being distributed at high tension to distributing centers called substations. The selection of the size and number of units for a plant requires careful consideration. Both prime movers and generators decrease rapidly in efficiency below 50 or 60% load, hence the sizes should be such that those in use will always be well loaded. There should be enough units to carry the maximum load, with one as a reserve. For example, a 200-kw plant ought to have three 100-kw units, a 600-kw plant four 200-kw units, and a 1000-kw plant three 500-kw units.

The Foundations for all apparatus should be separate from that of the building. They should be of ample dimensions and never less than those recommended by the manufacturer. Direct-connected generators, motor generators, and rotary converters, altho self-contained, should have substantial foundations in order to reduce the vibration and consequent wear on the bearings and insulation. Concrete foundations are the best and cheapest: they will safely carry loads of 7500 lb per sq ft. The safe bearing loads of various soils

are as follows: clay 4000 lb, coarse gravel and sand 2500 to 3500 lb, rock 10 000 to 30 000 lb.

Switchboards are designed to provide not only independent, easy and quick control of each generator, exciter, and feeder, but to show by means of instruments mounted on them the amount and character of the load. They are made up in panels of slate, marble, and artificial stone placed side by side, one panel for each machine and feeder. The board is usually installed along one side of the generator room with ample space in the front and rear. In low-tension alternating-current and direct-current plants, all circuits are brought to the switches and instruments on the board. Buses or heavy copper bars are mounted on the back of the board (often in duplicate) and connected to the various panels so that any number of generators and feeders may be connected in parallel. The circuits of high-tension plants are not brought to the switch-board but are controlled by switches under oil which are operated mechanically or electrically from the switchboard, the instruments being connected in the secondary circuits of instrument transformers.

The following distribution of items which make up the cost of power in various kinds of plants has been made by H. G. Stott (Power-Plant Economies, vol. xxv, Trans. Amer. Inst. Elec. Eng.).

Relative Cost of Power

Items	Reciprocating engines	Steam turbines	Reciprocating engines and steam turbines combined	Gas-engine plants	*Gas engines and steam turbines combined
Maintenance:

* A proposed combination where the exhaust gases from the gas engine would be used to generate low-pressure steam for low-pressure turbines. Both of these machines have a high efficiency and each would be used under the most favorable conditions.

The very large modern stations generate high-tension alternating current and all generators and feeders are controlled from a miniature remote-control switchboard. The main switches are operated by motors controlled by small switches on this control board. One operator can thus handle all of the outgoing power of a very large plant.

Direct-current generator and feeder panels are usually provided with knife switches, an automatic overload circuit breaker, a voltmeter and ammeter. Low-tension alternating-current panels are similarly equipped, with the addition of a wattmeter and a power-factor meter.

Cost of Power Plants. The cost of power plants depends upon location, type of plant, class of service, size, etc. HYDRAULIC PLANTS are on the whole less expensive than steam plants, tho in many cases the cost per kilowatt has far exceeded that of the best steam plants because of the great cost of impounding the water. The average investment per kilowatt will range from $50 to $150 per kilowatt, but some plants cost $400 per kilowatt. This is divided, in a typical case, about as follows: hydraulic works 50%, wheels and fittings 15%, building 5%, generators, exciters, and switchboard 20%, and step-up transformers 10%. STEAM PLANTS cost from $100 to $200 per kilowatt, and an average approximate division of the cost is: boilers and piping 15%, engines and condensers 25%, pumps and other auxiliaries 5%, generators and switchboard 20%, building, foundations, and smokestack 25%, coal-handling plant 5%,and engineering 5%.

The Cost of Producing Energy depends upon a great many factors, principal among which are the kind and size of plant, the cost of fuel, labor, and supplies, and the load factor. In hydraulic plants it will range from 0.4 to 1.0 cent per kilowatt-hour delivered to the transmission line. An average division of cost will be about as follows: interest and depreciation 65%, labor 15%, maintenance and supplies 20%. The average cost per kilowatt-hour at the bus-bars in steam plants may be taken at about 3 cents for 250-kw plants, 1.75 cents for 500-kw plants, 1.5 cents for 1000-kw plants, and 1.25 cents for 2000-kw plants. Very large plants of 50 000 kw and over probably produce power for less than 0.5 cent per kilowatt-hour. The cost in gas-engine plants will be less than in steam plants of the same size. This is particularly true of the smaller sizes. Producer-gas plants of 400 or 500 kw can produce energy at a cost of 1 cent per kilowatt-hour.

16. Transmission of Power

Losses of Electrical Power occur in transmission, the principal one of which is that due to the resistance of the conductors. The amount of loss which may be economically allowed will depend upon several factors such as cost of producing the power, the line investment, size of the load, load factor and the value of the power at the point of delivery. Much greater losses may be allowable and much larger distances covered under certain conditions than would be financially permissible under others.

When current flows thru a conductor, a loss occurs which is equal to the product of the current and the fall in potential between the ends of the conductor. From Ohm's law it follows that with a given percentage loss the distance that power may be transmitted will be proportional to the square of the voltage. High-voltage direct current is not commercially practicable, for altho a moderately high voltage may be produced by connecting generators in series, it cannot be readily reduced to low voltage for general distribution. On the other hand, alternating current can be transformed from low to very high voltage and vice versa with very simple and efficient apparatus called transformers.

It is now standard practice in large concentrated systems to generate all of the power in one station and transmit it at 2200 to 15 000 volts to various substations from which it is distributed at low potentials. The distance in such cases is, however, comparatively short. Where the electricity is generated by water power, it is usually necessary to transmit long distances to reach a sufficiently large market. In such systems it is customary to generate at 2200 to 15 000 volts and transform to 6600 to 150 000 volts, depending upon the distance. About 150 000 volts is at present the highest voltage in commercial use

and about 500 miles the greatest distance of transmission. Transmission at 200 000 volts is being considered but at this voltage the energy dissipated into the air (corona loss) begins to increase rapidly, particularly at high altitudes and specially designed conductors may have to be employed.

Transformers are essentially large induction coils without interrupters. Two coils are wound on a common core built up of laminated steel. They are thoroly insulated from the core and from each other with varnished cambric and similar materials. When alternating voltage is applied to one coil, the primary winding, an alternating flux is produced in the core. This flux induces an e m f in the other coil, the secondary winding. The ratio of the voltages will be practically the same as the ratio of the number of turns of wire in the two coils.

Classification. Transformers may be classified according to their application, whether for power purposes or for use with instruments. Power transformers may be either constant potential or constant current. The CONSTANT-POTENTIAL transformer is the most usual form and is used for all general power transmission at constant potential. Power from two-phase generators is transmitted with two transformers, one in each phase. Power from three-phase generators is transmitted with three transformers connected delta or star and with three-phase transformers in which three transformers are combined by placing three sets of windings on three parts of a common magnetic circuit. The three-phase transformer is cheaper than three single transformers, but the latter method is more flexible and permits operation with only two transformers if one burns out. CONSTANT CURRENT transformers convert power from low-voltage constant potential to constant current at variable high voltage. They are used for series lighting systems. INSTRUMENT TRANSFORMERS are used only to insulate instruments from the line and have only 10 to 200 watts power capacity. VOLTAGE transformers are connected to voltmeters and wattmeters. They transform the high voltage of the line to about 110 volts. CURRENT transformers are connected to ammeters and wattmeters. They insulate the instrument from the line, and also transform the current to a small value, usually 5 amperes.

Rating. The capacity of transformers is determined by the maximum temperature reached in operation. This is fixt at values which will not cause deterioration of the insulating materials. The Amer. Inst. Elec. Eng. recommends a temperature limit corresponding to 55° to 85° C. rise above a standard room temperature of not exceeding 40° C. after continuous operation, the limit of permissible rise depending upon the class of insulation employed. Various methods are used to dissipate the heat and thus increase the capacity. In AIR-COOLED transformers (a type which is, however, falling into disuse because of the greater space required per kw, lower efficiency, higher cost, and greater fire risk) the case is open at the top and bottom and air is forced thru the core and windings by blowers. In SELF-COOLED transformers the case is filled with oil. The oil, in addition to increasing the insulation, carries the heat by natural circulation from the core and coils to the sides of the tanks, from which it is dissipated by radiation and convection. The surface of the tank is made as large as possible by corrugating and by the addition of external pipes or reservoirs connected to the tank at the top and bottom. The WATER-COOLED type is the same as the oil-cooled type, with the addition of coils of pipe at the top thru which water flows and carries off the heat. Transformers up to 500 or 600 kw capacity are usually self-cooled, larger transformers are usually water cooled.

Losses and Efficiency. The losses in transformers are of two kinds: COPPER LOSS is due to the resistance of the windings and varies with the square of the load. The CORE LOSS is due to the rapid reversal of the magnetic flux in the steel core and is constant at all loads. In well-designed transformers these losses are about equal, except in distribution transformers (50 kw and under) where the iron loss is usually not over half the copper loss. The iron loss in a transformer is constant irrespective of the load and consequently is made a smaller proportion in distribution transformers for light and power (see article 17) where the load is on only a few hours a day but the iron loss is constant for 24 hours. In other words, the "all-day" efficiency becomes more important. The efficiency of transformers is comparatively high, as indicated by the following table:

Efficiency of Power Transformers

Size, kw	Per cent of normal load				
	125	100	75	50	25
5	96.75	97.0	97.0	97.0	96.0
50	97.75	98.0	98.0	98.0	97.5
100	97.0	97.0	97.0	96.25	93.5
500	98.0	98.0	98.0	97.5	96.0
1000	98.0	98.0	98.0	97.5	96.0
1500	98.25	98.25	98.25	98.0	97.0
3000	98.5	98.5	98.5	98.25	97.5
5000	98.75	98.75	98.75	98.5	97.75

These are approximate average values. The efficiency is slightly lower for 25 cycles than for 60 cycles. Also the efficiency is lower for high voltages than for low voltages. In the above table, the 5-kw and 50-kw values are for distribution transformers for 2200-volts; the 100-kw and 500-kw values are for 22 000-volt transmission transformers and the others are for 66 000-volt transmission transformers.

Regulation. With a constant primary voltage, the secondary voltage of a transformer will increase as the load decreases due to the resistance and inductance of the windings. The ratio of this increase to the voltage at full load is the REGULATION of the transformer. In designing, the aim is to keep the regulation as small and the efficiency as high as possible. The regulation at 100% power factor of well-designed transformers will range from 3% for a 5-kw transformer to 1.5% for a 1000-kw. It will increase very rapidly as the power factor decreases.

Specifications usually include the following: purpose for which the transformer is to be used, capacity, voltage, kind of cooling, efficiency at various 100% power-factor loads, regulation at 100% and 80% power factor, temperature after continuous operation at full load and after 2 hours at 25% overload, high-potential test of insulation at double normal voltage and an over-potential test by operating at double voltage for 5 minutes.

Cost. The cost of transformers of a given rating will depend upon the high-tension voltage, the frequency and the method of cooling. For example the approximate cost of 5 kw, 2200-volt distribution transformers is of the order of $25 per kw but for 22 000 volts, the cost is $80 or $90. The cost of a 3000-kw water-cooled transformer will vary from $1.75 to $2.00 per kw at 22 000 volts to $3.50 or $4.00 at 66 000 volts. Self-cooled transformers cost on the average 50% more than water-cooled. Sixty-cycle transformers are slightly cheaper than 25-cycle.

The Transmission Line is the weakest part of a transmission system, and therefore, where continuity of service is at all important, requires great care in designing. It is essential to have ample insulation under all weather conditions; ample factor of safety in poles, conductors and insulators under all temperature, wind, and sleet conditions; effective protection against lightning.

The earlier lines are run on wood poles with wood cross-arms. They are set 100 to 200 ft apart and the conductors are carried on rigid porcelain insulators. Modern lines are carried on towers built up of steel shapes thruout and set 400 to 800 ft apart. The conductors are suspended from the cross-arms by insulators made up of 3 to 8 porcelain disks fastened together with flexible joints. On large systems these towers are either rectangular, square, or triangular in shape and are very substantially built. The base will occupy a space 10 to 15 ft square, the height will vary from 40 to 60 ft, and they will withstand loads of 10 000 to 15 000 lb applied at the top of the tower. A two-legged flexible steel tower is being extensively used on transmission lines where a low investment charge is essential. Obviously such towers will not carry any stresses in the direction of the line so that substantial "anchor" towers or similar structures must be provided at intervals to give the necessary stiffness.

A very high voltage transmission line is usually run over a private right-of-way 50 to 100 ft wide with all tall and dead trees cut away on each side. To guard against complete shut down due to an accident to the line, large systems are frequently provided with a duplicate line. This line may be run beside the other, but is preferably run thru a different part of the country so that both lines would not ordinarily be subjected to a lightning storm at the same time.

The kind of material to be used for the conductors depends upon various factors such as topography (rough country may require some long spans where the strength of the conductors would be unusually important), climate (excessive wind and sleet storms would require high-strength conductors), importance of continuity of service, length of line and the economics of the proposition. Copper, aluminum, stranded steel, iron and copper-clad steel are used, but hard-drawn copper is by far the most generally employed.

Size of Conductor. The size of the conductors will depend upon many conditions including most economical energy loss, load factor, character of the installation (that is, whether temporary or permanent), strength required and voltage regulation necessary. With very high voltage especially at high altitutes, loss due to corona (which is greater with smaller conductors) must also be considered. So far as the energy loss is concerned, Lord Kelvin propounded the law that "the most economical area of conductor will be that for which the annual interest on capital outlay equals the annual cost of energy wasted."

Line Drop, Efficiency and Regulation. The line drop is the difference between the voltage at the sending end of the line and that at the receiver end under prescribed load conditions. It will depend upon the resistance and reactance of the line. The line efficiency is the ratio of the power delivered by the line (that is, receiver load) to the power input at the sending end under prescribed conditions at the receiver end. The regulation is the change in voltage at the receiver end where the prescribed load changes from no load to full load, voltage being maintained constant at the generator or sending end. It will depend upon, in addition to the resistance, the inductive reactance and capacitance reactance, which will vary with the frequency, and with the size and spacing of the conductors.

For calculations of these quantities for long lines and very high voltages, reference should be made to the numerous reference books on the subject. The following formulas will, however, be approximately correct for short lines of moderate voltage where capacitance reactance and capacitance current is negligible. E_s = voltage, sending end; E_r = voltage, receiver end; θ = angle of lag between current and voltage, receiver end; I = current in one conductor in amperes; R = total resistance of one conductor in ohms, x = total reactance of one conductor in ohms.

$$E_s = \sqrt{(E_r \cos\theta + IR)^2 + (E_r \sin\theta + IX)^2} \text{ (volts).}$$

Line drop $= E_s - E_r$ (volts);

Regulation $= \dfrac{E_s - E_r}{E_r} \times 100$ (per cent);

Power, receiver end $= E_r I \cos\theta$ (kw);

Power, sending end $= E_r I \cos\theta + I^2R$ (kw);

Power factor, sending end $= \dfrac{E_r \cos\theta + IR}{E_s} \times 100$ (per cent):

Efficiency $= \dfrac{E_r I \cos\theta}{E_r I \cos\theta + I^2R} \times 100$ (per cent).

In application, it is more convenient to use conductor-to-neutral rather than conductor-to-conductor voltage and the power in one wire only, converting back again in the final results. In a single-phase circuit this means ½ line voltage and ½ total power respectively, and in three-phase circuits, $\frac{1}{\sqrt{3}}$ line voltage and ⅓ power respectively. Resistance and reactance tables will be found in various handbooks.

Conductor Spacings are fixed by experience, but for moderate voltages the distance between conductors in inches may be made 20 + voltage in kilovolts between conductors.

Conductor Stresses. The general formula usually applied to the spans assumes that the conductor takes the shape of a parabolic curve. It is ordinarily approximately true. This formula is

$$T = \frac{L^2 w}{8 d}$$

where T = total tension at center of span in lb;
L = distance between supports (assumed same height) in ft;
w = weight of conductor in lb per ft;
d = sag at center of span in ft.

The tension at the point of support is:

$$T' = T + wd.$$

The length of the conductor between supports is approximately

$$L' = L + \frac{8 D^2}{3 L}.$$

The important factor of added load due to wind, sleet, snow and temperature changes depends of course upon the climate and for data, reference should be made to electrical engineering hand-books. This added load is taken as high as 0.75 inch of ice plus 11 lb wind pressure per sq ft projected area (including ice).

Lightning Storms are the cause of most interruptions to the service on high-tension transmission lines. The poles, conductors, and insulators are often struck by direct discharges. The potential of the conductors may be raised an excessive amount above that of the earth by electrostatic induction from the thunder cloud. This may break down insulators, cause arcing over and grounding of the circuit, or set up waves of high potential which would travel along the conductors to the power station or substation and seriously damage apparatus. LIGHTNING ARRESTERS are devices for allowing excessive voltages to be quietly dissipated without interfering with the service. The usual form of protection for a transmission line is an iron wire along the topmost points of the poles or towers and connected to the ground at frequent intervals. This is supplemented with special arresters wherever apparatus is connected to the line.

The voltage at the receiver end of the line will depend upon the inherent regulation of the line as mentioned above and the character of the load. With a low-power-factor load, it is customary to connect either a static or a synchronous condenser (a form of synchronous motor operated without load and with a field current above the normal value) to the receiver end of the line, thus neutralizing the lagging current and improving the voltage regulation by raising the power factor.

Substations are stations at the various centers of distribution where the high-tension power is transformed by "step-down" transformers to low-tension power. It is then distributed either as alternating or direct current, by any of the methods described in article 17.

With alternating-current distribution, the substation contains only the transformers which lower the voltage to the required value, and switchboards controlling the incoming and outgoing lines. For direct-current distribution, the alternating current is transformed to direct current either by rotary converters or motor generators. A ROTARY CONVERTER is essentially a double-current generator, a machine which, when driven as a generator, will give direct current at one end and alternating current at the other end. If the alternating-current end is connected to an alternating-current supply and operated as a motor, the machine becomes a rotary converter and direct current will be produced at the other end. The relation between the imprest alternating-current voltage and the direct-current voltage is fixt. Variation of the direct-current voltage must, therefore, be made with auxiliary apparatus which will alter the alternating-current voltage. The principal devices of this kind are the SYNCHRONOUS BOOSTER, a generator in series with the alternating-current supply; the INDUCTION REGULATOR, a single-winding transformer with a movable secondary coil by means of which the supply of voltage can be raised or lowered in small steps; and the SPLIT-POLE FIELD by means of which the wave

form of the machine and therefore the alternating-current voltage can be altered. A MOTOR GENERATOR is a synchronous or induction motor mechanically connected directly to a direct-current generator. This method gives complete electrical separation of the direct-current from the alternating-current systems, and greater control of the direct-current supply. The rotary converter, on the other hand, has a higher efficiency, especially at loads less than full load, occupies less floor space, and is somewhat lower in cost. The switchboards in substations, like those in central stations, are designed to give control over each machine and outgoing feeder. Control of the incoming high-tension current is provided by means of remote-control oil switches.

Rectifiers. Alternating currents of relatively small magnitudes are transformed to unidirectional current by several other methods. In the MERCURY-ARC RECTIFIER, the operation depends upon the fact that if a glass (or steel) tube is exhausted to a low pressure, filled with mercury vapor and has a pool of mercury at one end with a metallic electrode at the other, the resistance to the flow of current is low in one direction and high in the other. Thus a valve action is obtained which in the simple case and with alternating current, would permit current to flow only every other half cycle. It is necessary to start the action by first producing a momentary arc between the mercury and the other electrode which is usually accomplished by tipping the tube for an instant. In commercial rectifiers there are two positive electrodes (the mercury being the negative electrode) which are so connected to a transformer, suitable reactances and the direct current load, that both halves of the wave are utilized and a continuous but pulsating unidirectional current is obtained. They are built for use on two- and three-phase circuits as well as single-phase.

Mercury-arc rectifiers are available with current capacities up to 40 or 50 amperes with glass tubes and 300 or 400 amperes with steel tubes. Their most common application is for charging storage batteries in electric vehicles, operating moving picture arc lamps, etc., but the larger rectifiers have been used on electric locomotives, etc. High-voltage rectifiers are employed in conjunction with constant-current transformers to operate series, direct-current arc-lighting circuits (see article 18).

The "TUNGAR RECTIFIER" employs the principle of the thermionic valve which is as follows: If one of two electrodes in a vacuum tube is heated to a red heat, the resistance to the passage of current from one electrode to the other is very low in one direction and very high in the other. These rectifiers are limited to about 5 or 6 amperes capacity at voltages from 7.5 to 75.

MECHANICAL RECTIFIERS of various types have been developed in which the connection between the alternating-current circuit and the direct-current load is reversed each half cycle by means of a commutator driven by a synchronous motor having the same number of poles as the commutator has segments, or by means of alternating current electromagnets and a pivoted, contact-making, polarized magnet which changes the connection every half cycle. The former type is used with X-ray apparatus and the latter for charging automobile ignition batteries which require small currents at low voltages.

Auxiliary Steam Plants. Many water-power transmission systems have auxiliary steam plants connected to the system. These plants, in addition to assisting the water-power plant at times of low water, are kept under a low head of steam, so that they will be available on short notice in case of failure of the transmission line.

17. Power Distribution

Distribution Systems. Electrical power is distributed to consumers in two forms, direct current and alternating current. DIRECT-CURRENT systems are the most suitable for general service purposes and are generally used in closely settled districts where the distances are short. Direct-current motors, particularly in small sizes, are somewhat more efficient and convenient to operate than alternating-current motors. Direct current may also be used for many purposes where alternating current would be unsuitable, such as battery charging and electroplating. ALTERNATING-CURRENT systems are used where scattered districts are served because the distribution can be made at a higher voltage and thus greatly reduce the investment in copper. The power is usually distrib-

uted at 2200 volts and reduced to a lower voltage at the consumers' premises by small transformers called distribution transformers at each building or group of buildings. Direct current is distributed by series two-wire and three-wire systems. Alternating current is distributed by the series single-phase; two- and three-wire single-phase; three- and four-wire two-phase; and three- and four-wire three-phase systems.

Series Systems. In both direct- and alternating-current systems all apparatus is connected in series and the same current passes thru all. This system is used only for street lighting, where the smaller investment in copper required is a great advantage, The current is kept constant by automatic apparatus in the station and the voltage varies. with the number of lamps in the circuit. Open-arc lamps require 45 to 50 volts each, inclosed-arc lamps 75 to 80 volts each, and series incandescent lamps 15 to 30 volts each. Forty to one hundred lamps may be burned on one circuit, requiring a total of 2000 to 6000 volts. Provision is made in each lamp for automatically keeping the circuit closed when the electrodes of an arc lamp become too short or the filament of an incandescent lamp breaks. Incandescent lamps of different current ratings (and therefore different candle-power ratings) are used on the same alternating-current circuit by employing specially designed individual current transformers.

Two-and Three-wire Systems. The series system is not feasible for general distribution because lamps cannot be turned on and off individually without affecting the others on the circuit, series motors are not suitable for general use, and the high voltage of the series system would be dangerous to life and property if carried into buildings. Distribution to and within buildings is therefore made with constant-potential multiple circuits, either two-wire or three-wire.

In a Two-wire Direct-current System, pairs of cables (feeders) radiate from the central station, each pair dividing and subdividing into other pairs (mains) running to the premises of the consumers. The voltage varies from 100 to 125 volts and each lamp and motor is connected directly across these lines, each being independent of the others. Single-phase alternating current is similarly distributed at 2200 volts to transformers just outside of the consumers' premises and from which secondary distribution is furnished at 100 to 125 volts. The two-wire system requires a large copper investment to keep the potential drop within reasonable limits. Excessive drop in potential due to too high resistance in the circuit means not only lost power but flickering of incandescent lamps, since the candle-power of the latter changes 4 to 6% with 1% change in voltage.

The Three-wire System was developed to decrease the amount of copper required. Two direct-current generators are connected in series and feeders are run from each outer terminal of the two machines and the common connection between them. The distribution to the consumers' premises is made with three instead of two feeders and mains. The lighting load is divided, half being connected between each outer wire and the middle or neutral wire. Motors are connected to the outer wires in order to decrease the flickering of lamps which fluctuating motor loads produce. Furthermore, 250-volt motors are somewhat cheaper than 125-volt motors. In the three-wire system the advantages of the two-wire system are retained and at the same time only 38% as much copper is required for the same percentage loss. By keeping the load fairly evenly divided, the neutral feeders and mains may be made smaller and an additional saving affected.

Secondary distribution on single-phase alternating-current systems is made by the same method by winding the secondary of transformers for 200 to 250 volts, and connecting the third wire to the center of the winding.

Two-phase Systems. The two-phase system of distributing alternating current is very generally used where the load is both lamps and motors, the lamps being connected across each phase separately and motors across both phases together. Single-phase motors are not practicable except in small sizes, hence the two-phase system combines the advantages of a polyphase system for motors with those of the two- and three-wire systems for lamps. The current is generated with two-phase alternators and is distributed over four or three wires. In the four-wire system, each phase is distributed independently thru two wires. In the three-wire system, one wire of each phase is common.

Three-phase Systems of distribution are only used where the load is principally motors and where the power has to be transmitted considerable distances. About 25% less copper is required than for two-phase, four-wire, systems under the same conditions.

The current is generated in three phase alternators, usually at 25 or 60 cycles, and may be distributed directly to consumers up to 440 volts or transformed to a higher voltage for transmission to distributing centers, or directly to the consumers premises, where it is transformed to a low voltage. The primary distribution is always three-wire, but the secondary distribution may be made with four wires where there is a considerable lighting load. In such cases, lamps are connected between each of the three main wires and the neutral, while motors are connected to the three main wires.

Distribution Methods. The power is delivered to the consumers' premises from the power plant or substation thru feeders and mains carried on poles or placed underground. The former method is very much cheaper and is the general practice outside of large cities. In congested districts, the crowded condition of the streets, the unsightly appearance of pole lines, and the handicapping of firemen have caused the development of the underground method.

Overhead Distribution is made on wood, built-up steel, cast-iron, or reinforced concrete poles 30 to 60 ft high, and spaced 50 to 200 ft apart, depending upon the local conditions. The wires are carried on insulators attached to wood cross-arms. Glass insulators are used for low-voltage circuits and small porcelain insulators for 2200-volt circuits. Wire with weather proof insulation is commonly used. The cost of overhead distribution depends upon the kind, quality, height, and spacing of the poles, upon the number of circuits, condition of the streets, and so forth. It varies from $750 to $2000 per mile exclusive of the cost of the wire.

Underground Distribution can be divided into two general classes. In one class the conductors with their protecting covering are placed directly in the ground, and in the other class, called conduit systems, tubes are placed in the ground through which the conductors are afterwards drawn. Examples of the first class are the Edison tube system, now little used, and the wood-trough construction. In the Edison tube system, wires properly spaced in iron pipes are surrounded with a solid insulating compound poured in while hot. The lengths are joined together thru special junction boxes. The wood-trough construction consists of a wooden trough in which the conductors are laid on insulating spacers. The trough is filled with a hot compound which becomes solid when cold. This is the cheapest type of construction for underground distribution. Conduits are made of wood impregnated with creosote, sheet-iron pipe lined with cement, fiber, and vitrified clay. Wood conduit and sometimes fiber conduit is laid directly in the soil, while the other conduits mentioned are usually encased in concrete or cement mortar, a number of conduits being laid side by side. The conduit material most in use is vitrified clay. It is made in single-duct pieces about 18 in long, and in multiduct pieces, with any number of round or square holes (from two to sixteen), about 30 in long. On account of the greater strength and smaller number of joints, the multiduct conduit is frequently laid directly in the ground without cement encasement, the joints being wrapped in burlap, and well asphalted. Manholes built of brick or concrete are provided every 100 to 500 ft where service connections may be made, cables pulled in and out for repairs, and splices made. If distribution is made at 2200 volts, the step-down distribution transformers are installed in these manholes.

Interior Wiring. The system used for the distribution is usually continued thru the building. The materials and methods used in wiring buildings on which insurance is carried must conform to the rules of the National Board of Fire Underwriters. The building departments of all large cities also have rules which must be observed. The standard methods are open or cleat work, molding, rigid steel conduit, flexible steel conduit, non-metallic tubing and armored cable.

In Cleat Work, the wires are exposed and supported on walls and ceilings by porcelain cleats or knobs. Porcelain tubes are used where the wires pass thru walls or ceilings. This class of wiring is the cheapest but is entirely satisfactory when the work is properly done and appearance is of secondary importance.

In Molding Work the wires are imbedded in grooved strips of wood or metal, and covered with a thin strip of the same material. Special porcelain fittings are used where apparatus is connected. (Wood molding is no longer allowed in some of the larger cities.)

Rigid Steel Conduit Work consists of special soft-steel pipe run thruout the building and thru which the wires are pulled. Steel junction boxes are provided thru which the wires are pulled into the pipe and defective ones pulled out. This is the most expensive form of wiring, in first cost, but it completely protects the wires from mechanical injury, reduces the fire risk on the building to a minimum, and the maintenance cost is small, for old and defective wires can be readily replaced without injury to the cónduit.

Flexible Steel Conduit is a tubing of steel ribbon wound spirally in such a manner as to produce a very flexible steel tubing which is reasonably tight but not water-tight. Steel outlet boxes and junction boxes are used as with the rigid conduit. Altho this is a cheaper construction than the rigid pipe system it eliminates the unsafe features of molding work. It is particularly applicable in wiring old buildings.

Non-metallic Tubing is a stiff though sufficiently flexible hose of fiber composition which is a cheap substitute for the metal conduit. It is obviously not waterproof.

Armored Cable is similar to flexible steel conduit with the conductors included. The conductors are covered with suitable insulation and the steel ribbon wound directly over this insulation. This form of wiring is rapidly replacing the flexible conduit method for old buildings because conduit and wire are installed together.

Wires and Cables. There are three general classes of wires and cables used in electrical work: weatherproof, rubber insulated, and lead covered.

Weatherproof Wire is insulated with two or three layers of cotton braid impregnated with insulating compounds. It is used only for exterior wiring, principally for overhead distribution. It is the cheapest form of insulation, but also the least efficient. While sufficient protection is provided for pole-line purposes where the wires are supported on insulators, it is entirely inadequate for interior wiring.

Rubber-covered Wire forms the greatest percentage of wire used for electrical purposes. It is used exclusively for wiring buildings and extensively for high-tension cables. There are three standard grades of rubber insulation: National Electric Code Standard, thirty per cent Para, and Navy Standard. All grades consist of rubber, ground and mixt with various kinds of powdered mineral matter together with a certain amount of sulfur. After being applied to the wire by running thru dies, it is vulcanized by subjection to a high temperature. The difference in the grades is in the quality and amount of rubber used. National Electric Code insulation is made with various kinds of old and reclaimed rubber and rubber substitutes but must contain about 20% Para rubber. Before it can be used, it must be tested, past, and sealed by the inspector of the National Board of Fire Underwriters. Thirty per cent Para insulation contains at least 30% of new Para rubber gum. It is more durable than the National Electric Code wire and is used in all first-class interior-wiring work. Navy Standard insulation contains not less than 40% of new Para gum. It is used by the government on all battleships and is the highest grade of wire regularly manufactured.

Lead-covered Wires and Cables include various forms of insulation and are made up in a great variety of ways to suit any requirement for insulation and mechanical protection. Lead-covered cables are used where protection from mechanical or chemical injury is essential, as in underground distribution and under water. One, two, or three conductors may be in one cable. The conductors in two- or three-conductor cables may be side by side or one inside the other (concentric). The standard insulations are 30% rubber, paper, and varnished cambric. Paper insulation is applied in a narrow strip wound spirally on the copper to any desired thickness and saturated with suitable oil to increase the insulation and render the cable flexible. Varnished-cambric insulation is applied in the same manner. The capacity of wires and cables is fixt by the temperature at which the life of the insulation will be affected. The table on p. 1630 shows the carrying capacity of various kinds of wires and cables based on safe temperature limits.

The second column of this table gives capacity for wire in still air, at 125° F. The third and fifth columns give the capacities allowed by the Fire Insurance Underwriters (National Electric Code). The limits given for rubber are those beyond which deterioration (when exposed to air) may begin. Seventh column gives capacity at 125°F. and eighth column gives capacity at 175° F for still air at about 70° F. These data apply substantially to the conditions existing in a standard, single-duct, underground conduit. If the conduit is multi-duct with a loaded cable in each duct, the capacity

Current Capacity of Wires and Cables

* Sizes larger than No. 0000 B & S are stranded and are given in circular mils.

of each cable will be reduced from 5 to 25 or 30%, depending on the number and arrangement of ducts and cables.

The temperature of paper cables will be about 10% higher than that of rubber cables for the same current and thickness of coverings. Paper cables should not be operated over 190° F and rubber cables over 160° F. Cables immersed in water will carry, for the same temperature rise, 40 to 50% more current than indicated in the table, and if buried in moist earth, 10 to 25% more current.

The capacity of each conductor in a two-conductor, non-concentric cable is about 85% of that of a single-conductor cable; in a two-conductor, concentric cable, 80%; in a three-conductor, non-concentric cable, 75%; and in a three-conductor, concentric cable, 60%.

High tension cables should not be operated over 125° F. on account of the rapid decrease in dielectric strength with increase in temperature.

Wiring Table. The table on p. 1631 shows how far various currents may be transmitted with different sizes of wire and with given percentages of loss. Assuming the usual allowable loss of 2% and given the distance from the entrance of the service to the building, the size of a wire for a given load is at once found in the table. If the size found is less than that allowed by the Underwriters' rules for that current, the latter size should be used.

The current required at 110 volts by motors and lamps is as follows: Motors: 8 to 9 amperes per h p. Lamps: 16-c p carbon, 0.5 amp; 32-c p carbon, 1.0 amp: 40-watt (14 c p) metallized, 0.4 amp; 25-watt tantalum (12 c p), 0.25 amp; 40-watt tantalum (21-c p), 0.4 amp; 25-watt tungsten (18-c p), 0.25 amp; 40-watt tungsten (30-c p), 0.4 amp.

The Sale of Power. Systems of selling power are based on the direct cost of manufacturing; on the investment in power-station and distribution equipment; and on the reserve capacity of the plant required to meet unusual demands of the consumer. Among the numerous systems in use, the principal ones are FLAT RATE, STRAIGHT METER BASIS,

Wiring Table

and MAXIMUM DEMAND. In the FLAT-RATE method a fixt price, depending upon the size of the installation, is charged per month, irrespective of the hours of use. This is used only where power is cheap or the loads small. The METER SYSTEM is the usual system employed by central stations. Various discount methods, based on the total kw-hr consumption per month and on the size of the installation, are used. The MAXIMUM-DEMAND system makes the price paid depend upon the maximum power taken during any given period, as for instance during any 5-minute period in 24 hours. This system is extensively used where large quantities of energy are being consumed and is designed to take care of the investment in equipment not used except for a short time during each day.

Meters. The energy consumed is measured with watt-hour meters or ampere-hour meters. WATT-HOUR METERS, both direct and alternating current, are very small motors geared to a recording mechanism similar to that on gas and water meters. The speed is proportional to power and each revolution represents a certain amount of energy. Direct-current meters have their armatures connected across the circuit and their fields connected in series with the circuit. Alternating-current meters are induction motors with an armature consisting of a metal disk and a field produced by one coil across the circuit and another in series with the circuit. AMPERE-HOUR METERS measure the product of amperes and hours. They are of two types, the ELECTROLYTIC METER and MOTOR METER. The principle of the electrolytic meter is the decomposition of liquids by the passage of current. This decomposition is strictly proportional to the current, and by noting the decrease in volume a measure of the ampere-hours is obtained. In the motor ampere-hour meter the field is produced by permanent magnets and the armature consists of a metallic disk floating in mercury thru which the current flows to and from the disk. Ampere-hour meters may be made to read in kilowatt-hours by assuming a constant voltage and introducing the proper constant in the calibration.

18. Electric Lighting and Illumination

Lighting by electricity is accomplished by three methods: by the arc between two carbon pencils automatically kept a short distance apart, by the passage of current thru rarified gases, and by the heating of a refractory material to incandescence.

The intensity of a source of light is measured in terms of a unit source called a *candle-power*. The four principal standard sources of light are (a) the British standard candle, a spermaceti candle, (b) the English Harcourt lamp, which burns pentane vapor mixt with air in an Argand burner (c), the French Carcel lamp, which burns colza oil with a wick, and (d) the German amylacetate lamp, which burns amylacetate with a wick. The British candle is nominally the standard in this country but the amylacetate lamp is probably the most generally used standard lamp. All of these standards are of course arbitrary, and are made and used in strict accordance with very detailed specifications in order to insure reliable and reproducible results.

Illuminants are measured with a *photometer*, an instrument which gives the value of the unknown source in terms of a standard lamp. Because of the much greater convenience in commercial work, this standard is usually an electric incandescent lamp that has been carefully standardized against one or more of the above primary standards.

Rating of Illuminants. The theoretical standard of intensity of light, the candle-power, is a point of light giving a candle-power in each direction. *Mean horizontal candle-power* is the average candle-power in all directions in a horizontal plane thru the center of the source. *Mean spherical candle-power* is the average candle-power in all directions from the center of the source. *Mean hemispherical candle-power* is the average candle-power in all directions in a hemisphere with the source as the center.

Illuminants are sometimes rated in terms of the *lumen* which is the unit of light radiation. A lumen is equal to the light flux emitted by a source of one candle-power in unit solid angle. A source of one candle power emits a total light flux of 4π lumens.

All commercial illuminants have a more or less irregular distribution curve, that is, the candle-power is greater in some directions than in others, and in making comparisons between different illuminants it is therefore necessary to be specific. Formerly, it was customary to rate electric lamps on a basis of the maximum candle-power obtainable, Later incandescent lamps were rated on a mean horizontal candle-power basis and other illuminants on a mean spherical or mean hemispherical candle-power basis. The present practice, however, is to rate all electric illuminants on the basis of the nominal watts consumed. This applies particularly to incandescent lamps which are all labeled and described on this basis, the candle-power being omitted. This practice is the result of the wide use of reflectors, each form of which gives a different apparent candle-power.

Arc Lamps are extensively used for lighting streets, large interiors, and similar places where the illumination must be general but not necessarily high.

In the OPEN ARC, the earliest form of electric light, an arc is maintained between solid carbon rods in the open air. They are usually operated 40 to 100 in series, on both direct and alternating constant-current circuits. The standard sizes are 6.6 and 9.6 ampere lamps, requiring 45 to 50 volts. Altho this type is relatively very efficient as a source of light, it has been largely superseded by the ENCLOSED-ARC lamp, a lamp which is less efficient but also much less expensive to operate and giving a much better distribution of light. The arc is surrounded by a small, close-fitting glass globe which excludes the air and retards the consumption of the carbons, thereby increasing their life eight to ten times. These lamps are operated on both direct and alternating current, but more often on multiple circuits at 110 volts than on series circuits. The voltage per lamp is 75 to 80 and the current varies from 3.5 to 7.5 amperes. The MAGNETITE-ARC lamp is a direct-current open arc in which the electrodes are metallic copper and an oxide of iron. Its special features are long life of electrodes (about 150 hours), high efficiency, and light distribution particularly suited for street lighting. The FLAMING-ARC lamp is an alternating and direct-current open arc with small-diameter carbons impregnated with sodium or other similar salts which enormously increase the light emitted. They are the highest candle-power units in general use, 2500 to 4000 c p being given in the maximum direction, and are extensively used for spectacular and show purposes. MINIATURE ARC lamps are enclosed carbon-electrode lamps which have been developed to meet the demand for a relatively small unit of high efficiency for interior illumination.

Lamps with Luminous Rarified Gases are not used for general illumination but only where the special characteristics of the light are advantageous.

The Cooper Hewitt lamp consists of an arc in a tube 2 to 4 ft long, in which the cathode is metallic mercury and the arc passes thru rarified mercury vapor. The light is not due to the temperature of the arc, as in the ordinary arc lamps, but to the luminescence of the vapor. The light is therefore green in color, red and yellow being almost entirely absent from the spectrum. The actinic value of the light is high, hence it is used for photographing and blue-printing. It is also said to be less fatiguing to the eyes than white light, and is therefore desirable in drafting rooms. On account of the unnatural greenish tint of the light it is not suitable for general use. When a quartz tube is used instead of glass, the lamp can be operated at a much higher current density, and a higher efficiency as well as a whiter light is obtained. The Cooper Hewitt lamp operates on either direct or alternating current.

The Moore light is practically a Geissler tube about 1½ in in diameter and 100 or more feet long. It is placed around the room to be lighted in one continuous length and operated from a small high-tension transformer. The color depends upon the gas used, pure nitrogen giving a light which has practically the same composition as white light and is therefore particularly suitable for matching colors.

Incandescent Lamps are almost exclusively used for interior illumination where relatively high and uniformly distributed illumination is required.

An Incandescent Lamp is an illuminant where the incandescent material is in the form of a long thin wire of refractory material placed in a glass bulb. The types in most general use are distinguished by the material of which the filament is made, the carbon filament being the oldest. The others in the order of development are metallized (specially treated carbon), and tungsten. The essential difference between these is in the temperature at which the materials may be operated, the temperature of carbon being the lowest and that of tungsten the highest. For the same amount of light, thinner filaments may be used as the permissible temperature increases, and therefore less power is required. Where the power required per candle-power in carbon lamps is about 3.1 watts, that for tungsten lamps (gas-filled) is about 1 watt. All of these types operate equally well on alternating and direct current. The thin filament types of lamps require more careful handling than the carbon, altho they are now sufficiently rugged to be used on trolley cars and other locations subject to vibration. Rapid improvements in the manufacture of tungsten lamps are, however, making them more and more rugged.

The tantalum lamp was developed next after the metallized carbon lamp and came into quite extensive use but it has been completely superseded by the tungsten lamp. Osmium, osram, and zirconium lamps are similar high-efficiency lamps developed abroad in which the filaments are of those metals. They have also become practically obsolete. "Gem" and "Mazda" are trade names for metallized carbon and tungsten lamps respectively made by certain groups of manufacturers.

There are two types of tungsten lamps. In one type (known commercially as type "B") the filament operates in a vacuum while in the other type the bulb is filled with nitrogen gas at about atmospheric pressure ("type C"). The latter is operated at a slightly higher temperature and therefore a slightly higher efficiency than the vacuum type. The gas-filled type is made principally in the larger sizes where the increase in efficiency is most pronounced.

The table on p. 1634 shows the approximate candle-power, power consumption in watts per candle-power, and cost of carbon, metallized, and tungsten lamps. The sizes given are those most commonly used. The prices are approximate for a basis of not less than 5000 lamps purchased per year.

The Nernst Lamp consists of a short stout filament (glower) composed of highly refractory materials (thorium, osmium, etc.) and is operated in the open air. The resistance of the glower is high at normal temperatures, but decreases rapidly at higher temperatures. An auxiliary heating device is therefore provided to heat the glower to the temperature where its resistance will be sufficiently low to permit the passage of line current. The lamp is manufactured with 1, 2, 4, and 6 glowers. They are burned on multiple circuits, either direct or alternating current. This lamp has been practically superseded by the tungsten lamp which is more economical both in operation and in maintenance.

Operation of Incandescent Lamps. Incandescent lamps are used on series as well as multiple circuits, but series lamps are a small per cent of the total. Series lamps have

Candle-Power, Efficiency, and Cost of Incandescent Lamps

Nominal watts	Carbon			Metallized ("Gem")		
	Nominal mhcp	Watts per mhcp	Approx. cost	Nominal mhcp	Watts per mhcp	Approx. cost

100	100.0	1.0	.85	100	1.00	$1.10

NOTE: M h c p = mean horizontal candle-power, m s c p = mean spherical candle-power.

short thick filaments, requiring 15 to 30 volts, and are often connected in the same series circuit with arc lamps and placed in side streets, alleys, and similar places where high illumination is not required. Lamps of different sizes, that is different current ratings, can be operated from the same series circuit by employing a special type of current transformer. The continuity of the series circuit is maintained when a filament burns out by means of an automatic short-circuiting device in the lamp socket.

The life and candle-hours of incandescent lamps are seriously affected by changes in voltage for altho raising the voltage on a lamp increases its efficiency, the life is reduced at a much greater rate. The most economical operating voltage is therefore that where a balance is obtained between the decreased cost of energy consumption and the increased cost of lamp replacements. Fluctuating voltage also produces disagreeable flickering, consequently it is essential that the system be well regulated if satisfactory service is to be obtained. The following table shows the effect of change in voltage on the candle-power and life of carbon, metallized, and tungsten lamps (vacuum type).

Effect of Voltage Variation on Incandescent Lamps

Per cent normal voltage	Per cent normal candle-power			Per cent normal life		
	Carbon	Metallized	Tungsten	Carbon	Metallized	Tungsten
90	53	60	68	830	650	350

Enclosed arc, d.c. multiple	150–250	(m s)	3.0	100–125

* Manufacturers claim several thousand hours.

Notes: m h = mean horizontal candle-power; m s = mean spherical candle-power. 'he watts per candle-power of incandescent lamp decreases as the size of the lamp icreases.

The Relative Cost of Lighting depends not only on the amount of light produced er watt of power consumed, but also upon the cost of power, hours of burning, initial ıvestment, repairs, life, and cost of maintenance (cleaning glassware, replacing incanescent lamps, renewing carbons, glowers, and so forth). Hence the relative standing f the various illuminants will vary with conditions applying to each case, and no general :atement can be made that will be universally applicable. For instance where the cost f energy is low or the lamps are burned only a small fraction of the time, it would cost ess to use carbon lamps instead of any of the more efficient but also more expensive ımps.

Illumination. Illumination is exprest in terms of the FOOT-CANDLE, which is he illumination produced on a surface normal to, and one foot from, a source f one candle-power. The intensity of illumination varies inversely as the quare of the distance from the source.

Illumination of Interiors is usually effected by direct lighting, indirect, and semiıdirect lighting. In direct lighting the illumination is received directly from the light ources but in the indirect method, the light sources are concealed from direct view nd the light is reflected into the room from a highly reflecting surface, usually the ceiling. n the semi-indirect method, a part of the illumination is obtained by reflection and part y direct lighting usually by means of an inverted, translucent reflector or bowl. These wo latter methods have the physiological advantage of removing the light sources from he field of vision of the eye, but it requires considerably more energy for the same amount f illumination. In direct lighting, the intrinsic brilliancy of the sources is (or should be) educed by frosting the bulbs and by the use of enclosing, frosted or opalescent globes. 'his is accompanied, however, by a reduction of 8 to 15% in the amount of light.

The illumination generally accepted as sufficient for some classes of interior lighting indicated in the following table. The Illuminating Engineering Society has prepared ather complete and detailed codes of lighting for factories and school buildings. The

candle-power required in the lamps can be readily computed for a given case if the distance to the lamps and the curve of distribution of light around the lamps are known.

Class of service	Illumination, foot-candles	Class of service	Illumination foot-candles,
Auditoriums	1 to 3.5	Bookkeeping	3 to 5
Theaters	1 to 3	Stores, general illumination	2 to 5
Churches	1 to 3	Stores, clothing	4 to 7
Reading rooms	3 to 4	Drafting	5 to 10
Residences	1 to 3	Engraving	5 to 10
Desk illumination	2 to 5	Factories, gen. illumination	4 to 5

Street Lighting. The best method of illuminating streets is that which will produce the most uniform illumination for the same average illumination. This lies between the two extremes, large units placed far apart and smaller units placed close together. Cost considerations have dictated the very general use of the former method, the lamps being of such a size and so spaced that the minimum illumination midway between lamps will be at least that of average moonlight or about 0.02 foot candle. Obviously, the amount of illumination may be as much greater than this minimum as cost considerations will permit. The prices obtained for street lighting by electric companies vary from \$50 to \$125 per arc lamp per year, and the cost per mile of street will range from \$500 per year in villages to \$5000 for the important avenues in cities. The cost varies greatly even for the same illumination because of the varying conditions such as hours of burning, whether all night or only a part, and whether every night or on a "moonlight schedule"; type of construction, whether ornamental iron poles or wood poles, and overhead or underground distribution; cost of producing energy and so forth.

Reflectors. Efficient artificial illumination requires that as much as possible of the light emitted from the source fall upon the surface or objects to be illuminated. Care should be exercised to select the proper type and size of lamps for the particular case and to locate them where they will be most effective. Reflectors placed back of the lamps can be advantageously used to reflect the light from directions where it is useless to the object to be illuminated. Reflectors are now scientifically designed according to the laws of reflection and refraction. They may be obtained with various forms of distribution curves, either extreme concentration, moderate concentration. or wide diffusion.

19. Batteries

Primary Batteries. If two metals are placed in a liquid, an e m f is generated at the plates, the value of which will depend upon the metals and the liquid. Such a combination constitutes a VOLTAIC COUPLE. Those couples which produce the greatest potentials are used to a large extent as sources of electricity for telegraphing, signals, telephones, call-bell systems, and other purposes where very small amounts of power are required. They are called PRIMARY CELLS, and a number connected together form a primary battery. The various kinds may be divided into two classes: closed circuit and open circuit. Batteries in the first class always use a fluid electrolyte. Those in the second class use either fluid or nonfluid electrolyte.

Closed-circuit Batteries are those which can be discharged continuously. The most common battery of this class is the gravity battery, with electrodes of copper and zinc and a copper-sulfate electrolyte. Its construction is such that it operates best when kept connected to a closed circuit. The voltage of the gravity battery and the similar DANIELL battery is about 1 volt per cell, but the current capacity is only a few hundredths of an ampere. The gravity battery is used extensively for telegraph and railway signal work. POTASSIUM-BICHROMATE batteries use carbon and zinc electrodes with a solution of bichromate of potash. These cells have a potential of about 2 volts each and a comparatively large current capacity. Frequent renewal of the elements and electrolyte is necessary. The EDISON-LELANDE battery consists of zinc and copper electrodes and caustic-soda electrolyte. Its potential is about 1 volt per cell and the largest size will deliver about 7 amperes for nearly 100 hours on one charge of material.

Open-circuit Batteries are intended to be used only on intermittent service, such as call bells and short telephone lines. Very large quantities are used for pocket flash lamps. Practically all batteries in this class are carbon and zinc in a sal-ammoniac solution. The e m f per cell is about 1.5 volts. DRY BATTERIES are carbon-zinc-sal-ammoniac batteries made nonspillable by filling the space between the electrodes with sawdust or similar material which has been saturated with sal-ammoniac solution. They cannot be renewed when exhausted.

Standard Cells are cells used as standards of e m f. The two types in most general use are the Clark cell and the Weston cell. The Clark cell is made with zinc and mercury electrodes and a solution of zinc and mercurous sulfate. Its potential when made up in accordance with certain conditions is 1.434 volts at 15° C. The Weston cell is made with cadmium instead of zinc and the potential is 1.0183 volts at 20° C. Both will remain constant for years if no appreciable current is drawn. The Weston cell has a much lower temperature coefficient and a longer life than the Clark cell.

Storage Batteries are those in which the chemical process is reversible, and which, after being discharged, can be restored to the original chemical condition by sending current thru them in the opposite direction. In the best-known class, the elements or electrodes are metallic sponge lead (negativ plate) and lead peroxide (positiv plate) in a sulphuric-acid electrolyte. While discharging, both elements partially change to lead sulfate and when current is past thru the cell in the opposite direction (charging) they are converted back again to the original state. The two important methods of making the plates are the Planté method and the pasted or Faure method. In the Planté process the lead peroxide and the sponge lead are formed by chemical or electrochemical means directly on lead plates from the plates themselves. In the Faure process various oxides of lead are mechanically applied to the plates and then reduced electrochemically to sponge lead and lead peroxide, respectively. The Planté type batteries are usually used for stationary work where weight and volume are relatively unimportant. For motor vehicles, train lighting, and similar purposes where the maximum capacity per unit of weight and volume is essential, the pasted type is used.

The Capacity of a battery is measured in ampere-hours. A capacity of one ampere-hour means the ability to deliver one ampere continuously for one hour. The capacity of a battery depends upon the amount of active material; the area of the plates; the amount, temperature, and specific gravity of the electrolyte; and the current at which discharge is taking place. In order to get as great capacity as possible per unit volume, the effective surface of the plates is increased by cutting or casting grooves and ridges in the plates and by laminating. Batteries of any capacity are obtained by putting additional plates in the same cells and connecting all positive plates together and all negative plates together. The volts per cell, however, are the same irrespective of the size of the plates or the number connected in parallel, the total voltage required being obtained by connecting cells in series.

The capacity of a battery will vary with the temperature, increasing as the temperature of the electrolyte rises. The change per degree varies with the type of battery. The capacity is greater with currents below the normal rate and smaller with currents above the normal rate. Lyndon gives the following approximate figures for the capacity at high rates: 200% normal rate, 75% normal capacity; 300% normal rate, 58% normal capacity; 400% normal rate, 50% normal capacity.

Rating. The standard method of rating a storage battery is the current which it will give continuously during 8 hours for stationary batteries, and 5 hours for vehicle batteries. Automobile lighting and starting batteries are rated on two bases. One, the lighting rating, is the ampere-hour capacity obtained when discharging at 5 amperes and the other, the starting rating, is the current the battery will deliver continuously for 20 minutes.

Voltage. During discharge at normal rate the voltage falls rapidly at first from about 2.10 or 2.15 to 2.0 volts per cell, and then drops slowly to 1.90 or 1.85 volts. Beyond this point the voltage drops rapidly. In order to maintain constant voltage on the load

END CELL SWITCHES are often used by means of which an additional cell is cut in when the total voltage drops 2 volts.

Efficiency. There are two efficiencies of storage batteries, the WATT-HOUR and the AMPERE-HOUR. Watt-hour efficiency is the ratio of the total energy delivered during discharge to the total energy received during charge. Ampere-hour efficiency is the ratio of the product of amperes and hours during discharge to that of amperes and hours during charge. The watt-hour efficiency of lead batteries averages 75 to 80% and the ampere-hour efficiency about 85 to 90%.

Application. Storage batteries are used extensively in connection with power plants of all sizes. In small, isolated, or private plants, a battery is often used to carry the load during parts of the day when the load is too small to warrant running a generator. In the largest direct-current central stations and substations, large batteries are often installed for the sole purpose of carrying the load in case of an accident necessitating the shutting down of the regular source of power. Such a battery is designed to deliver very large currents for short periods of time. It is often connected across the buses all the time, so that it will deliver current automatically when the bus voltage falls below the normal value.

Care. Storage batteries require intelligent care and use if reasonable life is to be obtained. High rates of charge and discharge, repeated discharging to voltage below 1.70 volts per cell, and charging longer than necessary will rapidly disintegrate the active material and decrease the life. The specific gravity must be kept within the proper limits, the battery must be charged immediately after discharge, and should be charged at occasional intervals when not in regular use.

The most reliable indication of the state of charge or discharge is the specific gravity, hence in large plants readings of the specific gravity are taken at frequent intervals on certain representative cells called pilot cells. Autographic hydrometers have been devised which indicate and record the specific gravity at a point some distance from the cells, as for instance the switchboard.

Cost and Depreciation. The cost of stationary type storage batteries, installed, will range from about $1.50 per ampere per cell for small batteries of 5 amperes capacity to $1.00 for 500 ampere batteries. The cost will decrease slightly with larger capacities. Small portable batteries cost from $4 or $5 to $1.00 per ampere per cell. The depreciation of batteries varies enormously with the care and amount of use which they receive. The rate of depreciation for stationary batteries varies from 8 to 15% and for vehicle batteries from 20 to 50% per year.

The Edison Battery is an alkaline battery quite extensively used for vehicle and other purposes where weight is specially important. The elements are nickel and iron, and the electrolyte is sodium hydrate. It is considerably lighter than a lead battery and, according to the manufacturers, requires less care and attention. On the other hand it is considerably more expensive. The output per pound of cell is about 2.5 watts and 16 watt-hours, compared with about 1.25 watts and 12 watt-hours respectively for the vehicle-type lead battery. The efficiency of the Edison battery is, however, lower than that of the lead battery by about 15 to 20%.

SECTION 15

HIGHWAY ENGINEERING

BY

ARTHUR H. BLANCHARD

PROFESSOR OF HIGHWAY ENGINEERING, UNIVERSITY OF MICHIGAN

GENERAL DATA

1. Preliminary Investigations

A Reconnaissance Survey is of relatively as much importance in highway location as it is in railway location. Altho the elimination of distance is desirable from several standpoints, the distance and grade are so intimately related that in some cases a shortening of the distance will necessitate either the adoption of a steeper grade or an increased cost in the excavation to obtain a grade of a lower rate. The shortest route between two points may not be desirable for esthetic reasons, as is evidenced by a study of the roads of our park systems. Within the city limits and on suburban or country highways thru built-up districts the location already occupied can rarely be changed. A change of location that would improve the grade will sometimes be apparent in making a reconnaisance.

Grades. A maximum grade should be determined which should not be exceeded except in extreme cases. This limiting grade will depend to a large extent upon the locality, the nature of the traffic, and the loads to be hauled. Grades as high as 20% and more are found in mountainous districts, and as high as 15% within some cities. Many of the State highway departments never establish grades over 7%. The maximum grade established determines in many cases the type of road or pavement which may be used: for example, the maximum grades for stone block are 10 to 15%; brick pavement, 6 to 15%; earth, gravel and broken stone roads, 7 to 12%; bituminous concrete, bituminous macadam, bituminous surface, and cement-concrete, 5 to 8%; sheet asphalt, 4 to 5%; wood block, 3 to 4%. Minimum grades are governed by longitudinal surface drainage requirements.

Curves and Widths. All curves on country highways should be carefully investigated with a view to increasing the radius and eliminating obstruction. The First International Road Congress recommended a minimum radius of 164 ft for curves wherever possible. The width should be considered from the standpoint of future requirements in designing new highways. The New York City ordinance prescribes the following widths where no car tracks exist: Street, 60 to 66 ft 8 in, roadway, 50% of street width; street, over 66 ft 8 in, roadway, 80% of street width less 20 ft. The 1912 Standards of Newton, Mass., call for the following relative widths of streets and sidewalks:

30-ft street with curbing, sidewalks 4 ft 6 in; without curbing, 3 ft 6 in.
35-ft street with curbing, sidewalks 5 ft 4 in; without curbing, 4 ft 4 in.
40-ft street with curbing, sidewalks 6 ft; without curbing, 5 ft 6 in.
50-ft street with curbing, sidewalks 7 ft 8 in; without curbing, 7 ft.
60-ft street with curbing, sidewalks 9 ft 6 in; without curbing, 8 ft 6 in.

In English cities and towns a multiple of 9 ft has been adopted for width of traveled way, number of units depending upon number of lines of vehicles. Widths vary from 18 to 36 ft. In the United States interurban and country highways are built with an improved surface from 12 to 20 ft wide; in England, from 18 to 22 ft wide; and in France, National Roads, 23 ft wide.

Materials and Foundations. In connection with the reconnaissance, an investigation should be made relative to the materials suitable for road building that occur thruout the area. A knowledge that a certain material may be found in the vicinity may considerably reduce the cost of construction. The character of the natural foundations and the soil formation encountered along the different routes should also be ascertained. When rebuilding old roads the condition of the present surface should be carefully studied and the same be used, if possible, as a foundation.

Survey and Design. A survey should be made of the different routes determined

upon by the reconnaissance. Full information should be recorded relative to center profile and cross-levels and the location and elevation of curbs, gutters, property lines, manholes, abutting property, intersecting roads, culverts, catch-basins, car-tracks, hydrants, and bridges. Plans and cross-sections should be prepared from the survey notes. Grades can then be assumed and preliminary estimates of the cost of the work can be made. With the help of the plan, a further study should be made of existing conditions in the field in order to determine the best and most economical improvement, after which final estimates can be made. In connection with the proper selection of type of road or pavement, preliminary investigations should be made covering the following points: shade, methods in vogue for cleansing and watering, methods of maintenance, climate and range of temperature, the location of the street as to whether it is in a residential or business district or outside the built-up area, the character and amount of traffic, cost of materials, and character and cost of available labor.

2. Traffic Census

General Information. In connection with the preliminary investigations incident to the construction of a highway, a traffic census should be taken which will cover all classes of traffic to which the road is subjected at different seasons of the year. Other facts relative to traffic should be obtained, as, for example, the amount of loads, the direction of travel, the portion of the road occupied by various classes of vehicles, the relation existing between reduced grades, which incur increased distance between two points, and probable traffic, the kind of shoes worn by horses at various seasons of the year, the use of non-skidding devices employed by motorists, and the enforced traffic regulations governing the use of the road, especially with reference to limitations upon speed and loads to be carried.

The Classification recommended by the Special Committee of the Am. Soc. C. E. on Materials for Road Construction, in its final report in 1918, is as follows: Horse-drawn vehicle traffic: 1-horse vehicles, 2- or 3-horse vehicles, 4-or more-horse vehicles. Motor vehicle traffic: motorcycles, motor runabouts, motor touring cars (open or closed), motor-busses, motor trucks. These classes of traffic are further subdivided as empty vehicles, loaded vehicles and passenger vehicles. An estimate in pounds of the maximum load per inch of tire is also requested. Motor truck traffic should be also subdivided based upon total weight of truck and load, and kinds of tires.

Method of Taking Census. After the classification of the traffic has been adopted, the methods of securing traffic data must be considered. As a practical, economical and efficient plan, the following method is proposed for adoption under average conditions for the season from April to October inclusive for country highways in the northern States. The traffic should be taken during four periods of three days each, one period being in April, May or June, one in July, one in August, and one in September or October. As local conditions may dictate, either Friday, Saturday and Sunday, or Saturday, Sunday and Monday could be taken, thus insuring information relative to the usual abnormal Sunday motor-car traffic and, in some cases, the traffic above the week-day average on Saturdays, while the Friday or Monday traffic would give a fair indication of the normal week-day traffic. From a study of the meteoric records, it will be found that the climatic conditions are favorable to the adoption of the plan proposed. In the months from November to March, inclusive, two 3-day periods would be taken in certain cases; one in November or December, the other in February or March. This distribution of the periods would furnish statistics of the normal traffic in this season and would also afford opportunity for a study of traffic detail and condition of the road during the winter season. In many cases only a month will be available in which to make all the preliminary investigations. Under these conditions the traffic should be observed for 3-day periods using three sets, one of Friday, Saturday and Sunday, and two of Saturday, Sunday and Monday, one period in the first week, one in the

third, and one in the last week. The number of consecutive hours which shoul be taken during the day will depend upon local conditions and the period of th year when observations are made. In many cases 24 hr will be absolutel necessary, while in certain cases 8, 12 or 15 hr will be satisfactory. While it feasible to lay down general recommendations relative to traffic-census perioc for country highways, in the case of city streets the plan adopted will va in detail dependent upon local traffic characteristics and other condition Tillson points out that "traffic has been measured in this country by countir the number of vehicles passing over a street in a given time, so arriving an approximate tonnage without regard to width. In England efforts have bee made to arrive at more definite results, and the tonnage per yard of widt of roadway per day or year has been taken as the unit. This reduces it all to common standard, so that the traffic in one city can be easily compared wi that of another."

Since traffic is only one of several factors which affect the durability of a paveme other facts should be given due weight when examining a surface which has failed. Co siderable data on the relation between the traffic and the wear of the surface must collected and studied before definite conclusions can be reached as to the most economi and efficacious wearing surface to take a known traffic.

The following recommendations contained in the 1918 Report of the Special Co mittee on Materials for Road Construction of the Am. Soc. C. E. should be genera adopted in practise: "Your Committee desires to emphasize the fact that experie has demonstrated the value of traffic censuses taken both preliminary and subsequent the construction of a highway. The traffic census should be considered one of the m important variable factors in the solution of that important problem, the selection that type of road or pavement best suited to local conditions considered from both standpoints of economy and efficiency. In connection with the census returns on a road should be considered the traffic on cross and parallel highways, and the effect improvement of these highways on the traffic of the highways under considerati The bald return of a traffic census, however, should not be the sole basis of the select of the type of construction, but should be considered a guide. In considering the eff of traffic and its relation to the design and cost of maintenance, it is necessary to t into account the speed as well as the weight of the vehicles."

3. Comparison of Roads and Pavements

An Ideal Pavement should be durable, noiseless, sanitary, efficacious road users, easily cleaned and made dustless, provide good foothold for hor be non-slippery for all classes of vehicles under varying climatic conditic yield neither dust nor mud, have a low tractive resistance, low first cost, annual cost, low maintenance charge, and an esthetic and impervious surf The following table gives assigned values for some of these characteristics of different types of roads and pavements on the basis of 10 for the value of characteristic in an ideal pavement:

Ideal Relative Values of Pavements

Characteristic	Ideal Pavement	Sheet Asphalt	Brick on Concrete	Stone Block on Concrete	Wood Block on Concrete	Concrete	Bituminous Concrete	Bituminous Macadam	Bituminous Surface	Macadam with Dust Palliative	Macadam	Gravel
First cost	10	3	5	1	1	6	6	7	8	9	9	9
Ease of traction	10	10	8	3	9	9	9	8	8	6	6	5
Non-slipperiness	10	4	8	7	4	6	7	7	7	8	10	10
Ease of cleaning	10	10	9	7	9	8	9	9	9	3	3	1
Noiselessness	10	7	6	3	9	6	9	9	9	10	10	10
Dustlessness	10	10	9	8	7	7	9	8	8	6	4	3

Earth Roads. In some sections of the country where other material is not ailable, earth roads are the most economical proposition. If proper care is ‹en in their maintenance, they may be kept in fair condition thruout the year. ey are inexpensive and easy to build and maintain. Unless treated, however, th a dust palliative, they will be objectionable from the standpoint of dust. wet weather, if built of certain materials, they will be muddy. Sand-clay ıds, when built with the proper grades of material, give a much more durable ·face than ordinary earth roads, and hence eliminate some of the worst fea- es of the last-named type.

Gravel Roads are not as durable as broken stone roads. They are dusty in y weather unless treated with some dust palliative or built with a bituminous rface. They are practically noiseless. Water readily finds its way thru a avel road. The surface should be well crowned. This type of road furnishes excellent foothold for horses. A gravel road during continued wet weather periods when frost is coming out of the ground will usually have a muddy rface.

Macadam Roads, if properly built, withstand a horse-drawn traffic remark- ly well, but are not able to withstand a high speed heavy motor-car traffic. ‹e gravel roads, unless treated with a dust palliative or constructed with a bitu- nous surface, macadam roads are dusty. They are not noisy. Macadam ıds do not absorb moisture as readily as gravel. Horses can obtain a good othold on a macadam surface. Unless the dust, which results in part from abrasion of the stones by the traffic, is cleaned off, the surface will be muddy wet weather.

Palliatives. If a road is properly treated with a dust palliative, the dust ll be effectively laid. In wet weather, however, certain oils will emulsify with water and cause a muddy condition which is very objectionable. There are o some materials used as dust palliatives which have an offensive odor.

Bituminous Surfaces. A superficial coat of bituminous material, if applied a gravel or macadam road surface, will render the road more durable and better le to withstand the automobile traffic. A superficial coat of tar will not be sty if the road is in an exposed location. In general a surface treated with a avy asphaltic material will not be as dusty as a tarred surface. Roads having a perficial coat of tar are a trifle more noisy than ordinary macadam. The othold furnished and tractive effort required depends principally upon the ture and amount of the bituminous material used. For instance, a certain ıde of tar may furnish a poor foothold, under certain conditions, but decrease tractive effort, while the results would be just the reverse in the case of ·tain asphaltic materials. Both types of surfaces are easily cleaned and are actically impervious.

Bituminous Macadam Pavements are more durable than superficially ated macadam roads. Otherwise their characteristics are practically the ne as those of bituminous surfaces.

Bituminous Concrete Pavements are more durable than bituminous cadam pavements. Their surfaces are impervious, easily cleaned and intained, usually are noiseless, and have a low tractive resistance.

Cement Concrete Pavements are more durable than bituminous macadam vements. They are easily cleaned, practically impervious, non-slippery en dry and when wet if clean, and have a low tractive resistance.

Wood Block Pavements are not as durable as brick. Unless the blocks treated with some preservative, they are liable to decay rapidly. Altho the cks themselves are permeable, this does not seem to be a serious objection.

This type of pavement is practically noiseless, neither the noise from the horses' hoofs nor from the wheels being objectionable. Wood block pavements are very slippery under certain conditions. They afford a smooth surface, with little resistance to traction, and are easily cleaned.

Stone Block Pavements, if laid on a concrete foundation, are suitable to take the heaviest kind of traffic. Thoro sweeping and flushing are necessary to keep them from being dusty. All types of stone block pavements are noisy. These pavements are slippery in wet weather and when the pavements are sufficiently worn so that the surfaces of the blocks become smooth and rounded. Stone block pavements are not as easy to clean as some of the pavements with smoother surfaces. If constructed with a joint filler other than sand or gravel, a stone block pavement is impervious. More tractive effort is required on a good stone block pavement than on a good macadam surface. Durax pavement composed of machine-made cubes, is used in England on many of the inter-urban highways. It is durable, non-slippery, and not productive of much noise.

Brick Pavements on a concrete foundation are not as durable as stone block pavements, but, if correctly built, they are smoother riding. Having a smoother surface than stone block pavements, they are easier to keep clean, and are hence more sanitary. They offer a very good foothold to horse-drawn traffic, and very little resistance to traction provided they have an even surface. When constructed with a bituminous or cement grout filler, these pavements are impervious. If properly constructed and maintained, a brick pavement with a bituminous filler is generally not as noisy as pavements with a cement grout filler.

Sheet Asphalt Pavement is one of the most durable types of pavement next to stone block and brick. It has a smoother surface than any other type. On this account it has some advantages over many of the other pavements in that it is easier to clean and that it offers less resistance to traction. This pavement is impervious, and outside of the noise resulting from the horses' hoofs, it is noiseless. When somewhat dirty and enough rain falls to just moisten the dirt, the pavement becomes particularly slippery. Asphalt block pavements present a surface very similar to that of a sheet asphalt pavement. The surface has about the same characteristics as an asphalt surface, except that it is not so slippery.

4. Capitalized Cost

The Relative Economy of different types of roads and pavements can only be ascertained by comparing the annual costs. The annual cost is a combination of the following variables: interest on the initial cost of the road, the annual maintenance charge and an annuity which will in N years, the so-called life of the road, provide a fund equal to the cost of reconstruction. If we let C = annual cost, A = first cost, r = rate of interest, I = annual maintenance charge, and x = annuity (Sect. 12, Art. 7), the annual cost may be exprest by the formula:

$$C = Ar + I + x$$

In the case of types of roads permitting partial reconstruction every M years, a second annuity y should be included in the above formula to take care of this periodical reconstruction thru N years or the total life of the road. In order to make a fair comparison between the different methods, the same standard of maintenance in each case should be insisted upon. The ideal maintenance which should be striven for in every case is a method by which the surface of the highway is kept in as good condition as when accepted on the completion of construction.

Selection of Pavement. Altho theoretically the pavement giving the lowest annual cost would be the most economical one to build, there are other con

siderations which sometimes make it necessary to select some other type of pavement. For instance, the amount of money at hand for the improvement may not be sufficient to pay for the first cost of construction of a pavement which would give a low annual cost. In large cities the cost of cleaning the pavements is an item that should be taken into account, since the saving in this respect might be more than offset by the difference in annual costs between two pavements. Again, a road or pavement that might be the most economical would require such frequent repairs as to interfere with the traffic and business conducted on it, and would have to be seriously considered in a business district. Esthetics also influence the selection of the type of road or pavement.

Life of Pavements. Fixmer estimates the life in years as follows:

Granite block	30
Creosoted wood block	15–20
Brick	20
Sheet asphalt	16
Asphaltic concrete	12–20
Cement-concrete	6–10
Bituminous macadam	8
Broken stone	4

Application of Formula. In order to show the application of the formula, the annual cost of a granite block pavement laid on a 6-in concrete base will be computed. It will be assumed that the first cost is $3.50 per sq yd; interest at 4%; annual maintenance cost is 2.4 cents; that life is 25 years; that at the end of this time new blocks are laid on the old concrete foundation at a cost of $2.50 per sq yd, and that in this manner the life of the pavement is renewed for another 25 years. The annual cost then for 50 years, considering the whole pavement to be renewed at the end of that time, will be found as follows:

$C = \$3.50 \times \$0.04 + \$0.024 + \$0.023 + \$0.060 = \$0.247$ for the first 25 years,
$C = \$0.187$ for the second 25 years, and the mean of these gives $C = \$0.217$ average for 50 years.

5. Soils

Classification. Soils are formed by the decomposition of mineral, animal, and vegetable matter. They may be designated as sedentary or transported. Sedentary soils are those which remain near their source of formation, while transported soils have been carried by some geological agency from the place where they were first formed to some other. Soil as far as its composition and properties are concerned is extremely variable. The principal constituents of any soil, however, whatever its source, are nearly always silica, with varying amounts of alumina, oxides of iron, lime, magnesia, and the alkalies. A small amount of organic matter is also usually present. Soils are generally classified as gravel, sand, clay, loam, marl, peat, and muck.

Gravel consists of small pieces of rock, worn smooth by abrasive action, mixt with sands and clays in varying proportions. Gravels occur thruout the United States and Canada in those districts which were at one time covered with the glacier. Gravel should contain enough binding material, mixt with the stone particles, to bind the whole into a solid mass. Clay is the most common form of binder found in gravel in its natural state. If present in too large quantities, however, it is detrimental. If gravel does not have sufficient binding material, this can be remedied by adding some cementing material such as clay, shale, marl, loam, or stone screenings. Some gravels contain so much earthy material that it is necessary to screen them before they are suitable for road-making purposes. An indication of the binding qualities for pit gravel may be obtained by noticing the gravel in the pit. If the bank faces are vertical and the gravel breaks off into chunks, good binding qualities may be expected. River

gravel generally contains less clay and more silica than the pit gravel of the same locality. Soil classified as hardpan may mean either a very compact clay, or a gravel which is cemented with clay or an iron oxide.

Sand is largely the result of the breaking-down of sandstone rocks and a sandy soil so-called probably contains over 80% of pure sand. A sandy soil is hard to compact, and possesses little binding power unless wet or mixt with some cementing material such as clay. Quicksand is sand saturated with water, and possesses no stability.

Clay results from the decomposition of feldspar, oligoclase, and micaceous rocks. A clayey soil might be termed such when containing at least 60% of clay. Clay when wet will swell and puddle with water, becoming very plastic. When mixt in the proper proportions with sand or gravel, it makes a very satisfactory road material in localities where stone is unobtainable. Clays used for fire clays in the manufacture of brick, besides being plastic, must possess certain refractory qualities which enable them to withstand long periods of heat at high temperatures without fusing. Shales are chemically the same composition as clays, but they have a laminated structure, and are similar in appearance to slates. Shales however, will rapidly disintegrate on exposure to the atmosphere. In the southwestern States a clay of which mud bricks might be made is called "adobe."

Loams may be any soil between sand and clay. They contain more or less of each of these two materials. They may be classified as heavy clay loams clay loams, sandy loams, and light sandy loams, depending upon the quantity of the sand or clay content. In the Middle West a black loam which contain so much clay as to be sticky when wet is known as "gumbo."

Marl is a term which applies to all calcareous clays containing as a minimum 15% of carbonate of lime, and as a maximum 75% of clay.

Peat and Muck are generally distinguished from other soils by the presence of humus or vegetable matter. They are formed by the decomposition of vegetable matter under water, and are undesirable materials for road building.

6. Stone, Brick, Wood

Rocks used for road-building purposes are trap, granite, limestone, sandstone chert, slate, and field stones. The Special Committee of the Am. Soc. C. E. on Bituminous Materials for Road Construction recommends in its 1912 report that "whatever method of construction may be used, it is essential, as in water bound macadam construction, that a suitable quality of road metal be used."

Diabases and Basalts, which are dark-colored igneous rocks, are commonly know as trap. Trap is extremely hard and tough, and its excellent wearing qualities have cause its widespread use thruout those sections of the country where it is found. When use in the construction of broken-stone roads subjected to a light traffic, the wear on th stones will not be sufficient to make enough binder to hold the stones together. To pre vent the surface from raveling, more binder or a bituminous material must be applied.

Granite is made up chiefly of quartz and feldspar. In trade, gneiss, syenite and por phyry are commonly known as granite, altho not so in a geological sense. If the structur is close, even and granular, these stones make excellent road material for broken-ston roads. If of a coarse structure, they are not so desirable. Granite and syenite are mo largely employed for paving stones than other materials, the latter being one of the bes materials for this purpose. Stone blocks made of porphyry have been found to wea slippery, and their use in Europe is being discontinued.

Limestone possesses excellent binding qualities, but is neither hard nor tough and therefore only suitable for roads taking a light traffic. It is rarely used as a materi for the manufacture of paving-blocks.

Sandstone, due to the fact that it easily breaks up under the action of traffic, and lacking in binding qualities, is generally only considered as a fair material for broke

tone roads. Stone blocks, however, made of Medina, Potsdam, and Colorado sandtone have been used to a considerable extent with excellent results.

Quartzites, which are metamorphosed sandstones, give better results when used for roken-stone roads than sandstones, as they are harder.

Chert is a variety of quartz of a flinty structure. It occurs in certain parts of the ountry either as a solid mass or in a broken-up state, mixed with clay similar to gravel.

Field Stones are boulders which have been carried along by the glacier and are found ainly in those districts which were covered by the glacier. They are composed of a ariety of different kinds of rocks, some of which make good road-building materials. hose stones which show signs of weathering and decomposition should not be used. obblestones used for paving gutters and streets are small boulders which have been elected from field stones.

Slate, an indurated or hardened clay, is of not much value as a road-building stone n account of its fracture and low cementing value.

Chats is a term used in the West to denote the tailings of lead mines. It is a dolomitic mestone, and considered good for use in road construction.

Tests for Broken Stone. By making petrographic and chemical analyses, a ock can be identified and its constituents ascertained. For the purpose of etermining the value of a rock as a road-building material, several tests have een devised which are used both in this country and in Europe. The usual ests made of broken stone are for abrasion, toughness, absorption of water, pecific gravity, hardness, and cementing power. Results of tests on different inds of rocks are given in the Table on page 1648 prepared by the U. S. ureau of Public Roads.

The Abrasion Test, as adopted by the Am. Soc. for Testing Materials, is made y means of the Deval machine, and consists of placing 5 kg of broken stone of certain size in one of the cylinders, the cylinder being rotated for 10 000 revoıtions, at the rate of between 30 and 33 to the minute. The weight of the etritus that will pass a sieve of 1/16-in mesh is determined, and the percent of ear computed. The coefficient of wear, also known as the French coefficient, quals 400/W, in which W is the weight in grams of the detritus passing the bove sieve, obtained per kilogram of rock used. The number 20 was adopted s a standard of excellence. In interpreting results of this test a coefficient of ear below 8 is called low; from 8 to 12, medium; over 12, high. (See Form 168, J. S. Bureau of Public Roads.)

The Test for Cementing Capacity is made by preparing a small cylindrical riquette, 25 mm in height and 25 mm in diameter, of rock powder, which will ass thru a 0.25 mm mesh sieve, mixt with a small amount of water. The ylinders are made in a die and are subjected to a uniform compression of 100 kg er sq cm. The briquettes are dried in the air and steam bath, cooled, and then ested in a specially designed machine. The test consists in noting the number f blows of a 1-kg hammer falling 1 cm that it will take to destroy the briquette. he machine is provided with a self-recording apparatus which measures the umber of blows. The test is interpreted so that cementing values below 25 re called low; from 25 to 75, average; over 75, high. (See Form 168, U. S. ureau of Public Roads.)

The Test for Toughness, as adopted by the Am. Soc. for Testing Materials, made on rock cylinders, 25 mm in diameter by 25 mm in height, which have een bored out of the rock by a diamond core drill. These cylinders are placed n an impact machine underneath a plunger of 1 kg in weight, and the latter is ubjected to the blow of a 2-kg hammer. The hammer falls 1 cm for the first low, and the fall is increased 1 cm for each succeeding blow. The number of lows required to destroy the test piece is used to represent the toughness. Re-

sults of this test are interpreted so that rocks which run below 8 are called low; from 8 to 12, medium; and above 12, high.

The Test for Hardness is made on cores 1 in in diameter, cut from the solid rock, faced off and subjected to the grinding action of sand, fed upon a revolving steel disk against which the test piece is held with a standard pressure. When the disk has made 1000 revolutions, the loss in weight of the sample is determined. One-third of the resulting loss in weight in grams is subtracted from 20; thus a rock losing 6 grams has a hardness of $20 - 6/3$ or 18. Below 15, rocks are called soft; from 15 to 18, medium; above 18, hard.

Crushing Strength of Stone. (Recommended by Special Committee, "Materials for Road Construction," Am. Soc. C. E., 1918 Report.) "Cylinders shall be cut from a suitable block of the material to be tested each of which cylinders shall, as nearly as practicable, be 2 in in diameter and 4 in in length. After cutting, the dimensions of each cylinder shall be accurately measured and recorded. Each cylinder shall then be subjected to compression and the ultimate stress at which its failure occurs shall be noted. This stress divided by the average area in cross-section of the cylinder in sq in shall be reported. It is desirable that the test of the material shall be made on at least three such cylinders separately and the average of the three or more specimens shall be taken as the average resistance to crushing of the material. In making the

Maximum and Minimum Results on Rock Samples, Corrected to January 1, 1915

est the cylinder shall be so fixt in the testing machine as to be unsupported on its sides and to rest squarely on its ends and the compressive stress shall be applied cumulatively. The ends of the cylinder shall be at right angles to the long axis of the cylinder and the blocks or pieces of the machine in contact with ends of the cylinder and thru which the pressure is transmitted shall have such position and freedom of movement in the machine as will insure the application of the stress directly along or parallel to the long axis of the cylinder."

Common Commercial Sizes of broken stone are screenings, ⅜-in chips, ½, ¾, 1, 1¼, 1½, 2, 2¼, 2½, and 3 in. The size of the crusht stone depends upon the kind of stone, the crusher, and the screen, and the details of operation. The inclination of the screen and, if a rotary screen, the speed at which it is run, will make a variation in the separation of the sizes of the screened product. The form of specification recommended in 1918 by the Special Committee, "Materials for Road Construction," Am. Soc. C. E., is as follows:

The broken stone shall consist of one product of the operation of a stone-crushing and screening slant, without recombining or mixing, and shall conform to the following mechanical analysis, using laboratory screens:

Passing ...-in screen (having smallest holes selected) from	... to ...%
Passing ...-in screen (having next to largest holes selected) from	... to ...%
Passing ...-in screen (having largest holes selected) from	... to ...%

Example of mechanical analysis to be used in a specification:

Passing ¼-in screen	3 to 10%
Passing 1-in screen and retained on ¼-in screen	80 to 95%
Passing 1¼-in screen and retained on 1-in screen	2 to 10%

Specifications for Stone Blocks should call for a close, fine-grained, homogeneous material, durable, sound and uniform, with no outcrop, soft, brittle or laminated stone. The stone is tested for crushing, abrasion, and toughness. Cobble should be sound, durable and uniform stone, 4 to 8 in in diameter.

Cost of Broken Stone and Stone Blocks varies greatly, being governed to a great extent by local conditions, occurrence, and freight rates. From 1914 and 1915 quotations, the price delivered at New York was 85 cents to $1 per cu yd, and at Boston, 60 to 85 cents f o b at the quarry, varying slightly for different gages, at Pacoima, Cal., 53.5 cents per short ton at the plant. Price quotations of stone block 1910 and 1911 at various points: Quincy granite, $35 to $50 per thousand; granite, $2.15 per sq yd f o b Chicago; Rochester, Medina sandstone, $1.15 per sq yd f o b at the quarry; Cape Ann granite, $1.60 to $1.75 per sq yd delivered in New York; same, drest, $2 to $2.15 per sq yd; Baltimore, granite (1908), $68 per thousand; Toronto (1909), granite, $67 per thousand.

Clays for Making Vitrified Bricks are not often found in a natural state. A clay for this purpose should be fusible, plastic, and be able to be heated to a high temperature without losing its shape. Vitrification is obtained by subjecting the clay to heat, which changes the chemical properties of its constituents, making them coalesce with each other into a new and homogeneous solid. All clays are composed mainly of silica and alumina and certain impurities such as quartz, lime, magnesia, potash, and soda. The impurities, with the exception of quartz, act mainly as fluxes. An excess of silica will cause a weak and brittle specimen, while an excess of alumina will cause shrinkage, cracking, and warping. An excess of lime and magnesia hastens disintegration upon exposure. Shales are also used for the manufacture of paving-bricks. They produce a harder and more brittle brick than one of fire-clay. Paving-bricks are manufactured by crushing and screening the properly mixt clays or shales. This material is then mixt with water in a pug-mill to the right state of consistency, and is then pushed thru a mold, the clay being fed to the mold by means of an auger. The bar of clay as it comes from the mold is cut by machines into the size of brick desired. Paving-bricks are made with plane faces and also with some pro-

jections on the faces so that, when laid, there will always be a space between the faces which will later be filled with the joint filler. Some machines are designed so as to cut the brick with lugs on one side and grooves on the other. Other bricks are represt after being cut, and lugs or grooves, together with the curved edges, are formed by the die used in repressing. The raised letters on the brick serve this same purpose. After being cut or represt, the bricks are dried and then burned for from seven to ten days at temperatures varying from 1500 degrees F. to 2300 degrees F. The bricks are slowly cooled in the kiln after the fire is withdrawn, which serves to anneal and toughen them.

Tests for Paving Brick. Numerous tests have been devised, both abroad and in this country, for testing paving brick, the methods adopted in this country being almost without exception those proposed by the National Paving Brick Manufacturers Association as follows: the rattler test, which gives the amount of wear or abrasion on a number of identical sample test bricks, when subjected to a certain number of revolutions for a given time in a cylindrical hopper; the compression; the cross-breaking; and the absorption tests. Of these the first-named is essential, and according to the 1918 Standard Specifications of the Am. Soc. of Munic. Imps., any sample should not lose by weight more than 22% and the brick should not vary more than 8 points.

Cost of paving brick f o b at plants, 1915, varies from $12 to $21.50 per thousand, the average price being about $15.

Wood Blocks that have not been treated by some preservative process have given unsatisfactory results. Rectangular-faced blocks of Southern long-leafed yellow pine, Norway pine, and tamarack are usually specified, only one kind of wood, however, to be used on any one contract. Black gum and short leaf pine may be satisfactory under certain conditions, but require a different treatment than the woods first mentioned. The Australian hard woods, Jarr and Karrah, are slippery, and are considered too costly for use in this country. The common method of preserving wood blocks is to treat them with some pre-servative fluid, the most common being a pure creosote oil or a water-gas or a coal-tar product. In the United States the blocks are impregnated with th oil under a pressure of from 70 to 200 lb per sq in. The amount of oil absorbec by the wood varies from 10 to 22 lb per cu ft. In Paris one method of incor-porating the preservative fluid, which consists largely of creosote oil, is t immerse the blocks in a bath of this material for a short period. The resultin penetration of the fluid is of small amount.

Tests for Wood Block. The French practise is to conduct careful tests fo resistance to wear when saturated with water, absorption, compression, an impact, but in this country the most common tests of the treated blocks ar the determination of the amount of clear water absorbed after 24 hr and th analysis of the oil content to determine if it conforms to specifications fc creosote oil. Wood paving-blocks should conform to the following specification blocks shall be of sound timber with no sapwood and free from bark, loose c rotten knots; they shall be close-grained, sound and well seasoned; all block for a given contract shall be of same material, and dimensions must not var more than 1/8 in in different samples.

Cost of wood blocks from 1915 quotations is about $2 per sq yd surfac measure f o b New York, blocks to contain 20 lb per cu ft of creosote oil.

7. Bituminous Materials

The Bituminous Materials used in the United States may be classified follows: asphalts, asphaltic and semi-asphaltic oils, coke oven tars, coal-gas tar water-gas tars, combinations of coal-gas and water-gas tars, combinations asphaltic materials and tars, rock asphalts.

Nomenclature of Bituminous Materials and Their Uses. Definitions adopted by the Special Committee on "Materials for Road Construction" of Am. Soc. C. E. are noted thus, †; others adopted by the Am. Soc. Testing Materials are designated thus,* and others proposed by the Committee on "Standard Tests for Road Materials" (Committee D-4) of the Am. Soc. Testing Materials have been indicated thus, ‡.

Asphalt.†* Solid or semisolid native bitumens, solid or semisolid bitumens obtained by refining petroleums, or solid or semisolid bitumens which are combinations of the bitumens mentioned with petroleums or derivatives thereof, which melt on the application of heat, and which consist of a mixture of hydrocarbons and their derivatives of complex structure, largely cyclic and bridge compounds.

Asphalt Block Pavement.† One having a wearing course of previously prepared blocks of asphaltic concrete.

Asphalt Cement.† A fluxed or unfluxed asphaltic material, especially prepared as to quality and consistency, suitable for direct use in the manufacture of asphaltic pavements, and having a penetration of between 5 and 250.

Asphaltenes.†* The components of the bitumen in petroleum, petroleum products, malthas, asphalt cements, and solid native bitumens, which are soluble in carbon disulphide, but insoluble in paraffin naphthas.

Bitumen.*† A mixture of native or pyrogenous hydrocarbons and their non-metallic derivatives, which may be gases, liquids, viscous liquids, or solids, and which are soluble in carbon disulphide.

Bituminous Concrete Pavement.† One composed of broken stone, broken slag, gravel, or shell, with or without sand, portland cement, fine inert material, or combinations thereof, and a bituminous cement incorporated together by a mixing method.

Bituminous Macadam Pavement.† One having a wearing course of macadam with the interstices filled by a penetration method with a bituminous binder.

Bituminous Material.† Material containing bitumen as an essential constituent.

Liquid Bituminous Material.† Bituminous material showing a penetration at normal temperature under a load of 50 grams applied for 1 second of more than 350.

Semisolid Bituminous Material.† Bituminous material showing a penetration at normal temperature under a load of 100 grams applied for 5 seconds of more than 10, and under a load of 50 grams applied for 1 second of not more than 350.

Solid Bituminous Material.† Bituminous material showing a penetration at normal temperature under a load of 100 grams applied for 5 seconds of not more than 10.

Bituminous Pavement.† One composed of broken stone, broken slag, gravel, shell, sand or fine inert material, or combinations thereof, and bituminous cement incorporated together.

Bituminous Surface.† A superficial coat of bituminous material with or without the addition of stone or slag chips, gravel, sand, or material of similar character.

Blown Petroleums.* Semisolid or solid products produced primarily by the action of air upon liquid native bitumens which are heated during the blowing process.

Carbenes.†* The components of the bitumen in petroleums, petroleum products, malthas, asphalt cements, and solid native bitumens, which are soluble in carbon disulphide, but insoluble in carbon tetrachloride.

Coal-tar.†* The mixture of hydrocarbon distillates, mostly unsaturated ring compounds, produced in the destructive distillation of coal.

Coke Oven Tar.†* Coal-tar produced in by-product coke ovens in the manufacture of coke from bituminous coal.

Cut-Back Products.* Petroleum, or tar residuums, which have been fluxed with distillates.

Dead Oils.†* Oils, with a density greater than water, which are distilled from tars.

Dehydrated Tars.†* Tars from which all water has been removed.

Emulsion.† A combination of water and oily material made miscible with water thru the action of a saponifying or other agent.

Fixed Carbon.†* The organic matter of the residual coke obtained upon burning hydrocarbon products in a covered vessel in the absence of free oxygen.

Flux.†* Bitumens, generally liquid, used in combination with harder bitumens for the purpose of softening the latter.

Free Carbon.†* In tars, organic matter which is insoluble in carbon disulphide.

Gas-House Coal-Tar.†* Coal-tar produced in gas-house retorts in the manufactur of illuminating gas from bituminous coal.

Native Asphalt.†* Asphalt occurring as such in nature.

Normal Temperature.†‡ As applied to laboratory observations of the physical characteristics of bituminous materials, is 25° C. (77° F.).

Oil-Gas Tars.†* Tars produced by cracking oil vapors at high temperatures in the manufacture of oil-gas.

Petroleum.‡ Liquid bitumen occurring as such in nature.

Pitch.†* Solid residue produced in the evaporation or distillation of bitumens, the term being usually applied to residue obtained from tar.

Hard Pitch.† Pitch showing a penetration of not more than ten.

Soft Pitch.† Pitch showing a penenetration of more than ten.

Refined Tar.†* A tar freed from water by evaporation or distillation which is con tinued until the residue is of desired consistency, or a product produced by fluxing ta residuum with tar distillate.

Rock Asphalt.†‡ Sandstone or limestone naturally impregnated with asphalt.

Rock Asphalt Pavement.† A wearing course composed of broken or pulverized roc asphalt with or without the addition of other bituminous materials.

Sheet Asphalt Pavement.† One having a wearing course composed of asphalt cemen and sand of predetermined grading, with or without the addition of fine material, in corporated together by a mixing method.

Straight-Run Pitch.* A pitch run to the consistency desired, in the initial proce of distillation, without subsequent fluxing.

Tar.†* Bitumen which yields pitch upon fractional distillation and which is pr duced as a distillate by the destructive distillation of bitumens, pyro-bitumens, or organ material.

Water-Gas Tars.†* Tars produced by cracking oil vapors at high temperatures in th manufacture of carburetted water-gas.

Tests and Specifications for Physical and Chemical Properties. Va ous tests have been devised in order to determine the physical and chemic properties of bituminous materials. Tests are made for control of the man facture of bituminous materials, to obtain a record of the properties of materia used, and are employed in specifications to secure the materials desired f use in the construction and maintenance of roads and pavements.

The Special Committee on "Materials for Road Construction" of the Ame can Society of Civil Engineers, in its 1918 Report, recommended the adopti of the following lists of tests, as including all those probably of value in dete mining and recording the characteristics of the bituminous materials.

Asphalt Cements. Specific gravity at 25° C. (77° F.); flash point; solubil in CS_2 (carbon disulphide); solubility of bitumen in CCl_4 (carbon tetrachloride); so bility of bitumen in petroleum naphtha; penetration 4° C. (39° F.), 200 grams, 1 m penetration 25° C. (77° F.), 100 grams, 5 sec; penetration 46° C. (115° F.), 50 gra 5 sec; float test; melting point by ring and ball method; ductility at 4° C. (39° ductility at 25° C. (77° F.); fixed carbon content; paraffin content; loss on ev oration at 163° C. (325° F.), 5 hours; penetration of residue (same as for asphalt ceme melting point of residue, by ring and ball method, float test on residue; ductility residue at 4° C. (39° F.); ductility of residue at 25° C. (77° F.).

Tar Cements. Water; specific gravity at 25° C. (77° F.); flash point; solubi in CS_2 (carbon disulphide); specific viscosity, Engler; melting point, by cube metl

loat test; distillation by weight and by volume; up to 110° C.; 110° to 170° C.; 70° to 235° C.; 235° to 270° C.; 270° to 300° C.; specific gravity of total distillate t 25° C. (77° F.); melting point of residue, by cube method; float test on residue.

The tests used in a given specification depend upon the kind of bituminous material mployed and the method used. For example, a sepcification for a refined tar to be sed as a bituminous cement in a bituminous concrete pavement in which the aggregate onsists of broken stone composing one product of a stone-crushing plant, would include eference to tests for specific gravity, solubility in carbon disulphide, consistency with he New York Testing Laboratory float apparatus or with a penetrometer, melting point, istillation, specific gravity of total distillate and melting point of pitch residue remaining after distillation. In the case of an asphalt cement to be used in the above type of onstruction, the tests referred to in the specifications would include specific gravity, ash point, penetration at 4° C., 25° C., and 46° C., melting point or consistency with the New York Testing Laboratory float apparatus, loss on evaporation at 163° C. and peneration of the residue from evaporation, solubility in carbon disulphide, solubility of itumen in carbon tetrachloride, solubility of bitumen in paraffin naphtha, and fixed arbon.

For the purposes of this section it is not necessary to describe tests, the names of hich give an indication of the method of performing the tests. Such tests include specific ravity, solubility in carbon disulphide, carbon tetrachloride, petroleum naphtha, evapration, and distillation. For detailed descriptions of methods of conducting all of the ests for tars and asphaltic materials, see 1918 Transactions, Am. Soc. C. E., pages 1448 o 1462.

Flash Point. The material is placed in a cup fitted with a glass cover having a small pening. The temperature of the material is raised and a testing flame is inserted in he opening of the cover from time to time. The appearance, for a few seconds, of a aint bluish flame over the entire surface of the bituminous material will show that the ash point has been reached, and the temperature at this point is recorded.

Melting Point. The material is melted and molded into a ½-in cube. The cube s placed on a wire and suspended one inch above the bottom of a beaker. The temerature of the cube is then raised until the material softens and touches the bottom of he beaker. The temperature at this point of the operation is considered the melting oint of the material.

Consistency. The consistency of bituminous materials is determined by the Engler iscosimeter, the New York Testing Laboratory float apparatus, or the penetrometer.

With the **Engler Viscosimeter** the viscosity of liquid bituminous materials is deternined by noting the time which is required for a given amount of the material, having given temperature, to flow through a very small orifice. The result of the test should e exprest as specific viscosity, which equals the ratio of the number of seconds required or the passage of a given volume of the bituminous material at the temperature used ivided by the number of seconds required for the passage of the same volume of water t 25° C. (77° F.).

The New York Testing Laboratory Float Apparatus consists of an aluminum float nd a brass collar. The collar is filled with bituminous material and screwed into the ottom of the aluminum float and the apparatus placed on the surface of a water bath. s the plug of bituminous material in the collar becomes warm and fluid, due to the eat from the water bath which is maintained at any temperature desired for the test, t is gradually forced upward and out of the collar until water gains entrance to the aucer and causes it to sink. The time in seconds between placing the apparatus on the vater and when the float sinks is taken as the measure of consistency.

The Penetration Test is made by measuring the distance a weighted standard needle vill penetrate into the material at a given temperature in a given period of time. The emperatures, weights, and periods of time which are employed to a considerable extent re as follows: Penetration at 4° C. with a weight of 200 grams for 1 minute; penetration t 25° C. with a weight of 100 grams for 5 seconds; penetration at 46° C. with a weight f 50 grams for 5 seconds. When the penetration of a material is mentioned without eference to temperature, weight of the load, or time, it is understood that reference is nade to the penetration at normal temperature of 25° C. (77° F.) with a weight of 100 rams for 5 seconds. The unit of penetration is 0.1 mm. In literature and specifications he penetration is referred to in terms of the above unit either as a penetration of 6.4 nm or 64.

Ductility. In the ductility test a briquette of the material is formed in a standard briquette mold. The briquette with clips attached is placed in a ductility testing machine filled with water at a temperature of 4° C. or 25° C. The briquette is then pulled apart at a uniform rate and the distance in centimeters registered at the time of rupture of the thread of bituminous material is taken as the measure of ductility.

Fixt Carbon. Fixt carbon is the organic matter of the residual coke obtained upon burning hydrocarbon products in a covered vessel in the absence of free oxygen.

Paraffin. One hundred grams of the material is distilled rapidly in a retort to a dry coke. Five grams of the distillate is then thoroly mixt in a 60 cu cm flask with 25 cu cm of Squibbs' absolute ether. Twenty-five cu cm of Squibbs' absolute alcohol is then added, and the flask packed closely in a freezing mixture of finely crusht ice and salt for at least 30 minutes. The precipitate is filtered out quickly with a suction pump, using a No. 575 C. S. and S. 9 cm hardened filter paper. The flask and precipitate is then rinsed and washed with a mixture of equal parts of Squibbs' alcohol and ether cooled to − 17° C. (1° F.) until free from oil. When sucked dry, the filter paper is removed and the waxy precipitate transferred to a small glass disk and evaporated on a steam bath. The residue (paraffin) remaining on the disk is weighed, and from this weight the percentage on the original 5-gram sample is calculated.

Extraction of Bitumen from Bituminous Aggregates. The aggregate is prepared for analysis by heating it in an enamel-ware pan on a hot plate until it is sufficiently soft to be thoroly disintegrated by means of a large spoon. The disintegrated aggregate is then allowed to cool, after which a sufficient amount is taken to yield on extraction from 50 to 60 grams of bitumen. It is then placed in a mechanical extractor and carbon disulphide poured into the receptacle containing the aggregate. After allowing the material to digest for a few minutes, the machine is started, slowly at first in order to permit the aggregate to distribute uniformly. The speed is then increased sufficiently to cause the dissolved bitumen to flow from the receptacle. When the first charge has drained, the machine is stopt and a fresh portion of disulphide is added. This operation is repeated from four to six times until the liquid flowing from the receptacle is clear. After the aggregate is thoroly dried, it is weighed. The difference between this weight and the original weight taken shows the amount of bitumen extracted.

FOUNDATIONS AND DRAINAGE

8. Subdrainage

Object. It is of the utmost importance that the natural foundation of a road should be kept dry in order to provide a firm and unyielding support. This can only be accomplished by subdrainage in certain instances. If the subdrainage system is correctly designed it may serve to lower the level of the ground water and thus allow the ground to dry out; to remove water which is prevented from flowing off by an impervious stratum which underlies the road surface; to remove water which is always present in a road when the latter is thawing; to reduce the injurious action of frost by removing the moisture from the road; and to intercept water before it reaches the roadbed.

Porous Tile and Vitrified Pipe are used for this purpose. The pipes are cylindrical in shape and are manufactured in 1-ft or 2-ft lengths with varying diameters. The porous tile pipe is made with plain ends, while the vitrified pipe is provided with a bell end. It is good practise not to use a size smaller than 4 or 5 inches in diameter. Where a large quantity of water is expected, if its amount is known, the size of pipe may be determined by one of the well-known formulas for flow of water thru pipes.

The pipes should be laid in a properly constructed trench. The bottom of the trench should be covered with a layer of small-sized gravel or broken stone passing a ½-in screen. The pipe is laid in the trench with open joints, or with the

joints protected with small strips of burlap, and is then covered for a depth of about 1 ft with a material of a size similar to that used in the bottom. The rest of the trench is then filled with large size broken stone. The filling should be carefully tamped around the pipe. Where a pipe with a bell end is used, the bell is placed toward the high end of the trench. On macadam roads it is customary to lay the side drains at a distance of from 1 to 2 ft beyond the edge of the stone. The pipes are generally placed at a depth of from 2½ to 4 ft, and are usually laid to the grade of the road, but with a minimum of 2 in in 100 ft. The outlet end of the pipe should be protected by a small headwall of boulders to prevent the washing out of the pipe at this end. Whether a line of pipe is needed on one or both sides of the road is a matter of judgment. On side-hill work one line of pipe on the uphill side will generally serve. In constructing a road thru broad, flat, wet places, one line of pipe at the side of the road may not be sufficient, and a line on each side of the road will be necessary. Thru cuts two lines are sometimes specified. In streets tile drains should be laid under grass parkings, or, if such do not exist, under the gutters. For sizes of tile pipe under street pavements see Folwell's Sewerage, pp. 44–73. The 1915 cost, f o b factory, per foot for carload lots of small size pipe, either vitrified or porous tile, was approximately as follows: 4-in, 3 cents; 5-in, 4.6 cents; 6-in, 5.8 cents; 8-in, 9.5 cents.

Capacity of Tile Drains in Cubic Feet per Minute

From Spalding's Roads and Pavements, 1911, p. 36

Slope per 100 Ft		Diameter of Pipe in Inches				
Inches	Feet	4	6	8	10	12
2	0.17	4.0	12.0	27.0	49.5	81
4	0.33	5.5	16.5	38.0	70.0	114
6	0.50	6.5	21.0	46.5	86.5	143
9	0.75	8.0	25.5	57.5	106.5	176
12	1.00	9.5	29.5	66.0	122.5	204
24	2.00	13.5	41.5	92.5	173.0	288
36	3.00	16.5	51.0	114.0	212.0	353
48	4.00	19.0	59.0	132.0	245.0	408
60	5.00	21.0	66.0	148.0	275.0	456

Box Drains may be used in place of pipe in localities where stone is available. They should never be built of wood.

Blind Drains. Subdrainage is sometimes accomplished by digging trenches either across or alongside the road, afterward filling them with stone. The depth and distance apart of the trenches will depend upon the conditions encountered.

The V-Drain Foundation of the Massachusetts Highway Commission has given very good satisfaction on poor subsoils. It is built by excavating the full width of the surfaced roadway from 6 to 8 in deeper at the sides and from 12 to 18 in deeper at the center than usual, thus producing a flattened V-shaped trough. This trench is filled with stone varying in size from ½ in to 12 in in longest dimensions. The large stones are placed at the bottom of the trench. The grade of the trench is parallel to the finished grade of the road. The water follows the trench to the low points, where it is led to the sides of the road by a culvert across the road.

Soil Treatment. In places where the soil is very poor and is a hindrance to drainage, an improvement can be made by excavating the soil for a certain

depth, depending upon conditions, and refilling with field stone, broken stone, or a good gravel.

9. Surface Drainage

Surface drainage is accomplished by giving the road or pavement surface a crown or transverse slope, which sheds the water to the side ditches or gutters. The ditches or gutters have a longitudinal grade which generally corresponds to the grade of the center of the road and the water is carried by them to the point where it is discharged. In this manner the flow of water is confined to a small area.

The Crown of the road or pavement is formed by the intersection of two planes or as a parabolic curve. At street intersections, the crown will have to be modified to fit the grades of the intersecting streets. On curves of main trunk highways the crown should consist of one plane sloping up from the inside edge of the curve. On streets that are bordered with curbs the elevations of which cannot be changed, a uniform slope both ways from the center of the road can be obtained in some cases by making one gutter deeper than the other. Frequently, however, it is necessary to use a different slope each side of the center.

Amount of Crown. The Special Committee on "Materials for Road Construction," Am. Soc. C. E., in 1918, recommended the following crowns:

Kind of Roadway	Inch to the Foot		Kind of Roadway	Inch to the Foot	
	Maximum	Minimum		Maximum	Minimum
Asphalt block	¼	⅛	Cement-concrete	⅜	¼
Bituminous surfaces	½	¼	Gravel	1	½
Bituminous concrete	½	¼	Sheet-asphalt	¼	⅛
Bituminous macadam	½	¼	Stone block	½	¼
Brick	⅜	⅛	Wood block	¼	⅛
Broken stone	¾	½			

Crown Formulas. The following formulas, originated by Mr. Andrew Rosewater, M. Am. Soc. C. E., give the crown for brick, stone-block and sheet asphalt pavements. Let C = crown of pavement in feet, W = distance between curbs in feet, and f = grade of street in feet per 100. For brick, stone-block, wood-block, and comprest European rock-asphalt, $C = W(100-4f)/6000$. For American sheet asphalt composed of sand and asphalt, or of comprest natural sand rock, $C = W(100-4f)/5000$. The formulas are based on the laws of the parabola, and the crown C is the total rise at the center above the pavement at the curb. The crown can be found for any other point by deducting from C an amount equal to C times the square of the distance, exprest as a fractional part of the half width, from the center to the point in question.

Ditches for country roads are made by either cutting out a trapezoidal-shaped section at the edge of the shoulder, or by a more gradual rounding off of the road at this point, giving a flatter and shallower ditch. The latter is preferable particularly if a road-scraper is used to any extent in the maintenance of the road. Ditches to be more effective should be given a good bottom slope and should be kept clean. The slope of the ditch is made the same as the grade of the road surface, except in some cases where the grade of the road surface is very slight.

Gutters. Cobblestone, brick and stone-block gutters are laid on steep grades where water may wash out the sides of the road. They are also commonly used on many city streets that are surfaced with macadam, bituminous macadam and bituminous concrete. Gutters are made from 1½ to 6 ft in width, and have the same slope as the road surface. It is better, however, to drop the center so as to form more of a trough section. Concrete curbs and gutters which are built on the spot are coming into more popular use. On streets surfaced with brick, stone-block, wood-block and sheet-asphalt pavements, the pavement is carried to the curb in most cases.

The Minimum Longitudinal Grade recommended by some engineers is 0.5%. If the road surface is kept in good repair and the water has a chance to run off at the sides, a flatter grade than 0.5% can be used.

Methods of Construction. During construction the shape of the surface may be obtained in four ways: by measuring from a string at grade which is stretched across and along the road at intervals; by blocks placed on the subgrade and each course; by using a board template corresponding to the curvature of the cross-section; and by a series of stakes set at intervals across the roadway. Where the cross-section is composed of two planes the string method is rapid and accurate. Where the cross-section is a parabolic arc, the board template or stakes are preferable.

10. Pipe Culverts

Capacity. The size of opening may be determined by formulas, or an estimate of the run-off of water may be made and a size of pipe designed to take care of this amount. If the required area calls for a size of pipe that either is too large to be used, or cannot be obtained, two or three lines of smaller pipes may be substituted for it. It is, however, inadvisable to use a pipe less than 12 inches diameter because a smaller pipe than this is liable to become choked up.

Loads. Culverts are required to support the weight of the material which covers them and the weight of any superimposed loads. They may also be subjected to severe expansive forces caused by water freezing within. The latter, however, would be a very rare occurrence in a well-designed culvert. The amount of load carried to the culvert is indeterminate on account of the unknown action of earth pressure and the distribution of forces thru the same. The load reaching the culvert will have to be assumed. In using standard pipes of cast iron, corrugated metal, or vitrified clay, it is ordinarily not necessary to investigate their strength as far as load-carrying ability is concerned, since they have been used under sufficiently varying conditions to prove that they will resist successfully any load that they are likely to receive, provided the pipes are properly put in.

Construction. Pipe culverts of all types should be laid on a firm bedding. If the soil furnishes a very poor support, the pipes should be bedded in a layer of concrete or broken stone. This is more essential for culverts of vitrified pipe than for those made of the other materials. The trench should be excavated to the grade of the pipe. After the pipe is laid in the trench, good earth or small stone should be filled in around it and carefully tamped so that the pipe will be supported thruout its length. Headwalls should be constructed in every case. Concrete makes the best headwalls, since it is cheap, durable, and can be molded in any form desired. The headwall for small culverts are generally built parallel to the center line of the road, with a thickness of at least 12 in. The bottom of the headwall should be 18 in or more below the bottom of the pipe to prevent the water from flowing around the outside of the pipe and thus washing it out. The headwalls must be made long enough to keep the earth away from the pipe

With the larger-sized culverts it may be advisable under certain conditions to construct the headwalls with wing walls as would be done for an arch culvert, in which case the walls should be designed as retaining-wall sections.

Vitrified Pipes used for culverts should be the best quality salt-glazed sewer pipe of the double strength type, with socket joints. This pipe is made in 2-ft lengths with diameters from 12 to 36 in. The pipes are laid in the trench with the socket end toward the inlet, so as to have at least 15 in of material over the top of the pipe. The joints are sometimes filled with cement. Under conditions ordinarily encountered in highway work vitrified pipe makes a very satisfactory as well as a cheap culvert. During 1911 the approximate costs per foot in less than carload lots were: 12-in, 35 cents; 15-in, 47 cents; 18-in, 66 cents; 20-in, 79 cents; 22-in, $1.05; 24-in, $1.15; 27-in, $1.58; 30-in, $1.93; 36-in, $2.45. The cost per linear foot of vitrified pipe culverts in place, as given by the Massachusetts Highway Commission, is approximately as follows: 12-in, 75 cents; 18-in, $1.50; 24-in, $2.50; 30-in, $3.75.

Cast-Iron Water Pipe with bell and spigot joints has been used in culvert construction for a long time. It is manufactured in 6-ft and 12-ft lengths, and hence is not so easily adaptable for use. It is very strong and will last for many years. This kind of pipe can be placed within 6 in of the road surface without danger of breaking. The principal objection to cast-iron pipe, outside of its cost, is its weight, which makes it expensive to handle. The cost will vary between 1.5 cents and 2 cents per lb. The weight per foot of heavy-weight pipe for some of the sizes from 12 to 72 inches diameter is as follows: 12-in, 85 lb; 18-in, 200 lb; 24-in, 300 lb; 36-in, 500 lb; 48-in, 850 lb; 60-in, 1250 lb; 72-in, 1750 lb. The cost per linear foot of cast-iron pipe culverts in place, as given by the Massachusetts Highway Commission, is approximately as follows: 12-in, $2.25; 18-in, $3.50.

Corrugated Metal Pipe is made in any length desired, ranging by multiples of 2 ft up to 36 ft or is made in nest sections that are later bolted together in the field. The pipe may be laid to within 6 in of the road surface. Since it weighs about one-twentieth as much as cast iron it is much more easily transported. The nest sections are of a particular advantage in this respect. Care should be taken to select pipes made of the proper kind of metal. Wrought iron is superior to steel as far as its non-corrosive properties are concerned, and hence pipes made of iron generally have a longer life. The non-uniformity of results obtained with metal culverts of different makes has been due almost entirely to the different kinds of material used in the manufacture. The approximate cost per linear foot of a few sizes of one type is as follows: 8-in, 54 cents; 12-in, 72 cents; 18-in, $1.04; 24-in, $1.44; 36-in, $2.84; 48-in, $4.14; 60-in, $5.18; 72-in, $6.29. The cost per linear foot of corrugated metal pipe culverts in place, as given in the 1910 Report of the State Highway Commissioner of Maine, is approximately as follows: 12-in, $1; 18-in, $1.40.

Concrete Pipes may be cast and laid as any other form of pipe. The joints are made tapering, or with some form of socket. The pipes are built in lengths of from 4 to 8 ft, with thicknesses varying from 2 to 6 in, depending upon the diameter. Concrete pipes weigh more than cast-iron pipes, but may be constructed so as to cost about one-fourth as much. In the case of concrete pipes constructed in place, the use of reinforcement will not be economical until they exceed 4 ft in diameter.

Special Forms. There are several types of special forms of culverts manufactured of cast iron, all of which are cheaper and more easily handled than the ordinary cast-iron water pipe.

11. Foundations

The loads due to traffic are transmitted by the wearing surface to the foundation. If the foundation fails, the pavement or surface above it will fail. The kind of foundation and its thickness depend upon the amount of traffic, and the nature of the underlying subsoil.

The Different Materials Used as a foundation are the subsoil encountered, gravel, broken stone, slag, broken brick, hydraulic cement concrete, bituminous macadam and bituminous concrete, and old pavements. When a poor subsoil is encountered, the poor material should be excavated for a depth of several inches and refilled with a good gravel. Sandy subsoils may be improved by the addition of clay, and clayey soils by the addition of sand.

Broken Stone. The lower course of a macadam road, when the latter is built in two courses, is the foundation for the upper or wearing course. Ordinarily this course is about 6 in in depth after compaction. Where the subsoil is poor or the road is subjected to heavy traffic, or it is desired to aid the subdrainage of the road, the lower course should be increased in thickness, or an additional layer of broken stone should be used. This extra layer varies from 3 to 10 inches in thickness, and is composed of the larger-sized products of the crusher. Instead of this layer of broken stone, a telford base is sometimes constructed, which consists of placing by hand stones broken into sizes 6 to 8 inches deep, 3 to 8 wide, and 6 to 15 long. The stones are placed on edge with their longest dimensions at right angles to the axis of the road. The spaces between the stones are filled with spawls, after which the whole surface is thoroly rolled. Large stones laid flat instead of on edge are sometimes substituted for telford. The cost of either a broken stone or a telford base depends upon the amount of stone used. A telford base as described above has cost about 35 cents per sq yd. Slag and brickbats, where available, can be used in place of broken stone. Gravel foundations are usually laid 6 to 8 in in thickness.

Cement-Concrete foundations should ordinarily be used under all types of stone block, wood block, brick, sheet asphalt, and bituminous concrete pavements. The thickness of the concrete foundation varies from 4 to 8 in, 6 in usually being employed. An 8-in foundation is necessary when the traffic is exceptionally heavy. The usual proportions of the cement, fine aggregate and coarse aggregate varies from 1 : 2 : 5 to 1 : 3½ : 7. Whenever a concrete foundation is constructed, traffic should be kept from it for 7 to 10 days in order to allow it to set up thoroly. Concrete is manufactured by three methods: mixing, *in situ*, and grouting.

Mixing methods. The proportions having been adopted, the various ingredients are measured out by volume and mixed together with water until the desired consistency is obtained. The concrete thus mixt is placed upon the prepared roadbed to the required thickness. The concrete is then tamped and smoothed with the backs of shovels until the free mortar rises to the surface. In pavements where a layer of some kind of material is interposed between the surface of the foundation and the wearing coarse material, any very slight irregularities in the surface of the foundation will not cause trouble. When a smooth surface is required the concrete should be struck with a template. Altho hand mixing is used, usually mixing machines of the batch or continuous type are employed.

The *in situ* method consists of spreading and rolling a layer of broken stone of the required thickness in a manner similar to the construction of the bottom course of an ordinary broken stone road. A 1 : 3 mixture of cement and sand in a dry state is spread over the surface and swept into the voids. The surface

is flushed with water, rolled, and more dry mortar spread during flushing and rolling until all voids are filled.

In the grouting method, a layer of broken stone, of sufficient depth to make the requisite thickness of concrete, is deposited on the subgrade. The layer is thoroly rolled and is then poured with a 1 : 4 grout. The grouting and rolling are continued until the voids in the stone layer are filled.

Bituminous Macadam and Bituminous Concrete foundations are frequently used under sheet asphalt and certain types of bituminous concrete pavements. They should be used with caution, since they are not as stable as hydraulic cement foundations, and since the economical use of the wearing surfaces of sheet asphalt and certain types of bituminous concrete usually implies a traffic which requires first-class foundations. With a firm natural foundation allowing thoro compaction, good results have been secured.

Old Pavements of brick, cobble and stone block have been used as foundations for asphalt pavements. Where the old surface is firm and unyielding, this method has given fair satisfaction, but where the original surface was very uneven and required much relaying of the brick or stone, or filling of depressions, the resulting surface has not been satisfactory. Old macadam surfaces have also been made to serve as a foundation for asphalt and other bituminous pavements.

Rough Stone foundation in Connecticut, according to C. J. Bennett, consists of a depth of from 12 to 18 in of rough stone laid on the subgrade of the road with frequent outlets to water courses and without great regard to the uniformity of the sizes of the stones themselves. This method should be used in the building of roads thru clayey material, which is liable to become saturated and flow, and should be extended beyond the edge of the roadway surface proper.

ROADS

12. Earth and Gravel Roads

A large percentage of roads in this country are constructed of earth, and these roads will have to be maintained as earth roads for many years to come. An earth road will be defined as one built of native soil, other than gravel. A gravel road will be defined as one built of gravel. Gravel roads are used to a large extent in the construction of park roads and on many of the State, county and town highway systems, where good material is available and the traffic is not very heavy.

Characteristics. Since earth roads may be constructed out of any kind of soil, it is difficult to compare their characteristics. Soils act differently under different conditions. Sand makes the best road in wet weather, and clay a very poor one. All soils contain more or less of each of these materials, so that it is quite customary to find earth roads very dusty in dry weather, and muddy in wet weather. They are, however, the most inexpensive type to build, and under proper maintenance, can be kept in fair and passable condition at a very small cost, provided the traffic is not excessive for this type of road. A gravel road is cheap, fairly durable, noiseless, and offers good foothold for traffic. On the other hand, a gravel road is dusty in dry weather, and muddy during continued wet weather, or when frost is coming out of the ground.

Construction of Earth Roads. Good drainage is an absolute necessity in the construction of earth roads. Proper subdrainage and surface drainage must be provided. In providing for surface drainage the slopes from the center to

the sides should not be made too steep; a slope of from ¾ in to 1 in per ft is used, the latter being a maximum. The surface of the road may be made to conform to the arc of a circle or may be made up of two planes meeting at the center and sloping to the ditches. Care should be taken in constructing the ditches to see that they have sufficient fall to carry the water away. In places where the country is flat and the work involved is simply that of giving a crown to the road, earth roads may be constructed most economically by means of road scrapers or graders. If the soil is not too compact, the use of the plow could be done away with in using the road grader. The latter is usually worked by beginning at the sides, going down one side and back the other, gradually approaching the center, the blade being so adjusted as to plow to the proper depth, and move the earth up from the sides toward the center. The material deposited by the grader is sometimes harrowed and then rolled; when rolling is not resorted to, the material is left to be packed down by traffic. Care must be taken to spread the material evenly and in layers usually recommended not to be over 6 in deep. Where much grading is involved, the bulk of the work will have to be done by the common methods of earth excavation, the road grader being used to finish the road to the desired surface. Among the tools used in the construction of earth roads are drag scrapers, wheel scrapers, buck scrapers, road scrapers, elevating graders, plows and wagons.

Some specifications require that in the construction of any embankment less than 2 ft deep, the old surface shall be broken up and all sod and vegetable matter removed from the area to be occupied by the road, and that no sod will be allowed to be placed in the embankment nearer than 4 ft from the edge of the pavement.

Sand-Clay Roads are constructed somewhat differently, depending upon whether the subsoil is of sand or of clay. The amount of clay necessary is that amount which will just fill the voids in the sand. It will also depend upon the character of both the sand and the clay. It may be approximately determined by finding the quantity of water which is contained in a known volume of sand, the amount of water representing the percentage of voids. Proper drainage must always be provided. The construction of a sand-clay road is a slow process, and the best results can only be obtained by giving the road constant attention for some time after it is first finished.

If a sand-clay road is to be constructed of a sandy subsoil, the road bed is shaped up to the desired crown. The clay is brought onto the road and spread in a layer of 6 to 8 in at the center, tapering off to a thin layer at the sides. If construction is begun at the end of the road near the source of supply of the clay, the road will be somewhat compacted during construction by the teams on the work. It is necessary that the clay be thoroly mixt with the sand. All lumps should be broken up. Altho in many cases this clay layer can be covered with sand and left for the traffic to mix and compact, quicker and better results can be obtained by plowing, harrowing and rolling. Water is necessary to puddle the clay, hence it may be necessary to harrow and further mix the materials soon after or during rainy weather. More sand or more clay may be required in places where the road tends either to be sticky or to pulverize. The surface should be kept in shape by means of road drags or road scrapers.

Maine 1918 State Highway Commission Specifications for construction of sand-clay roads are, in part, as follows:

"Sand and clay shall be furnished by the contractor from sources approved by the engineer. Sand shall be composed of hard, sharp, angular particles, at least 50% of the volume of which, by dry weight, shall be retained on a 50-mesh sieve. Rounded grains of sand will not be accepted. If plastic clay is used it shall be placed upon the road in pieces not larger than 3 in in size. Slaking clay shall be placed in pieces not larger than 6 in in size.

"Sand Subsoil. Wherever the subsoil is sand, 6 in of clay shall be uniformly spread over the surface to a width of 16 ft, unless otherwise directed by the engineer. Each

load of clay should be spread uniformly as soon as deposited and before being driven over. Immediately after the clay is spread it should be covered with a layer of clean sand 6 in in depth unless otherwise directed by the engineer, and shall then be deeply plowed with a heavy plow until all lumps are thoroly broken up and the clay and sand are thoroly mixt to a depth of 14 to 16 in as directed by the engineer.

"Clay Subsoil. Wherever the subsoil is clay, 8 in of sand shall be uniformly spread over the surface to a width of 16 ft unless otherwise directed by the engineer, and on this layer of sand 4 in of clay shall be uniformly spread and then deeply plowed with a heavy plow as above specified to a depth of 14 to 16 in as directed by the engineer."

The Maintenance of Earth Roads consists principally in keeping the surface shaped up and the ditches cleaned out so that the water will not have any chance to stand either in the road or at the sides. Water, if it has a chance to soak into the road, soon softens it to such an extent that it is easily cut up by the action of traffic and is soon destroyed. Two of the most useful tools for the maintenance of earth roads are the road scraper and road drag. There are many different types of these machines. The road drag, which is the simplest, consists of two blades about 7 to 9 ft long set parallel to each other about 30 inches apart. The blades may be made of steel, of plank, or of split logs. This device is so hitched to the team that it may be dragged along the road at an angle at about 45 degrees with the axis of the road. Work with the drag scraper is done in a similar manner as with the road scraper; namely, starting in at the side of the road and working up toward the center. Dragging may be done at all seasons, but should be carried on only after a rain when the road is in a moist condition. If the road is properly drained it will be found that the surface can be kept in excellent condition by the use of the road drag or road scraper at frequent intervals.

The Cost of Earth Roads is an extremely variable quantity, since it depends upon the width and the number of cubic yards involved in the grading. The cost of 10 sand-clay roads built in various sections of the country during the years from 1914 to 1916 under the direction of the U. S. Bureau of Public Roads, ranged from 4 cents to 23 cents per sq yd, with an average of 13 cents. This cost does not include the bulk of the grading, but does cover the construction of the sand-clay surface.

Burnt Clay Roads have been constructed to a limited extent in some of the Southern States where the soil encountered is mainly a plastic, sticky clay known as "gumbo," and the fuel is abundant and cheap. The road is first plowed and graded. Furrows are then dug across the road 4 ft apart for the full width of the roadway. Cord wood is laid across the ridges of these furrows, forming a floor on which is placed more cord wood, built up in a crib formation. The clay is packed on this wood. Successive layers of clay and cord wood are built up in a similar manner until three layers are obtained. The top layer of clay should not be less than 6 to 8 inches thick, and should be tamped and rounded off so as to keep the heat within the flues. The process of burning changes the gumbo to a light clinker which combines well with the plastic clay of the remainder of the road.

Gravel Roads may be constructed in several ways. The road bed should always be well drained and shaped to the desired crown. In one method, the gravel as it comes from the pit or bank is placed at the side of the road or on dumping boards on the road, and spread to the desired depth on this prepared surface. Care should be taken to make the distribution of fine and coarse particles as even as possible the coarser particles being placed in the bottom. The thickness of the gravel at the center is generally more than it is at the sides. The gravel, after it is spread to the desired surface, is thoroly rolled and compacted. A better form of construction is to build a gravel surface in a shallow trench in a manner similar to that used in building broken stone roads. The

subgrade is formed with shoulders to the desired cross-section, which is the same as that of the finished surface. The gravel is spread on this surface in two or three layers, which are each individually rolled. The thickness of the separate courses varies, but the total thickness is about 8 in at the center, and is decreased to about 6 at the sides. In constructing any road with a gravel surface water should be used to help the consolidation of the surface, but care should be taken not to use an excess of water, since it may wash out the binding material or soften the subgrade. Whether or not the gravel should be screened before being placed in the road depends upon the character of the gravel in the bank or the pit. Some gravels have a very uniform composition, while others vary so much that they must be screened in order to produce the best results in the road surface.

Specifications require that no sod, vegetable soil or strippings be mixt with the gravel. Also in many cases that not more than 25% shall be binding material. For road work in Maine, gravel is specified to contain not less than 75% of pebbles that will be retained on a sieve of ⅛-in mesh and pass thru a sieve of either 1½ or 2 inches mesh, depending upon the size required. Some specifications require that the gravel be graded into three or four sizes similar to those generally specified for broken stone for road construction. In this latter case the gravel surface should be constructed exactly the same as one of broken stone.

American Society for Municipal Improvements 1918 Specifications covering quality and sizes of gravel are as follows: "All gravel shall be hard and tough. Gravel which contains over 10% of disintegrated stone shall not be used. No. 1 product (for 2-in top course) shall consist of a mixture of gravel, sand and clay, with the proportions of the various sizes as follows: All to pass a 1½-in screen and to have at least 60 and not more than 75% retained on a ¼-in screen; at least 25 and not more than 75% of the total coarse aggregate, material over ¼ in in size, to be retained on a ¾-in screen; at least 65 and not more than 85% of the total fine aggregate, material under ¼ in in size, to be retained on a 200-mesh sieve. No. 2 product (for middle and bottom courses 3 in each) shall consist of a mixture of gravel, sand and clay, with the proportions of the various sizes as follows: All to pass a 2½-in screen and to have at least 60 and not more than 75% retained on a ¼-in screen; at least 25 and not more than 75% of the total coarse aggregate to be retained on a 1-in screen; at least 65 and not more than 85% of the total fine aggregate to be retained on a 200-mesh sieve."

Maintenance of Gravel Roads. All ruts and pot holes should be filled up as soon as formed with gravel as near the same size as possible as that used in the surface. Water, if allowed to soak into a gravel surface, will soften it and cause its rapid deterioration. The intelligent use of the road drag and road scraper will do much toward keeping a gravel surface in good condition. In resurfacing a gravel road with gravel better compaction will be obtained if thin layers of gravel are put on frequently rather than thick layers not so often.

The Cost of a Gravel Surface varies from about $1 to $1.50 per cu yd in place. The highest price includes screening. The above prices do not include cost of grading old surface.

13. Broken Stone Roads

Characteristics. An ordinary macadam road, if properly built of the right kind of stone, is a very economical and satisfactory surface for medium horse-drawn vehicle traffic. It affords an excellent foothold, is noiseless, does not offer much resistance to traffic, and is comfortable to use. In dry weather, however, a macadam surface is extremely dusty unless the surface is treated with a palliative or coated with bituminous material.

Foundation and Subgrade. The lower or foundation course of a macadam road may be strengthened by a telford base, a V-drain foundation, or by increasing its thickness. The construction of telford and V-drain foundations has

been described in Art. 11. When traffic and soil conditions are favorable, however, it is customary to build the foundation course directly upon the subgrade. The subgrade is a shallow trench composed of two or more planes or a curved surface sloping from the center to the sides of the road. The trench is the same width as the broken stone surface. The sides of the trench are formed by the earth shoulders, generally 3 to 5 ft wide. The subgrade should be brought to true line and grade and be thoroly compacted with a steam roller. Any low spots which appear during compaction should be brought up to grade with good material and rerolled.

Size of Stone. Broken stone roads are ordinarily built in three courses. The sizes of stone and the materials used vary in different specifications. For the first or foundation course the size of the stone is often from 1 to 3 inches in longest dimensions, while sometimes it is specified as from 1¼ to 2½ in. Gravel and slag are sometimes substituted for broken stone in the foundation course. The second course is composed of stone ranging from 1 to 2 inches, or from ½ to 1¼ inches in longest dimensions. The top course consists of screenings varying from ½ in down to dust. Since nearly all of the broken stone used for road construction is screened through a rotary screen, it should be noted that the speed at which the screen is revolved, the pitch, the length and the size of holes in the screen all influence the grading of the stone into different sizes. The sizes of stone as specified in some of the different States are as follows:

State	Foundation Course	Upper Course
Massachusetts	1¼ to 2½ in	½ to 1¼ in.
New Jersey	2½-in stone or stone that will pass a 3-in ring, minimum length 2 in	1½-in stone or stone that will pass a 2-in ring, maximum length 2 in, minimum length 1 in.
New York	2¼ to 3¼ in	1¼ to 2¼ in.
Maryland	2½ to 1 in, maximum length 2½ in.	1 to 2 in, maximum length 2 in.

Laying the Stone. Some engineers advocate laying the larger stone on top of the smaller in cases where the stone is low in hardness and toughness and is liable to be crusht during rolling. Large stones in the surface wear longer than smaller ones, but more rolling is required to secure a smooth surface. In foreign practise larger sizes are used than is the custom in this country. To gage the thickness of a layer, wood cubes of a depth equal to the thickness of the layer are sometimes placed at intervals in the roadway and the stone is filled in to the tops of them. Another method of obtaining the same result is to set longitudinal strings at the proper elevation at the sides and center of the roadway. Stone for the foundation course, if brought in patent-bottom dump-wagons, may be dumped directly upon the subgrade and spread with stone forks or with a stone spreading machine. Stone brought to the work for the second course should be dumped on boards and shoveled from there to the road to prevent the segregation of sizes which might occur if the stone was dumped directly upon the road from the wagons.

Rolling. The first and second courses are each laid to the required thickness and separately rolled, being sprinkled with water to aid compaction if necessary before the next course is placed. The roller used in compacting this material should be at least 10 short tons in weight. The process of rolling should be to begin at one edge of the roadway, roll longitudinally and work toward the center. After reaching the middle of the road, the roller should pass to the other side, again roll longitudinally, and work toward the center. This manner of rolling keeps the road in shape and prevents either pushing the crown out of line or flattening it. Careful rolling is absolutely necessary in order to obtain a good shape to the road surface. Steam or gasoline rollers always should be

used as horse-driven rollers are not sufficiently heavy to properly compact broken stone. Usually 12 to 18-ton rollers should be used for hard, tough rock, and 10 to 12-ton rollers for soft stone.

It is stated in some specifications that the voids in the foundation course be filled with stone screenings, sand or gravel, the binding material to be thoroly swept in and rolled. No surplus material, however, is allowed to remain on the surface of the foundation course. This method of construction provides a firmer foundation than where the voids between the stones are not packed. This same treatment is also frequently used to facilitate the rolling of the foundation course, where the stone is of such a nature that it will not readily compact under the action of the roller without the addition of some mineral binder. If in the first passage of the roller over the surface any low spots are detected, they should be immediately brought to the proper level by the addition of more stone of the same sizes as are used in that course, before further compaction takes place.

Applying Screenings. Having finished and rolled the second course as above described, the surface is covered with a layer of stone screenings and thoroly sprinkled with water in order to fill the voids in the stone with the screenings. More screenings are added as desired and rolling is continued, the surface being sprinkled in front of the roller. When the proper amount of water and screenings have been used, a wave of grout will be pushed along in front of the roller. A coating of screenings should be left over the entire surface, no more being used than is necessary to cover the stone. The stone screenings resulting from the crushing of the rock with which the first two courses are built are generally used for the binder. When this material is unsuitable for this purpose, clay, loam, sand, or screenings of a different rock are substituted for it.

The Thickness of the Courses varies in different specifications, and is governed by the amount of traffic which the road is to receive, and the condition of the subgrade. Common values are 4, 6, and 8 in in total thickness after rolling, where the subgrade furnishes a good support. The upper course is from 2 to 3 in in thickness after rolling. In some States the stone surfacing is the same thickness thruout its width, while in others the thickness is reduced at the sides from 1 to 2 in.

Maintenance. Water, if allowed to stand on a macadam surface, will soften the latter and cause it to wear out rapidly. When the frost is coming out of the ground the surface will also be in a soft condition and require attention. Thoro surface and under drainage is just as essential as it is in the case of an earth or gravel surface. The effect of horses' feet is most frequently observed in the formation of the "horse-path" so-called at the center of the road. If the surface is given a flat crown this will be prevented to some extent, since it will tend to make the traffic use the entire width of surface. The grinding action of the wheels wears the stone and forms dust which, when in a dry state, is swept away by the wind, thus leaving the stone in the top course exposed. The action of traffic will then displace the stone in the surface, and "raveling" results. A heavy traffic of motor-cars traveling at high speed will cause a macadam surface to ravel very quickly when the mosaic of the upper course is exposed. Tracking of traffic will concentrate the wear on the surface and form ruts. This action is particularly disastrous when the road is in a soft condition. To maintain the surface under the above conditions, the side ditches should be kept clear, ruts and pot-holes should be filled up with stone, and the whole surface kept in as perfect shape as possible to facilitate the shedding of water. Sand, stone screenings, or other binding material should be spread on the surface, where lacking, in order to prevent raveling. Two systems of maintenance are in vogue, namely, the continuous and periodic. The continuous method is to repair the surface constantly so that it is always kept in good condition. In maintaining a road by the periodic method, the top surface is allowed to practically wear out and is then resurfaced. A scarifier is especially advantageous

in breaking up the old surface of a macadam road to form a bond with any new stone that may be added. The work will be done better, quicker and at a smaller expense than in any other way.

Material Data. The weight of a cubic yard of broken stone depends upon the specific gravity of the stone and the percentage of voids in the mass. The weight of stone will vary approximately from 2200 lb to 3000 lb per cu yd, measured loose. It will take 1.5 cu yd of broken stone of the ordinary sizes measured loose to make 1 cu yd compacted in place.

The Cost of a Macadam Road per square yard varies with the thickness. The cost per cubic yard of stone compacted in place varies between \$2.50 and \$6. An average cost is \$4.50. The average cost per sq yd, thickness 8 in, is \$1.00.

Slag Roads. Blast furnace slags are produced in the manufacture of iron and steel, and, in some cases, are very similar in appearance to close-grained igneous rocks. In some cases, blast furnace slag may be excavated from slag banks by means of a steam-shovel, which serves to sufficiently break up the material so that it may be screened. The slag from the open-hearth process is generally run into molds. Usually it is broken up in a rock crusher into sizes suitable for road work. The methods used in building slag roads are similar to those described for the construction of broken stone roads.

Shell Roads. The State of Maryland has built many miles of oyster shell roads along the eastern shore of Chesapeake Bay.

Maryland State Roads Commission Specifications stipulate that the subgrade shall be firm and well rolled. The depth of the first course of shells is either 5 in or 5 in at the center and 3 in at the sides. The depth of the second course is either 3 in or 5 in at the center and 3 in at the sides. The shells are spread upon the roadbed with shovels from piles along the road or from a dumping board. They are rolled with an 8-ton roller and are sprinkled with water or bound with sand during the process of rolling until the surface is firmly compacted. The third course is composed of clean, sharp sand, spread just thick enough to cover the second course after the latter has been thoroly compacted. Shell roads cost from 40 to 50 cents per sq yd.

14. Dust Prevention by Palliatives

Classification. Dust preventives, which may be classified as palliatives requiring application with more or less frequency, include water, calcium chloride, salt solutions, tar and oil emulsions, and certain light oils and tars. Palliatives are more especially adapted for urban and suburban districts, for parkways, and for use on highways before races, festivals and processions.

Water is the oldest and most common palliative, its binding power consisting solely in the mechanical bond produced, which varies to great extent with different rocks. The best practice stipulates careful regulation of flow, varying with type of surface, and application one to four times per day, depending on climate, temperature and local conditions.

Horse-drawn carts are equipped with two types of sprinkling devices, one discharging vertically, the other horizontally. For use on pavements, the vertically discharging valves are preferable, as they are easily manipulated to avoid damage to pedestrians, and the action of the water flushes the dust to the gutters without damage to pavements. The vertical discharge has a destructive effect on waterbound broken stone or gravel surfaces, hence horizontal discharge valves should be used.

Sea Water has been tried in a number of instances, being applied with the ordinary water-cart. In one instance it was found that in dry weather it formed a hard, salty scale, while in wet weather the mud contained so much salt that it injured the iron and varnish of vehicles.

Calcium Chloride in granulated form is shipped in airtight steel drums. When applied dry to the road surface, a special distributing apparatus should be employed. (Cost of 1-horse machine with spread of 5 ft, $55, 2-horse machine with spread of 10 ft, $70.) About 1½ lb should be used for an application per square yard. Usually two applications per season in the North will give good results. When applied wet, it is recommended that the calcium chloride should be dissolved at the rate of 1 lb to 1 gal of water, using about ⅓ gal solution per sq yd. For the application of solution ordinary watering-carts are generally used. The usual method is to distribute in two applications along the center of the street and one at the sides. To secure freedom from dust, about ten applications should be used per season in Northern States.

Judges' 1909 and 1910 Reports, The Roads Improvement Association, state that: "We are of opinion that the results of the tests of calcium chloride applied in granular form by the 'dry' method have shown that it is a very effective dust layer; that the treatment has the ill effects of causing, during the winter months, an abnormal quantity of sticky mud, a decided tendency to licking up, and a disintegrating action upon the macadam surface."

Oil Emulsions are made by the addition of some saponifying agent to water which, forming a chemical solution, renders it readily miscible with the oil. They sometimes contain a deliquescent material as an aid in retaining moisture. Their use is common where a light palliative is sought. Alkaline such as potash, soda, ammonia, crude carbolic acid, and various soap solutions are the mediums most commonly used with asphaltic or paraffin oils. Among the numerous processes are: casein added to tar oil; water lyes from wood-pulp factories; fat or grease from wool scourings, emulsified with either deliquescent salt solutions or creosote; an oil emulsion containing a deliquescent salt; waste sulphite cellulose liquor; waste-molasses solutions; and mixtures of saccharine and lime. Tar emulsions are used to a small extent in this country. Distribution is usually made with an ordinary watering-cart on the unprepared surface, altho better results may be obtained by using some type of pressure distributor. In one place a light sand coat was added, but as a rule the surface is left uncovered. A typical emulsion (Wickes) consists of 5% resin soap added to 30% water at 50 degrees Cent. The mixture is thoroly agitated and 65% oil added. A 20% solution mixed at 32 degrees Cent was first used, and for retreatments 5 to 10% solution (see Trans. Am. Soc. C. E., vol. 73). In Boston a 16% solution was first used with 5 to 10% solution for retreatments. Other reports give 5 to 25% solutions, the latter figures being for first application, and the former for retreatments. Applications vary from one to four weeks, according to requirements, generally using about 0.5 gal of material per sq yd.

Light Oils and Tars are generally palliatives. Belonging to this class are vegetable oils, paraffin and asphaltic petroleums, certain tar oils, and the heavy dead or creosote oils. There is sometimes enough binding base to cement the particles, and such materials are preferable, as a number of applications result in an accumulation of binding material at the end of a season. They are fairly efficient, but should not be applied in too great an amount, as a soft greasy surface will result. Heavy rains may either cause washing or an oily, disagreeable mud and pools of oily water. Light coal-gas and water-gas tars have proved satisfactory for use as palliatives. Prior to application of a tar all dirt and surplus dust should be removed by light brushing over the roadway surface with hand brushes or machine sweepers. The materials are usually applied cold. Pressure distributors should be used in order to secure uniform application of a small amount of the material. Two to four applications per season are usual, altho in some instances one coat has lasted for the entire season.

Costs. Watering in Boston (1907) three coats per day for 148 days, was 2.37 cents per sq yd; in 1909, 2.1 cents; East Orange, 2.8 cents per sq yd. Whinery states that 20 to 70 gal of water will cover one season's treatment, and ought not to exceed 3 cents per sq yd for the season. Calcium chloride: Metropolitan Park Commission, Mass., season 1908, 2.5 cents per sq yd; 1909, 1.8 cents; 1910, 3 cents; Pennsylvania, 3 to 4 cents; City of Boston, 1.6 to 4.2 cents; District of Columbia, 2.1 cents. Oil emulsions in numerous American cities (1908 to 1910) ranged from 1.25 to 3.8 cents per sq yd (average, 2 cents for the season). Light oiling is about 3 to 4 cents per sq yd for the season, using from 0.3 to 0.4 gal of material per sq. yd. Treatment with a light tar was from 2.4 to 5 cents per sq yd for the season.

15. Bituminous Surfaces

Bituminous surfaces are used principally on macadam and gravel roads, on bituminous and concrete pavements, and occasionally on brick and wood-block pavements. The different kinds of bituminous materials used are asphaltic oils, cut-back asphalts, refined water-gas tars, refined coal-gas tars, combinations of refined tars, and combinations of refined tars and asphalts.

Characteristics. A bituminous surface renders a road more durable. The ease of traction and foothold are closely connected and depend upon the character and amount of the bituminous material used. Certain materials may increase the traction and offer a good foothold, while the use of others may result in a surface that has about the same characteristics in regard to these two points as asphalt pavement. The surface can usually be easily cleaned. About the same amount of noise will result as is characteristic of a wood-block pavement when asphaltic materials are used. The surface is practically impervious, yields no dust, and is comfortable to use.

Preparation of Road Surface. Before constructing a bituminous surface on a macadam road all depressions, pot-holes, ruts or other irregularities should be carefully repaired by filling the same with bituminous coated stone so that the whole road surface is even. All surplus dust should be removed from the surface by the use of horse sweepers or fine bass brooms, or both, so that the surface of the stones in the upper course is exposed. When the application is made, the surface should be bone-dry. When certain asphaltic materials are used, however, if the surface is slightly damp when the material is applied better results may ensue in obtaining a more even distribution of the material. The road should be closed to traffic during the progress of the work, or if this is impossible, half of the width should be done at one time. Work should be done only on pleasant days.

The Application of the Bituminous Material may be accomplished in a variety of ways, as follows: by hand-pouring cans; by hand-drawn distributors; by pressure tanks to which is attached flexible hose, provided with one or more nozzles; by gravity distributors; by pressure distributors. It is difficult to secure uniform distribution with hand-pouring cans unless the material is brushed after application. The same objection is true of distribution with pressure hose. The selection of either of the last two types of machines will depend upon the nature and amount of material used and local conditions. The uniform distribution of material is accomplished in some cases by hand-brooming or squeegeeing after application by gravity distributors, or by brushes attached to the distributors. Bituminous material suitable for this class of work should set up under average climatic conditions so that tracking is not noticeable in from 36 to 72 hr. Many types of refined tars, combinations of refined tars and asphalts, and certain types of heavy asphaltic materials possess this property.

The Amount of Bituminous Material used per square yard will depend somewhat upon the condition of the surface, but as a general rule from 0.25

to 0.5 gal is used in one treatment. If it is necessary to allow traffic on the road at once, the coat of bituminous material should be covered with a coarse sand, gravel, or screened stone chips varying from 1/8 in to 1/2 in in longest dimensions. The amount of sand, screened stone chips, or gravel used per square yard will depend upon the quantity and nature of the bituminous material. From 5 to 22 lb per sq yd have been used. The coat is improved by rolling. When heavy asphaltic oils are used the covering of mineral matter is an absolute necessity. With some grades of tar, however, satisfactory results have been obtained by omitting the covering of mineral matter. This practice is common in some sections of England where the traffic can be kept from the road until the tar has set up. Gravel roads may be treated in a similar manner except that it is not possible to clean the surface as thoroly as it is in the case of the broken stone roads.

Conclusions relative to Surface Treatments as included in the 1918 Report of the Committee on "Materials for Road Construction," Am. Soc. C. E., 1918, Transactions, page 1404.

"If the surface to be treated is a gravel, broken stone, slag, or other porous and non-bituminous crust, practise has proven that bituminous material of such consistency that it can be applied at a temperature below 52° C. (125° F.) is preferable to heavier material, and that on any crust the application of a quantity in excess of 1/2 gal per sq yd is inadvisable. It is advisable to apply the material in quantities not exceeding 1/4 gal per sq yd at a time. Heavier material in less quantity, however, should be used on bituminous roadways; otherwise there will be tendency toward an objectionable softening of the material previously used in the construction of the roadway.

"The surface to which a bituminous treatment is to be applied should be dry, compact, and free from depressions and dust. The bituminous material, in all cases, should be applied by a pressure distributor designed so that the material will be spread uniformly and with a pressure of not less than 20 or more than 75 lb per sq in. The application, in all cases, should be carried over the outside edges of the rolled metal.

"After the bituminous material is applied it should be covered with the toughest grit obtainable, preferably of a size that will pass thru a screen having openings of not less than 3/8 in nor greater than 5/8 in, just enough of such material being used to cover the bituminous material. It is advantageous, but not entirely necessary, to roll with a steam-roller after the application of the grit."

Details of Methods, as used under various conditions in the United States and Europe, follow:

Extracts from "General Directions for Surface Tarring" recommended in 1911 by The Road Board of England follow: "Surface tarring may be advantageously applied either to an old road surface in good condition or to a new surface after it has been consolidated and dried, but the tarring should never be carried out unless the road is thoroly dry. If there are any depressions, pot-holes, waves, grooves, or other irregularities, these should as far as practicable be made good before tarring is commenced so as to provide an even surface. If it is intended to tar an old surface, it is advisable to take advantage of the early months of the year to scrape or brush the road during wet weather as a preparation for subsequent tarring, and especially to keep the road free from caked mud. The road whilst being tarred should be closed to traffic over half its width, or, where practicable, over its whole width."

"The road should be thoroly brushed and cleaned before application of the tar. Wet brushing should be used some time previous to dry brushing, if there is any caked mud. Any method of brushing may be used which will scour and clean the road thoroly, the best being horse brushing, followed by hand brushing. In order that the tar should be applied to the road as hot as possible, it is advisable, if the method of application is by hand, to use flexible pipes to convey the tar from the boiler to the point of application. If these are not available, it will be found convenient in case of hand pouring, to use 3-gal cans specially constructed for the purpose, fitted with spouts leading direct from the bottom of the cans, and being not less than 1.5 in in diameter at the orifice. Immediately on application the liquid tar should be brushed so far as necessary to ensure regularity

in thickness of the coating. The quantity of tar required will vary according to the physical conditions of the road, but generally, in the case of a road to be treated with tar for the first time, the quantity should be 1 gal to coat from 5 to 7 sq yd."

"If the road must be opened to traffic before the tar has set hard, grit should be spread on the surface to prevent the tar from adhering to the wheels of vehicles, but gritting should be delayed as long as possible, and the quantity of gritting material to be spread should be no more than sufficient to prevent the tar from adhering to wheels. Stone chippings, crusht gravel, coarse sand, or other approved material (free from dust) not larger than will pass thru a ¼-in square mesh should be used for gritting, in quantity not exceeding 1 ton for 300 to 350 sq yd if grit is used, and 1 ton for 200 to 250 sq yd if coarse sand is used."

"On heavily trafficked roads it is advisable to apply a second coat to either the whole width or from 9 to 12 ft of the center of the road in quantity of 1 gal to coat from 8 to 10 sq yd about two or three months after the first application. Surface tarring should be renewed annually on all important roads, and as required on roads with light traffic. On such re-coatings the quantity of tar to be applied will vary with the extent to which the previous coating of tar has been removed by weather or by traffic."

"In all cases careful record should be kept of the condition of the road surfaces in winter and summer, both before and after tarring, the quantity and quality of tar used, the superficial area covered, the state of the weather when the work is being done, the time occupied in actual work, and in waiting whilst work is stopt owing to wet weather, the number of men employed, and full details of the cost of labor and material. Surveyors are recommended to have samples of the tar supplied to them under contracts properly tested by a qualified analytical chemist."

Maryland State Roads Commission 1917 Specifications for Tar and Oil for Cold Application are as follows:

"Sweeping. The road surface shall be swept with a rotary rattan broom drawn by horse or motor power in such a manner as to remove from the surface all dirt or other foreign materials, and should the rotary sweeper not remove all the dirt or foreign material, giving a clean surface, then the contractor will be required to scrape the foreign material from the surface with hoes or other tools, and cleanly sweep it with rattan brooms by hand.

"Applying the Material. No material shall be distributed except by a motor-drawn pressure distributor of a type satisfactory to the engineer, and no material shall be applied when the surface is wet, frosty, or when, in the opinion of the inspector, it is unfit to receive the application. All material will be applied at the rate specified by the inspector, but in no case is more than ⅓ gal of material to the square yard to be applied to the surface in one application and where ½ gal per sq yd is applied, it shall be put on in two applications. When two applications are specified, all the stone chips shall be evenly and uniformly distributed over the surface as hereinunder specified, after the first application of oil or tar has been made, and then the second application shall be made, but in no case shall more than 24 hours elapse between the first and second application of the tar or oil. In order that the traveling public may be accommodated as much as possible, the contractor will apply the oil to one-half of the road surface at a time, and as soon as one truck load is applied to one side of the road it will be covered with chips by the contractor or the State, as the contract provides.

"Spreading Stone Chips. The stone chips or gravel required to be spread on the road after the application of the oil by the contractor will be deposited along the road on one side or the other in approximately even piles, at regular intervals of 25 ft. Approximately 80 tons will be used to a mile of 14-ft surfacing to be treated. The contractor will be required to spread these chips or gravel evenly and uniformly over the surface of the road immediately after the oil is applied and fill in all holes or inequalities, and in no case must more than 2 hours elapse between the application of the oil and the complete covering of the surface with the chips or gravel, and under no circumstances will work be permitted to remain uncovered during the night. The term 'evenly and uniformly' shall be construed to mean that each and every square yard of surfacing shall have the same amount as each other square yard within a variation of not more than 10%."

Cement-Concrete Pavements. A bituminous surface constructed on the surface of a concrete pavement protects the surface of the concrete from abrasive action of traffic, offers a better foothold with certain kinds of bituminous mate-

rials, eliminates the dust which is otherwise liable to form on a concrete surface, and does away with the objectionable glare which results when a strong sunlight shines on the concrete. The bituminous material used is either a refined tar, a tar-asphalt, or an asphalt cement. It is applied to the surface in the amount of ½ gallon per square yard, and spread by means of hand methods or by distributing machines. It is considered that the best bond and most even surface is secured by applying the bituminous material by a pressure machine in two applications of ¼ gallon each. The bituminous material is sometimes swept in with either a rotary sweeper or with hand brooms. It is then covered with sand or fine stone chips to a depth of ⅜ to ½ an inch.

Bituminous Concrete Pavements are in many cases finished with a seal coat either consisting of the same kind of bituminous material as is used in the upper course of the pavement, or a material more suitable for a bituminous surface. Certain types of asphalts, penetration 25° C., 55–75, and combinations of refined tars and asphalts have given excellent results. The amount of bituminous material used per sq yd varies from ⅛ gallon for Topeka bituminous concrete pavement to from ½ to 1 gallon for a bituminous concrete pavement having a mineral aggregate composed of one product of a stone-crushing plant. The best method of applying such a flush coat is by the use of a hand-drawn gravity distributor and a rubber squeegee.

Maintenance. The life of a bituminous surface depends principally upon traffic conditions and the nature of the bituminous material used. With the heavier grades of bituminous materials adaptable for this work, if a broken stone road carries normal traffic, retreatment is necessary every one or two years. Under extreme traffic conditions with the same grade of material, it may be necessary to retreat the road twice each year, as is done in the case of the Avenue du Bois de Bologne, Paris. Retreatments, however, can generally be accomplished by using a smaller amount of bituminous material, about half the amount used in the first treatment. The same care should be taken in preparing the road surface as is done in the original treatment. An average price of maintaining a bituminous surface is 3 to 4 cents per year.

Cost. An average cost of constructing a bituminous surface using 0.5 gal per sq yd of bituminous material, either an asphaltic or tar product, or a combination of the two, is 7 cents per sq yd.

Philadelphia Cost Data. Table I gives the cost of labor and materials from 1913 to 1916, and Table II gives detailed costs of construction in 1916.

Table I

Labor and Material	Unit Costs			
	1916	1915	1914	1913

16. Guard Rails and Road Signs

Guard rails should be placed at the tops of all embankments and at culvert ends where there is the slightest element of danger. Wood, iron and concrete are the materials used in the construction of guard rails. Guard rails on fills are placed 12 inches from the edge of the embankment toward the center of the road; on masonry headwalls they are generally in the center of the masonry.

Wooden Guard Rails are usually built so that the top rail is 3 ft 6 in above the ground. The posts are 6 inches diameter and 7 ft long. They are spaced 8 ft center to center. The top rail is 4 in square, set cornerwise in V-shaped notches sawed in the tops of the posts. The tops of the posts are sometimes sawed off slanting toward the center of the road and the top rail is then 2 in by 6 in, laid flat. The top of the lower rail is placed about 1 ft 3 in below the bottom of the top rail. The lower rail is generally 2 in by 6 in, nailed to the road sides of the posts, which have been previously notched to fit same. The posts are of chestnut or of cedar with the bark shaved off. The rails are planed timber, usually pine or spruce. All joints and exposed surfaces are well painted with a light-colored paint, white lead often being specified for this purpose. The first cost of wooden guard rails in place is ordinarily between 20 cents and 30 cents per

n ft, and the cost of maintenance is from 5 cents to 6 cents per lin ft per ear.

Iron Rods are used sometimes in place of wooden posts where a guard rail needed for a culvert headwall or for a ledge. The top of the rod is forked receive the 4-in square wooden rail. The lower rail is frequently omitted.

Gas Pipe Railing is also used on headwalls of culverts, or on ledge. The pipe sed is 1.5 or 2 inches in diameter. The railing is 3 ft 6 in high, and is built ith two or three lines of pipe. If two lines are used, they are spaced about 21 in part; if three lines are used, they are placed about 13 in apart. The iron posts e spaced generally 8 ft center to center. The pipes are fixt at the bottom by nchoring the bases in the ledge or concrete for a depth of 9 in, or else the ottoms are set in a cast-iron flange which is bolted to the ledge or masonry. he cost of gas-pipe railing, erected, is about 75 cents per lin ft.

Concrete Guard Rails, as described in the 1910 New York State Highway ommission Report, consist of concrete rails set on top of concrete posts. The ils are built with an inverted rectangular trough section, and are 8 ft long y 7 inches deep by 9 wide. Each rail is fitted with three cross diaphragms conecting the sides and top, one being placed at the center and one 4 in back from ach end. The rails are reinforced with four ⅜-in square rods, one being placed t each corner, and the diaphragms are reinforced with a loop of the same size od. The rails are set 3 ft 2 in above the ground on concrete posts, the sides nd end diaphragms of the rail forming a socket into which the top of the post ts. The posts are 6 ft 6 in long and 5 in by 7 in square, and are reinforced ith a ⅜-in square rod in each corner. The posts are set 3 ft 6 in in the ground. he cost of concrete guard rails is estimated to be about 50 cents per lin ft, nd the maintenance cost is practically nothing.

Road Signs. The New York State Highway Commission Standards contain tandard designs for a mile post, danger signal, and guide sign. The mile post built of concrete, 6 ft long and of triangular cross-section. The post is set ft 6 in in the ground. The danger sign is a pine board 20 by 30 inches, attached a galvanized iron pipe which is set into a concrete base. The sign is inscribed ith the word "Danger" in black letters on a large red arrow head. Small igns designating the highway number are also attached to the same standard. uide signs are concrete posts 14.5 ft long, tapering from a 9-in section at the ase to a 6-in section at the top. The posts are set 4 ft into the ground. A 2-in rought iron pipe extends thru the center of the post for practically its entire ength. At a distance of 7 ft above the ground surface the sign boards are ttached, two being placed on one face of the post and two on a face at right ngles to the other. The four sign boards are of white pine, 6 in wide and 3 ft in long, spaced 2 in apart vertically, and faced with a galvanized sign.

In Europe there has been considerable discussion as to the relative advantages of one anger sign meaning reduce speed and a number of symbolic signs describing the specific anger. The signs generally adopted are four in number, each bearing a different symbol esignating respectively, curves in the road; obstacles along the road, such as ditches, umps, and bridges; barriers, such as road crossings or railroad crossings when protected y barriers, except where such crossings should be classed as dangerous crossings; and angerous crossings, such as road crossings or railroad crossings when not protected by arriers. The signs are placed from 600 to 800 ft from the point of danger. The signs n France are 27 inches in diameter, the symbol being painted white on a dark blue ackground.

PAVEMENTS

17. Stone Block Pavements

In the United States, stone block for pavements usually are made from granites and sandstones. Limestone and trap blocks are used to a limited extent. Durax, a special type of stone pavement developed in Europe, was first used in America in 1913. Square blocks and rectangular blocks of a smaller size than is common in this country are also used in some parts of Europe.

Characteristics. The chief advantage of a stone block pavement is its durability, and its chief defect is its rough and noisy surface. It is adaptable to use on grades up to 15% if the joints are filled with bituminous materials, and on grades up to 10% if cement grouted joints are used. Some blocks become slippery from wear. Unless properly constructed and maintained, a block pavement is unsanitary.

Cobblestone pavement is now rarely laid except on unimportant streets or alleys, or as a substitute until a better pavement can be obtained. The stone should be hard and durable, from 4 to 6 inches deep, and from 2 to 4 across the head. The stones are laid on end in a bed of loamy sand about 6 in thick. The stones are set compactly together so as to break joints as much as possible. The surface is then covered with sand which is swept into the joints, after which the stones are tamped with a rammer weighing about 50 lb. When there is no further settlement of the stone the surface is covered with a layer of sand about ½ inch deep. A cobblestone pavement, if subjected to a heavy traffic, soon gets out of shape and the principal maintenance work consists in relaying such portions of the surface. The cost of a cobblestone pavement is about 70 cents to 90 cents per sq yd. One cu yd of sand will be sufficient for about 5 sq yd of pavement.

Belgian Block pavements were constructed with blocks approximately 6 in square on the upper face, with a bottom face smaller than the top, and of variable depths. Confusion as to the meaning of the name Belgian block is caused by the fact that many rectangular block pavements constructed with trap rock are now so named. The method of construction was similar to that described for laying cobblestones. A square yard of pavement required about 27 blocks. The cost per square yard of pavements was $1.25 to $1.45.

Size of Blocks. Pavements are built usually of blocks having rectangular faces. From 1910 to 1918, the depth was reduced from 8 to 5 in in many localities, thus saving in the cost of the blocks. The blocks should be drest so as to be rectangular on the faces, having parallel sides and ends, with right angle corners. Some specifications do not allow bunches or depressions on a face exceeding ¼ in. If the faces are not free from bulges and hollows, it is impossible to get close and even joints in laying the blocks. Blocks are from 5 to 8 inches deep, 3 to 4½ wide, and from 8 to 12 long. The 1918 Report of the Am. Soc. of Mun. Imps, states that the blocks shall be so drest that the joints shall not exceed ½ in in width at the top and for 1 in downward and not more than 1 in in width at any other part of the joint.

Laying the Blocks. The subgrade should be rolled hard with a 10-ton roller, and should be shaped with the same crown as the finished surface. The concrete foundation is then laid as described in Art. 11. The thickness of the foundation is variable, depending upon the traffic conditions, 6 inch being an average value. After the concrete has set, it is covered with a layer of sand 2 to 2½ inches deep, which forms a cushion for the blocks to rest on and allows for any variation in the depths of the blocks. The blocks are placed by hand as closely together as possible, usually in straight parallel courses with the long dimensions per-

pendicular to the curbs. The blocks in one row should break joints with the blocks in another row, by at least 3 in. At street intersections, in order to prevent the traffic of the cross streets from traveling parallel to the long joints and thus forming grooves, the blocks are laid with their long dimensions parallel to one or both of the diagonals of the square formed by the intersecting streets. The work of laying the blocks is started from the curb lines at either side and progresses toward the center of the street. The crown of a stone block pavement is usually parabolic in shape, and the amount of crown can be obtained from formula (see Art. 9). The blocks may be laid to the desired crown by the use of strings, cross-section stakes or a board template. After placing the blocks to the proper lines, they are thoroly tamped with a tamper weighing from 60 to 70 lb until no further settlement occurs. The blocks should all lie perpendicular to the sand bed. If any blocks settle more than others, they should be taken out and relaid. The joints should be filled with a suitable material.

Sand Filler. A filler of sand works out of the top of the joint and leaves the edge of the block exposed so that it soon wears off, thus making a rough pavement. When a sand filler is used, the sand is sometimes spread on the pavement and swept into the joints before ramming is commenced. After ramming, more sand is added to completely fill the joints.

Tar-Gravel Filler. The theory of a tar and gravel joint is that the gravel will keep the blocks in place and the tar compound will fill the voids in the gravel, thus rendering the joint waterproof. It is not possible, however, in practise to uniformly attain this ideal condition, since the gravel will pack in some joints or the tar compound will cool in pouring and thus not enter the joints. The gravel should be of such a size that it will all pass a sieve of ½-in mesh and be retained on a ¼-in mesh. A ¾-in joint is necessary for this type of filler. The gravel should be heated and swept into the joints until they are filled to within 3 in of the top. By using a small iron rod or stick the gravel can be poked down well into the joints. Enough bituminous material is poured to fill the joints to the top of the gravel. The joints are then filled to the top with gravel and poured again with the bituminous material until entirely filled.

Bituminous Fillers are used as joint fillers without previously filling the joints with gravel, but it is necessary in this case, if successful results are to be expected, that the blocks be so drest that very narrow joints can be obtained. Mixtures of sand and asphalt or tar also are used for fillers.

Cement Grout composed of one part of Portland cement and one part of clean sand is also used as a filler. The blocks are laid with thin joints and poured with grout. Traffic should be kept off the pavement for a period of seven days, or until the cement has set up, otherwise good results will not ensue. This type of filler makes a smooth and durable pavement. The surface, however, will be more slippery than where the other types of fillers are used. Repair work will also be more costly, since in removing the blocks more will be broken due to the bond furnished by the cement.

The Maintenance of a stone block pavement, if properly constructed, is practically nothing for the first few years. The life of a granite block pavement constructed on a concrete foundation and with joints well maintained varies from 20 to 30 years.

The Number of Blocks used per square yard will depend upon the size of the block and the width of the joints. Using the ordinary-sized blocks laid with ½-in joints, the number per square yard will vary from 25 to 32.

The Cost of a granite block pavement laid on a concrete base with a bituminous or cement grout filler varies from $2.25 to $3.75 per sq yd, the average

price being about $3.50 per sq yd. When a sand filler is used the cost varies from about $1.50 to $3.00 per sq. yd.

Character and Cost of Stone Block Pavements in 1916 in Several Cities

* Price covers pavement, foundation, and grading. † Does not include grading.

Recut Granite Block Pavements on 5-in concrete foundations cost, according to Howell, in one case in Newark, $1.82 per sq yd, and in the Bronx, N. Y., from 1909 to 1914 an average of $1.72 per sq yd.

Kleinpflaster is used very extensively in Germany both for city streets and highways subjected to a heavy motor-car traffic. The blocks are so cut that when laid they form circular or parabolic arcs. The blocks are roughly 2¼ by 2¼ by 2¾ in. They are laid on a foundation of gravel, macadam or concrete with a cushion coat of sand and gravel, and with joints filled with sand or gravel or in some cases a cement grout. This type of pavement has given satisfactory service for nine years on automobile roads leading into Berlin. A kleinpflaster pavement on a gravel base costs from $1.06 to $1.48 per sq yd; constructed on a 10-in to 12-in stone layer the cost in one instance was $1.90.

Durax, which is a small stone pavement used in England, is a modification of kleinpflaster. The small stones vary in size, according to the traffic to be taken. They are laid on a mastic cushion ½ in thick of bituminous material mixt with sand on a foundation of broken stone or concrete. The joints between the blocks of the wearing surface are filled with bituminous cement. Finally a coat of shingle gravel is spread over the surface.

18. Brick Pavements

Vitrified Bricks are now almost universally used in the construction of this type of pavement. Both represt and wire-cut lug brick are used. The common size of a paving brick varies from about 2½ by 4 by 8 in to 3½ by 4 by 8½ in.

The dimensions of brick given in the 1918 Specifications of the Am. Soc. of Mun. Imps. are as follows: "The standard size of block shall be 3½ inches wide, 4 inches deep, and 8½ inches long. They shall not vary from these dimensions to exceed ⅛ inch in width and depth, and not more than ½ inch in length. If the edges of the brick are rounded, the radius shall not exceed 3/16 in. Only brick with four raised lugs on one side not to exceed ¼ inch nor less than ⅛ inch in height shall be used."

Characteristics. A brick pavement is durable, easy to clean, offers light resistance to traction, is good from the standpoint of non-slipperiness and is

non-productive of dust. This type of pavement, however, when constructed with a cement grout filler is sometimes objectionable from noise.

Laying the Bricks. Broken stone and sand foundations have been used under brick pavements in some cases with good results, but for even medium commercial traffic a 4-in to 6-in concrete foundation should be built (see Art. 11). Generally the cost of brick would not justify its use on any but a concrete foundation. The subgrade should be well compacted with a roller. The concrete foundation should conform to the same crown as the finished surface.

Sand cushion. The concrete is covered with a 2-in sand cushion, which is carefully smoothed off with a board template and rolled with a hand-roller so as to be parallel to the finished surface. For details of construction of template see 1911 Standard Specifications for Brick Pavements of the Am. Soc. Mun. Imps. The bricks are laid on this cushion with their longest dimensions perpendicular to the curbs and so that the end joints are broken by at least 3 in, the work progressing from the sides to the center of the street. At street intersections the bricks are laid in a manner similar to that in stone block pavements. Care should be taken in laying the bricks not to disturb the sand cushion. This may be accomplished by requiring the men to stand on the bricks as they are laid. The bricks are laid to the required crown by the aid of strings, stakes, or board templates. A formula for the amount of crown as given in Art. 9.

Sand-cement Mortar Bed. In this method, the concrete is covered with a mixture of one part cement and four parts sand which is smoothed by a template and rolled to a depth of 1 in. The brick are laid as described above, but this method presupposes the use of a cement grout filler.

Green Concrete Foundation. In this type of construction, the concrete, as soon as deposited, is roughly surfaced. A thin coating of a mixture of one part cement to three parts sand is then spread by means of a double metal template, which first smooths the concrete and then a $^3/_{16}$-in bed of the mortar. Upon this bed the brick are laid in the usual manner.

Expansion Joints. To allow for expansion of the pavement, in cases where cement grout filler is used, it is common practise to insert a board, 1 or more inches thick, between the curb and the pavement during construction, and after the pavement is otherwise completed to remove the board and fill the space left with a bituminous cement. The thickness of this cushion depends upon the width of the street, but it should never be less than 1 in. Some specifications provide for a transverse expansion joint, constructed in a similar manner, at a distance of every 25 to 50 ft along the street. In others, however, this requirement is omitted.

Rolling. After the bricks are laid the surface should be swept and then be rolled with a roller, weighing from 3 to 5 short tons, in a longitudinal direction, starting from the curb at either side and working up to the center of the roadway. After this is accomplished the surface should be rolled transversely in both directions at 45 degrees to the curb lines. It may be necessary to tamp by hand some parts of the pavement which are inaccessible to the roller.

Joint Fillers. The joints between the bricks are filled with sand, with Portland cement grout, or with a bituminous material. In places where the traffic is very light, sand has been successfully used, but as a general rule it will not make a desirable filler.

A Cement Grout Filler is made of 1 : 1 mixture of Portland cement and clean sand, which is mixt in boxes. This mixture is spread on the pavement and brushed into the joints. After a distance of from 45 to 60 ft has been covered in this manner, the same area is regrouted by the same gang in a similar

manner with two parts Portland cement to one of sand. The consistency of the grout is about that of thin cream. The pavement should be sprinkled both before and after the grout is applied. While the initial set is taking place, the surface should be sprinkled and all surplus mixture should be swept into the joints, filling them flush with the top of the brick. After the grout has hardened a ½-in layer of sand is spread over the pavement, and if the weather is very hot, it should be dampened by occasional sprinkling. Traffic should not be allowed on the pavement for at least ten days.

A Bituminous Filler is composed of a tar compound, an asphalt, or a mixture of the two. In applying a bituminous filler, the joints are poured until they are filled to the top of the brick, after which, while the filler is still soft, the surface is covered with a layer of sand. The use of a bituminous filler usually will result in a less noisy pavement than one in which the joints have been filled with a cement grout. A bituminous filler will also take up the expansion of the brick to a great extent. The use of a bituminous filler makes the brick pavement practically impervious.

Cost Data. In the following table are given, for several localities thruout America, 1916 prices of brick pavements constructed with various types of fillers and different thicknesses of sand cushions and cement concrete foundations.

Character and Cost of Brick Pavements in 1916 in Several Cities

* Price covers pavement, foundation, and grading. † Does not include grading.

Maintenance. The maintenance of this type of pavement consists mainly of rectifying any low spots which appear in the surface, due to defective bricks or to insufficient foundation. The maintenance clause of 1918 Specifications of the Am. Soc. of Mun. Imps. is as follows: "The period of guaranty shall be five years. During the period of guaranty, whenever the surface of a vitrified brick pavement becomes uneven, holding water ¼ in or more in depth in a distance of 4 ft or less, or when the pavement has settled over trenches existing previous to the completion of the pavement, then the brick shall be taken up and relaid to proper crown and grade. Any brick which may be found soft, unsound, broken or disintegrated, and all portions of the pavement which may have

become rough by reason of the chipping or breaking of the edges of the brick, so as to produce joints exceeding ½ inch at a point ¼ inch below the surface of the brick, shall be removed, and properly replaced with sound material."

Material Data. The number of bricks required per square yard will vary from about 40 to 65, depending upon the size of brick and the width of joints. The amount of filler will also vary with these factors.

19. Wood Block Pavements

Size and Kind of Blocks. Wood block pavement has been employed with increasing frequency in certain cities of this country. Rectangular blocks treated by some preservative process are universally employed. The commonest sizes of blocks are 5 to 10 inches long, 3 to 4 wide, and 3½ to 4 deep, Variations of $^1/_{16}$ and ⅛ inch in the depth and width of the blocks respectively are allowed after the particular size has been determined upon. Southern yellow pine, Norway pine, black gum, and tamarack are the woods in most common use in this country.

Preservative. The 1918 Specifications of the Am. Soc. of Mun. Imps. state that the amount per cu ft shall not be less than 16 lb of water free oil at the completion of treatment.

Characteristics. A wood block pavement properly built is durable and noiseless. It furnishes a smooth surface which can be easily cleaned, but which, when damp, offers a very poor foothold for horses.

Laying the Blocks. The subgrade should be thoroly compacted with a heavy roller. On this surface a cement concrete foundation should be built as described in Art. 11. The depth of the concrete varies with the traffic conditions, 6 in being common. The surface of the foundation should be finished parallel to the final surface of the pavement. The amount of crown may be determined by the formula as given in Art. 9. A cushion of either sand or cement mortar is spread upon the concrete foundation and struck with a template so as to be parallel to the finished surface. The sand cushion is usually 1 inch thick. A 1 : 3 mixture of Portland cement and sand, spread to a depth of ½ to 1 inch, is specified for the mortar cushion. The concrete foundation should be sprinkled with water before the mortar bed is laid. The blocks are placed upon the cushion with the fiber of the wood vertical and in courses which are straight lines, in most cases at right angles to the curb, but in some instances at an angle of from 45 to 65 degrees with the curb line. The joints are overlapped by at least one-third of the block length, and the blocks are so laid that the joints will not be more than ⅛ inch wide. An expansion joint, about 1 in wide, and filled with bituminous material, should be provided next to the curbs, and it is sometimes specified that one or two rows of blocks, depending upon the width of street, be laid next to the curb with the longest dimensions parallel to the curb. Sometimes transverse joints are required every 100 ft. After the blocks are placed in position, the surface should be rolled with a light steam roller. Care should be taken, if a mortar cushion is used, to finish the rolling before the mortar has set.

Joint Fillers. The joints are filled with either sand, bituminous material, or cement grout. After the joints have been filled, a ½-in layer of fine sand is spread over the whole surface, left for a time, and then removed.

The 1918 Specifications of the Am. Soc. of Mun. Imps. state that: "The joints between the blocks shall be filled with either a pitch or asphalt filler. The filler shall be brought to the proper temperature and poured into the joints, and any filler on the surface of the pavement must be spread as thin as possible by means of squeegees."

Bituminous materials used as fillers are coal-tar pitch, asphalt, or specially prepared

materials. A bituminous filler tends to make the pavement more waterproof, and also provides for expansion to some extent, but it is liable to bleed.

A cement grout filler is composed of equal parts of portland cement and sand. It is of such a consistency that it will readily flow, and should be swept into the joints until they are completely filled. The pavement must be kept closed to traffic for at least seven days in order to give the cement time to set. Very few pavements are laid with grout filler.

Maintenance. The preservative fluid will in some cases ooze from the blocks and be very objectionable. The cause of this "bleeding" has been attributed to the adulteration of the creosote oil used as the preservative with coal-tar pitch; the expansive effect of heat on the blocks; and use of too much preservative fluid per cubic foot. These places in a pavement may be remedied by spreading sand over them or by scraping off from time to time the material that has exuded. The maintenance of wood block pavements, outside of taking care of the "bleeding," consists essentially in periodically sanding to prevent slipperiness, removing any decayed blocks, and in making minor repairs, such as raising low spots or fixing places where the blocks have bulged up. In France and England the experiment is being tried of coating the wood pavements with a bituminous surface. The life of some wood pavements in France has been prolonged by taking up blocks after several years' service and sending them to the municipal plant, where the tops are sawed off so that the blocks are again of uniform depth. These blocks are then laid with the original bottom surface as the wearing surface.

Cost. The average cost of wood block pavements in 1916 in several American cities in the New England and North Atlantic States was about $3.25 per sq. yd. These pavements were laid on a concrete foundation and constructed with bituminous or sand fillers. The average price of the same type of pavement in the South Atlantic, North Central, Northwestern, and Southwestern States was about $2.75 per sq yd.

20. Sheet Asphalt and Asphalt Block Pavements

Characteristics. Sheet asphalt is waterproof and ideal from the standpoint of traction, ease of cleaning, and healthfulness. It is non-productive of dust Noiselessness and comfort of use rank fair. Foothold, however, is poor in we

weather, and while asphalt has been used on steep grades, it is not adapted to over 3.5% grades. In cases where illuminating gas has come in contact with it chemical action has taken place, resulting in a spongy surface. It is repaired without difficulty, as an effective bond can be secured between old and new work. Asphalt blocks do not require skilled labor to lay. Many asphalt blocks are chipped off at the edges.

Foundation. It is essential that the foundation for sheet asphalt should be firm and unyielding as the weight of traffic must be carried by it. Usually, therefore, a 1 : 2 : 5 to 1 : 3 : 6 cement concrete is used, being 4 to 6 inches in thickness, depending upon the amount of traffic and subsoil conditions. Concrete must be thoroly set before the binder course is laid. Bituminous concrete has been used in a number of instances, in which cases the binder course is not needed, but this foundation is not advised, since the bond between it and the wearing surface is so firm that the latter can only be removed with difficulty when repairs are necessary and, furthermore, the foundation is not sufficient in most instances where sheet asphalt is economically employed. A 4-in to 6-in macadam coated with asphalt or coal tar has been used, and also ordinary macadam, depressions being filled with a mixture of stone and asphalt. This practise should not be followed.

Binder. Upon this foundation the binder course is laid 1 to 1½ inches deep after rolling, about 40% being allowed for compression. This coat is usually composed of broken stone, sand and asphalt cement, or broken stone and asphalt cement. Material is brought on at 200 degrees to 325 degrees fahr in covered dump carts, deposited, and smoothed down with hot shovels and rakes, taking care not to displace the stone aggregate, and then compacted with a 5-ton to -ton tandem roller.

Specifications for binder stone recommended in 1918 by the Am. Soc. of Mun. Imps. follow: "This shall be clean, hard, broken stone, free from any particles that have been weathered, or are soft. If the stone does not contain the proper amount of material passing the one-half (½) inch screen, the deficiency may be made up by the addition of gravel or sand. Ninety-five (95) percent of the binder aggregate shall pass a screen having circular openings whose diameter shall be three-quarters (¾) the thickness of the binder course to be laid. The remaining five (5) percent shall not exceed in their smallest dimension the thickness of the binder course to be laid. The binder aggregate shall be so graded from coarse to fine as to have the following mesh composition (sieves to be used in the order named):

Passing 10 mesh	15 to 35%	Total passing ½ in, 35 to 85%
Passing ½ in circular opening and retained on 10 mesh	20 to 50%	

The above limits as to mesh composition are intended to provide for such permissible variations as may be rendered necessary by the available sources of supply and the character of the work to be done."

Wearing Surface. The aggregate consists of a finely graded sand and a fine filler, such as stone dust or Portland cement. The wearing surface, consisting of the aggregate and the asphalt cement, is usually laid 1½ to 2 inches deep. The amount of bitumen used varies from 9 to 13% and the filler from 6 to 12%. It is brought on at 280 degrees to 325 degrees fahr, dumped and spread on the binder surface, and then tamped around all manholes, gutters, and curbs, and rolled with a tandem roller weighing 5 to 10 short tons. A continued rolling is very essential, as a constant kneading action is necessary for a well compacted surface. About 200 sq yd per hr should be rolled. Special care must be taken along street-car rails to secure thoro compaction. Usually one to three courses of stone block or brick are laid next the rail. Eighteen to 24 in adjoining the curb are often painted with hot asphalt cement to secure imperviousness to water.

The 1918 Specifications of the Am. Soc. Mun. Imps. covering the manufacture of the surface mixture state that: "The sand and the asphalt cement shall be heated separately to such a temperature as will give, after mixing, a surface mixture of the proper temperature for the materials employed. The sand when used must be at a temperature between 275 degrees and 375 degrees fahr. The asphalt cement when used must be at a temperature between 250 degrees and 400 degrees fahr. The various ingredients shall be brought together and mixt for at least one minute in a suitable apparatus until a homogeneous mixture is produced in which all the particles are thoroly coated with asphalt cement. The weights of all materials entering into the composition of the wearing surface shall be verified in the presence of inspectors."

Asphalt Cement. Satisfactory asphalt cements, as shown by service tests, have been made from California, Mexican and Texas asphaltic oils, gilsonite and asphaltic oil, and "Bermudez" and "Trinidad" refined asphalts.

Sand and Filler. The following description of sand and filler may be considered typical for the materials of a wearing course to be subjected to medium traffic. The sand should be clean, hard grained, and moderately sharp. The product used should show the following mesh composition:

Passing 200 mesh sieve	0 to 5%	25 to 35%
" 100 " and retained on 200 mesh sieve	14 " 25%	
" 80 " " " " 100 " "	6 " 21%	
" 50 " " " " 80 " "	15 " 30%	40 to 50%
" 40 " " " " 50 " "	10 " 25%	
" 30 " " " " 40 " "	8 " 20%	20 to 30%
" 20 " " " " 30 " "	5 " 15%	
" 10 " " " " 20 " "	2 " 15%	

The 1918 Specifications of the Am. Soc. Mun. Imps. covering filler are as follows: "This shall be thoroly dry limestone dust or dust from other equally satisfactory stone or portland cement, the whole of which shall pass a 30-mesh per lin in sieve and at least 66% of which shall pass a 200-mesh per lin in sieve. The surface mixture shall contain from 6 to 20% of this filler, depending upon the kind of sand and asphalt used, and the traffic conditions upon the street or streets to be paved."

Inspection. A. W. Dow recommends that the plant laboratory should be equipped with a set of standard sieves, 10, 20, 30, 40, 50, 80, 100, and 200 mesh; sand scales, a stiff brush for cleaning the sieves, preferably a small one with good stiff bristles; a sand sampler; four screens for testing binder stone, 1-in, ½-in, ¼-in, and ⅛-in screens; thermometers for use with the penetration test and for testing temperature of the paving materials; one penetration machine; a dishpan or other receptacle for holding water at the standard temperature, in which to immerse the asphalt cement samples for testing; two trowels, one 4-inch and the other 6; a 4-in wall brush; a pancake turner for sampling paving mixture while in the mixer; two wooden paddles; pads of unglazed manila paper, 9 by 12 inches is a convenient size; two iron pails and a gas or oil stove, as the conditions may permit.

Maintenance. Failures of sheet asphalt are usually due either to defective foundation, dirt on the binder, too soft asphalt in binder, frost, gas, kerosene or oil, fires, poor construction generally, or lack of traffic to compact. The usual method of repairing sheet asphalt is to cut away the surface for a short distance about the affected spot and then strip it up from the foundation. The edges are cut down square, and after being painted with asphalt cement, a new binder and surface mixture are laid as in new construction.

Asphalt Block Pavements. Compressed asphalt blocks usually have been made of graded trap rock screenings, passing a ¼-in screen, mineral dust and asphalt cement. Good blocks also have been made using copper conglomerate, and for medium traffic, hard limestone has been used as a substitute for trap

rock. The most satisfactory mineral dust, used as a filler, is uniformly pulverized limestone. Portland cement has been used, but it is no better than limestone, and costs more. The blocks usually contain from 6.5 to 8% of bitumen.

Shape and Size of Blocks. Well-made asphalt blocks are uniform in composition, texture and shape; have parallel faces; straight, unchipped and unrounded edges, and unbroken corners; and are not warped or otherwise deformed. The usual dimensions of the face of the block subjected to traffic are 5 by 12 in. The blocks are generally manufactured in three thicknesses, 2, 2½ and 3 in. Blocks should not vary more than ¼ in in length and ⅛ in in width and depth from specified dimensions.

Method of Laying. Asphalt block pavements should be laid on a strong foundation, usually of cement-concrete at least 5 to 6 in in thickness, and, in cases of the heaviest traffic which this type of pavement can carry, 8 or 10 in in thickness. On cement-concrete foundations, the blocks are laid on a ½-in fresh 1 : 4 cement mortar bed. The blocks should be laid with close joints on grades as high as 6%. After being laid, the blocks should be covered with a thin layer of dry, clean, fine, sharp sand, which should

be thoroly swept into the joints, and the surplus left upon the surface for at least 30 days. On grades above 6%, ⅜- or ½-in joints filled with portland cement have been used. After the grout has partially set, the joints are raked out to a depth of about ½ in. On roadways subjected to heavy motor traffic, anchor blocks should be used.

Cost. The cost of sheet asphalt pavements in 1916, in a number of American cities, averaged $1.90 per sq yd, not including grading. The cost of asphalt block pavements averaged $2.40 per sq yd.

21. Bituminous Concrete Pavements

In 1866 the first bituminous concrete pavement was laid in the United States. Since 1910 there has been a general recognition of the value of the many different types of bituminous concrete pavements for use on roads and streets. The mixing method has not been used as much as the penetration method in the construction of bituminous pavements composed of one product of broken stone on account of the cost of mixing and the fear on the part of public officials and engineers of litigation. The introduction of efficient, low-priced mixing machines and the court decisions of test cases have overcome these drawbacks to such an extent that on account of its inherent advantages the use of this method will rapidly gain favor. The characteristics of bituminous concrete pavements are somewhat similar to those of bituminous macadam pavements. Bituminous concrete pavements are, however, more durable than bituminous macadam pavements.

Classification. Bituminous concrete pavements differ principally in the character of the mineral aggregate and the bituminous material of which the surface is composed. They generally may be grouped in three classes.

Class A. A bituminous concrete pavement having a mineral aggregate composed of one product of a crushing or screening plant.

Class B. A bituminous concrete pavement having a mineral aggregate composed of a certain number of parts by weight or volume of one product of a crushing or screening plant, and a certain number of parts by weight or volume of sand, broken stone screenings or similar material, with or without a filler.

Class C. A bituminous concrete pavement having a predetermined mechanically graded aggregate composed of broken stone, broken slag, gravel or shell, with or without sand, portland cement, fine inert material or combinations thereof.

Foundations. For all classes of bituminous concrete pavements, foundations of gravel, broken stone or slag, old macadam, bituminous macadam and concrete, old brick and stone-block pavements, and cement-concrete have been used. The foundation should be strong enough to carry the traffic to which the pavement is to be subjected. Many failures have occurred due to laying bituminous concrete pavements on weak foundations.

Mixing Plants. A plant for hand mixing of unheated aggregate with hot bituminous cement consists of a mixing platform, three or four heating kettles, long-handled shovels, long-handled dippers, and small tools. Unheated broken stone has been mixed with tars or heavy asphaltic oils in the ordinary type of concrete mixer. Asphalt cements of low penetration at normal temperatures cannot be mixed with unheated aggregates by hand mixing or in this type of plant, as it is generally impracticable to coat the unheated broken stone with the hot asphalt cement.

Cement-concrete mixers with heating devices are used to some extent. There are several different types of this class of mixing plants in current use. In one type, the heat, in the form of hot air, is passed into the mixer by means of a large iron pipe, which runs from the fire-box to the outlet end of the mixer. A second

ype consists of a cylindrical mixer mounted on a four-wheeled truck; heat is btained from a hot-air jacket entirely surrounding the cylinder except on the nds, and by means of a kerosene torch inserted within the drum. In a third ype, hot air obtained by the combustion of oil in air is used to heat the mineral ggregate in the mixing chamber; after the aggregate is heated, the bituminous ement is added. A fourth method of utilizing concrete mixers is to use a rotary rier, as a part of the plant, for drying the aggregate.

In a complete plant for the manufacture of bituminous concrete, the aggregate carried by bucket-elevators to rotary driers, where it is dried and the dust xhausted; from the drier the aggregate is raised by elevators to storage bins r to screens from which the aggregate, in several sizes, falls into storage bins; hen required the aggregate is drawn from the bins to a weighing device, and om there deposited into a mixer. Such plants are also equipped with bitumin-us cement heating tanks and weighing buckets. Plants, especially designed for ne manufacture of sheet-asphalt binder and surface mixtures, have been used a limited extent.

Aggregate of Wearing Surface. The thickness of the wearing surface varies om 1½ to 3 in after rolling in all the classes enumerated. The mineral aggre-ate of class "A" is composed of broken stone, of which a size varying from ⅛ 1¼ inches in the longest dimensions represents average practise. The 1918 pecifications of the Am. Soc. of Mun. Imps. describe an aggregate typical of ass "A" as follows: "Broken stone for the mineral aggregate of the wearing ourse shall consist of one product of a stone crushing and screening plant. It nall conform to the following mechanical analysis, using laboratory screens aving circular openings: All of the broken stone shall pass a one and one-uarter (1¼) inch screen; not more than ten (10) percent nor less than one) percent shall be retained upon a one (1) inch screen; not more than ten o) percent nor less than three (3) percent shall pass a one-quarter (¼) inch reen." In Washington, D. C., bituminous concrete pavements of class B" have been constructed in accordance with the following specifications overing the mineral aggregate. "The paving material shall be composed of usht trap rock screenings, concrete sand, and mineral dust in the following oportions: Trap-rock screenings, two parts; concrete sand, one part, and ineral dust, at least 5 percent of the above aggregate; mixt with asphaltic ement." The trap-rock screenings referred to above varied in size from 1 inch screenings and were devoid of dust. A graded aggregate of class "C," nown as the "Topeka" grading and which nas been used in the construction pavements in many parts of America, is given below. It has been mutually greed that the construction of a pavement with this aggregate as specified is ot an infringement of the Warren Brothers' patent No. 727505.

Bitumen from	7 to 11%
Mineral aggregate passing 200-mesh sieve	5 to 11%
" " " 40 " "	18 to 30%
" " " 10 " "	25 to 55%
" " " 4 " "	8 to 22%
" " " 2 " "	less than 10%

As the Bitulithic pavement has a predetermined graded aggregate, it belongs class "C."

The Bituminous Cements which have been used successfully include asphalt nd tar cements, and cements which are combinations of refined tars and phalts. All types are used in the construction of Class A pavements. Usually phalt cements are used for pavements of Classes B and C. The amount of tumen in bituminous concrete mixtures varies as follows: Class A pave-ents, from 5 to 8% by weight; Class B, 6 to 9%; Class C, 7 to 11%.

Laying. In cases where neither curbs, gutters nor edgings are used, thoroly compacted shoulders are constructed. To serve as definite boundaries and to prevent the bituminous concrete from being forced out over the shoulders during rolling, 2-in planks may be placed on the shoulders at the edges of the roadway and allowed to remain until after the seal coat is applied.

After the bituminous concrete has been deposited on the foundation course, it should be uniformly spread by raking to a depth such that when compacted the wearing course will have the desired thickness, which is usually 2 in. For stiff bituminous concrete mixtures, heated shovels should be used for depositing the mix on the foundation course and hot rakes for spreading the bituminous concrete. Care should be taken to see that shovels and rakes are not overheated, as otherwise the mix may be burnt. Usually the back of the rakes should be used to spread the mix uniformly. If the tines are used for this purpose, the larger stones of the mix may be segregated in the surface of the wearing course.

After being uniformly distributed, the bituminous concrete is rolled while it is still warm and pliable. The rolling should begin at the edges and work towards the center. Rolling should continue, without interruption, until all roller marks disappear and the surface shows no further compressibility. Any places which the roller cannot effectively compress should be compacted with hot iron tampers. Excellent results can be secured by the use of tandem rollers, weighing between 10 and 12 tons and having a compression under the rear roller of from 250 to 350 lb per lin in of roll. Equally good results have been obtained by using a 5 to 8-ton tandem roller to shape up the wearing course, and a 12-ton three-wheeled roller for the thoro compaction of the bituminous concrete. In order to prevent ashes from dropping onto the bituminous concrete, each roller should be provided with an ash pan.

Seal Coat. After the wearing course has been rolled sufficiently so that the wheels of the roller do not make any creases, a coat of bituminous cement is applied to the surface. The seal coat should not be applied unless the surface is clean and absolutely dry. From ⅛ to 1 gal per sq yd of bituminous cement should be used, the requisite amount varying directly with the openness of the compacted bituminous concrete surface and the kind of bituminous cement used. Usually, a seal coat is not used on Topeka pavements. The best method of constructing a uniformly distributed seal coat is to use a hand-drawn gravity distributor or a hand-drawn pressure distributor. As soon after the application of the bituminous cement as possible, a thin layer of dry, clean chips should be uniformly spread over the coat of bituminous cement, the total amount of chips being preferably distributed in two applications.

The Maintenance of bituminous concrete pavements consists in covering with bituminous material all spots where the broken stone is exposed on the surface. Places which disintegrate should be cut out and refilled with either a mixt aggregate or by building the hole up with successive layers of aggregate and bituminous material, the former method giving the best results. At varied intervals it is economy to renew the bituminous surface on the pavement, using from 0.1 to 0.45 gal per sq yd. It will be found that the patrol system of maintenance will do much toward prolonging the life of the pavement at a small expense.

The Cost of Bituminous Concrete Pavements varies with the kind and quantity of bituminous material used, the character of the aggregate, and the method of construction employed. Using an aggregate of stone varying from ⅛ to 1¼ inches in longest dimensions, mixt with 1.5 gal of bituminous material per sq yd and with a flush coat of 0.75 gal per sq yd, the cost would be about 30 to 50 cents in excess of ordinary macadam. The cost of pavements with mixt aggregate varies from $1 to $2.50 per sq yd, including foundation and light grading.

22. Bituminous Macadam Pavements

aterials. The bituminous materials used in the construction of bituminous ments built by penetration methods are: asphalts, heavy asphaltic oils, ed water-gas tars, refined coal tars, combinations of refined tars, and inations of refined tars with certain kinds of asphalts. Broken stone, l, sand, shell, and slag have been used as the road metal. The char-istics of bituminous pavements constructed by penetration methods are ar to those noted for bituminous concrete pavements. The penetration od has come into popular use in constructing country roads and resi-l streets due to low first cost, and the large yardage which can be con-ted per day.

nstruction. In the construction of bituminous macadam pavements it is ed to secure, (1) a stable wearing course consisting of broken stone or similar rial thoroly rolled so that it will be well compacted and keyed together and the several sizes of material uniformly distributed, and (2) a uniform dis-tion and penetration of the bituminous material within the upper 1½ to 3 the crust. Several methods of construction have been devised with a view eeting the above prerequisites. The pavement is generally built in 2 or 3 es, the foundation course or courses being from 4 to 8 in thick after rolling, he top course from 2 to 3 in after rolling.

ethod A. When the metaling in the upper course consists of a naturally ed aggregate with sufficient smaller sized product to practically fill the in the larger, say crusher-run stone from 1¼ to ½ inch in longest dimen-, it is not necessary to further fill the voids by the application of a finer ict before applying the bituminous material. An analysis of the type of er-run stone referred to follows:

Passing	¼-in screen	trace
"	½-in "	18.9%
"	¾-in "	43.1%
"	1-in "	34.4%
"	1¼-in "	3.6%

the upper course is laid the bituminous material is applied, either before or the surface is rolled, some favoring the former method because of the er depth of penetration secured. If the rolling is postponed until after pplication of the bituminous material, the wheels of the roller will have wet or oiled to avoid picking up the surface. When the upper course is l preceding the second application of the bituminous material, a coat of ral matter is spread over the surface before rolling. In certain cases this od is also followed where the upper course is not rolled preceding the cation of the bituminous material. The necessity of a seal coat or a second cation of a bituminous material is determined by the traffic conditions; urface should be given a seal coat if it is to be subjected to a heavy combined -drawn vehicle and motor-car traffic. The material used for the seal coat ne cases has a less penetration and a higher melting point than that used e first application. Certain asphalts and combinations of asphalts and ed tars, penetration 25° C., 55–75, have been used with success for this ose.

ethod B. In case the metaling of the upper course is a uniform product out 1 or 1½ inches in size, it is deposited in a layer of the required thick- on the foundation course and lightly rolled. The bituminous material is applied in an amount from 1½ to 2 gal per sq yd and screened stone chips t ⅜ inch in size are spread on the surface and thoroly rolled. The surface xt broomed with stiff brooms, removing all excess chips, and another coat

of bituminous material, of ½ to 1 gal per sq yd, is applied, covered with a layer of stone chips and rolled. This method is also used with metal of the upper course varying from 1½ to 2½ in, in which case ¾-in stone is used in place of the ⅜-in chips.

Method C. In some forms of construction the voids in the foundation course are filled to a certain extent with sand or small-sized broken stone. After rolling, the excess sand or broken stone is broomed off, and the upper course of metaling spread and lightly rolled. Coarse sand, gravel, or stone chips are then spread and broomed until the voids of the metaling are filled to within about 1 in of the top of the surface. The bituminous material is then applied, using about 1½ gal per sq yd; this coat is covered with a layer of sand, gravel, or screened stone chips and thoroly rolled. This method is often used when the material composing the upper surface is of a large and uniform size. As a rule a second application of bituminous material is not made in this method.

Method D. Another method used, when the metaling of the top course is of a large and uniform size, is to place a layer of sand, ¾ in thick, on the bottom course, the voids of which have been filled. The bituminous material is then distributed on this layer, using about 1 gal per sq yd. The upper course of metaling is immediately placed on the mastic and rolled. Continued rolling forces the material of the upper course down and draws the bituminous mastic up into the voids. Another coat of bituminous material of a lower penetration, using about 1¾ gal to the sq yd, is then applied to the surface of the upper course. A layer of ⅜-in stone, ½ to ¾ inch thick, is spread over this and rolling continued. The work may stop here, or may be carried on a step further by brooming off the excess ⅜-in stone, afterward applying another coat of bituminous material, ½ gal per sq yd, adding a layer of screened stone chips and rolling the same. The Gladwell system, which originated in England, is essentially the same in principle except that a course of screened stone chips mixt with bituminous material is substituted for the sand layer and its coat of bituminous material.

Method E. A bituminous macadam pavement called Pitchmac by the inventor J. A. Brodie, City Engineer of Liverpool, has been used to a considerable extent in England and has been adopted as a standard type by the Road Board of England. It is constructed on a foundation of stone. The wearing course of broken stone varies from 2 to 4½ in in depth, dependent upon traffic conditions. If the wearing course is from 2 to 3 in in thickness, it is constructed in one layer, and if from 4 to 4½ in in two layers. The single layer and, in the case of two layers, the upper layer is composed of broken stone ranging in size from 1¼ to 2½ in. After thoro rolling the bituminous material is applied to the single layer or to each of the layers of the two-layer wearing course. The bituminous compound used in England consists of hot sand mixt with tar pitch. From 1¼ to 2 gal per sq yd are used for the one-layer wearing course and from 3¼ to 3½ gal for two layers. To assist in completely filling the voids, chips varying in size from ⅜ to ¾ in are applied during the rolling of the bituminous grouted layer. This type of pavement has been used to a limited extent in Massachusetts.

Method F. In order to secure uniform sizes of road metal in the course upon which is to be applied the first application of bituminous binder, in some cases recourse has been had to harrowing. After harrowing, the course is shaped and thoroly compacted before the bituminous material is applied. With the limestones commonly used in Illinois, this method has produced satisfactory results when suitable asphalt or tar cements have been properly used in accordance with the specifications of the Illinois State Highway Dept.

Method G. In some cases, when heavy asphaltic oil has been used for the ituminous cement, the following method has been employed. Upon a course f broken stone, prior to rolling, about ½ gal per sq yd of asphaltic oil is distributed. The course is then harrowed, after which the second application of about ½ gal per sq yd is made. The course is next thoroly rolled during which screenings are spread. In some cases, the pavement is finished by a third application of ½ gal per sq yd of oil, screened and rolled. In other cases, the third treatment is followed by a fourth using from ¼ to ⅓ gal per sq yd.

The Maintenance of bituminous macadam pavements consists in covering pots with mineral matter where either an uneven distribution or an uneven enetration has caused an excess of bituminous material to exude on the surface. Otherwise the maintenance is similar to that recommended in Art. 21.

Cost. The cost of bituminous pavements built by penetration methods aries largely with the amount and kind of bituminous material and road metal sed, and the method of construction employed. An average cost, using a otal of 2 to 2¾ gal of bituminous material per sq yd, varies from 25 to 40 ents per sq yd in excess of the cost of ordinary macadam.

Bituminous Macadam Pavement Cost Data by Ill. Highway Commission. ength, 1500 ft; area, 3500 sq yd; thickness, 3 in; labor, 25 cents per hour; teams, o cents per hour; average haul, ½ mile; bituminous binder, 2.54 gal per sq yd; constructed, Sept. 29 to Nov. 25, 1915.

Cost of Labor and Materials

	Per sq yd
Superintendence and inspection	$0.077
Cost of stone and gravel	0.430
Cost of sand and chips	0.085
Cost of bituminous binder	0.217
Hauling stone, gravel and chips	0.210
Spreading stone and screenings	0.058
Rolling	0.039
Heating and applying bituminous binder	0.060
Incidental expense	0.019
Total cost	$1.195

Bituminous Macadam Pavement Constructed with Pouring Cans, Alexandria, a. Cost data compiled by E. C. Dunn, City Engineer. "The cost for an average square rd exclusive of grading was $1.01 in 1915 and $1.135 in 1916, the difference being due increased cost of material in 1916. The details of the average cost per square yard 1916 were as follows:

Concrete Base

	Cents	Cents
Materials:		
Water	0.25	
Sand delivered 165 lb at ½ cent	8.25	
Cinders, on cars, $^1/_7$ cu yd at 16⅔ cents	2.38	
Cement, on cars, $^{11}/_{100}$ bbl at $1.47	16.17	
Tools, etc	1.00	28.05
Labor:		
On concrete and placing 50 lb stone	13.00	
Teams	4.00	
Supervision	0.50	17.50
Total cost of concrete base		45.55

Top Wearing Surface

Material:		
Stone, 350 lb trap on cars at 0.69 cent	24.15	
Asphalt, 2½ gal on cars at 8.4 cents	21.00	
Fuel	0.80	
Tools, etc.	2.00	47.95
Labor:		
Men	12.50	
Teams	6.00	
Supervision	1.50	20.00
Total cost of top wearing surface		67.95

Total cost per square yard $1.135.

Wages: Foreman, 25 cents per hour; laborers, 17 to 18 cents; carts, 30 cents, and double teams, 40 cents per hour; haul, 0.95 mile, average. Work done by day labor, City Engineer's wages not included."

Bituminous Gravel Pavements. The use of gravel in the construction of bituminous pavements by penetration methods has been usually limited to those localities where broken stone costs more than gravel. It is self-evident that it is impracticable to secure the same keying effect with gravel as can generally be obtained with broken stone.

The method of construction and the conclusions relative thereto, as contained in the following abstracts of a statement by P. E. Green, are typical of the practice of many engineers who have used gravel in this class of work. "It was specified that the gravel, as spread on the street, should be of a size that would pass a ring of 2 in diameter and be held on a ring of ½ in diameter. After a small yardage has been spread under these specifications, it was found that there was no lock at all between the stones, and that when filled with the bituminous cement but little strength was secured. This yardage was taken up and the gravel afterwards used was still further screened so as to eliminate practically all pebbles below ¾ in in size. After the surface had been rolled to the satisfaction of the inspector, 1½ gal per sq yd of Texaco asphalt was poured over the pavement, and, immediately behind the asphalt, pea-size gravel was lightly spread over the surface, and the whole rolled again. This was then covered with ½ to ¾ gal per sq yd of asphalt cement, and over this second coat of cement was spread coarse sand, and the whole again rolled. On account of the fact that so much care had to be taken with the gravel used, and that it all had to be screened after being received in order to eliminate small pebbles which prevented the locking together of individual stones, it would probably have been cheaper to have purchased crushed limestone in the first place. Some conclusions may be drawn as to this method of construction. They are as follows: Gravel can be made to lock and bond only after a great deal of labor and trouble are taken with it. It would probably be economical to pay twice as much for crusht stone as for gravel to get equal results."

23. Concrete Pavements

Characteristics. A concrete pavement furnishes a smooth surface, is easy to clean, and is not productive of much dust. It is somewhat noisy, and is more slippery than a broken stone road but less slippery than a sheet-asphalt pavement. Its resistance to traction is low. Cracks may be easily repaired but depressions and disintegrated spots are difficult to repair satisfactorily without cutting away the concrete. A worn out cement-concrete pavement sometimes may be used economically as a foundation for a wearing course of some other kind of paving material.

Foundation. Concrete pavements should only be laid on a well-compacted and well-drained subgrade. If the subgrade is of clay or other heavy soil, it should be replaced with clinker, broken stone, cinders, gravel, or some other suitable material. This surface should be flat or parallel to the finished surface

of the pavement and should be thoroly rolled with a heavy roller. Prior to the deposition of the concrete, the subgrade should be thoroly wet, otherwise the subgrade will absorb water from the concrete.

Ingredients and Proportioning. The materials used for the fine aggregate of a cement-concrete pavement are generally sand or stone screenings, and for the course aggregate either broken stone or gravel. The broken stone employed should be obtained by crushing hard, tough rock. Preferably the stone should be composed of naturally graded sizes and free from dust or dirt. What has been said relative to broken stone applies as well to gravel, since a screened gravel with the fine material eliminated allows a more accurate determination of the correct proportions. The sand used should be clean, sharp, and coarse, free from loam, clay, and vegetable or organic matter. The cement should be a first-class portland cement that will meet the standard specifications of the American Society for Testing Materials. Care should be taken to use clean water, since water which contains any alkalies or acids will be detrimental to the concrete. The proportions which are used in connection with the construction of concrete foundations are not rich enough in either cement or mortar to make satisfactory concrete which is to be subjected to the abrasive and impact forces of traffic. The proportions used for the best class of one-course cement-concrete pavements are about one cement, one and one-half or two fine aggregate, and three coarse aggregate. For two-course pavements, the base may have the proportions 1 : 2½ : 4 and the top, 1 : 1 : 1½.

Construction. In plain cement-concrete pavements constructed by the mixing method, the concrete is deposited in one or two layers. Usually the average transverse slope does not exceed ¼ in per ft. The thickness varies from 5 to 10 in, dependent on traffic requirements and other local conditions. More attention should be paid to obtaining a smooth and regular surface in constructing cement-concrete pavements than is usually accorded concrete foundations. The use of templates to strike the surface of the concrete, and of bridges, which span the concrete surface, thus enabling the laborers to work over the surface without standing on it, should be insisted upon. The surface may be finished by the use of wood floats, belts or light rollers. It is also important to protect the surface from too rapid drying out while the concrete is curing, otherwise shrinkage cracks are liable to occur. This is accomplished sometimes by covering the pavement as soon as it has taken its initial set with a canvas which is kept moist for a few hours. The canvas is then removed and the surface is covered with layer of sand or earth, which is kept thoroly moist for a period of two weeks.

Expansion Joints. Transverse joints always should be provided. There will be more or less contraction and expansion of the concrete due to changes of temperature, variation in the moisture content of concrete, and variation in the condition and character of the subgrade. If expansion joints are not present, when the concrete contracts, the tensile strength of the concrete will be exceeded and the pavement will crack; when it expands it will tend to crush, spall, or bulge. The edges of the joints must be protected from the abrasive action of the traffic, and it is obvious that the joints should be filled with a material that will allow some movement between the joints as the pavement expands and contracts. The width of the transverse joints depends upon the distance between them. It is considered better practice to construct narrow joints at short intervals apart rather than wide ones far apart. Transverse joints are placed from 15 to 50 ft apart, 30 ft being an average distance. If curbs are used, longitudinal joints should be constructed adjacent thereto. The width of the longitudinal joints will depend somewhat upon the width of the pave-

ment. They are usually made from ½ to 1½ in wide and are filled with a bituminous filler or a patented expansion joint is employed.

Reinforced Pavements. Reinforced cement-concrete pavements are usually constructed by the two-course method. The reinforcement usually consists of woven wire or expanded metal, altho a mesh work of small round bars is sometimes used, and generally is placed between the base and the wearing course. At the 1916 National Conference on Concrete Road Building, a committee reported that "it is only recently that reinforcement has been used to any great extent, and the interval is too short for the accumulation of the data necessary to standardized practice."

The Cost of Concrete Pavements varies from $1 to $2 per sq yd, depending upon the location of the work and the amount and character of the materials employed, an approximate average price for a 6-in pavement being $1.35.

24. Sidewalks, Curbs and Gutters

Width and Slope. In business districts sidewalks usually extend from property line to curb, but in residential districts it is common to find a grass plot or row of trees placed between the footway and the curb, while on rural highways the walk is entirely omitted or restricted to a narrow foot-worn path at the side of the road. The widths of sidewalks from property line to curb vary from 4 to 6 ft in residential sections; 8 to 20 ft in business districts. The usual width for each sidewalk is from one-fifth to one-sixth of the total width between property lines. The transverse slope of the sidewalk varies from ⅛ to ½ in per ft, depending upon the kind of material with which the surface is constructed.

Concrete sidewalks usually have a 6-in well-compacted foundation of broken stone, gravel, or cinders. The total thickness of concrete is 3 to 5 in, and it is composed of a 1 : 2 : 4 or a 1 : 2½ : 5 mix. The upper inch, however, is a wearing coat composed of 1 : 1 or 1 : 1.5 mixture of cement and ¼-in sand or stone. The concrete is laid in sections which form slabs 4 to 8 ft long, the wearing course being placed on the lower concrete before the latter has set up. The joints which mark off the slabs in many cases extend thru the entire depth of concrete, thus providing for expansion and contraction. The wearing surface is finished off smooth by troweling and later, if desired, may be marked with a grooving or perforating tool.

For Brick Sidewalks concrete may be used as a foundation, but a good stone, sand, or gravel bed is most common. The bricks are laid either diagonally or perpendicularly to the center line of the sidewalk. The joints are filled with sand, and a light coat of sand is spread over the surface upon completion. The latter, however, is ultimately removed by the action of traffic or otherwise.

Flags of Blue Sandstone or Granite are laid on a 3-in to 4-in foundation of sand or other suitable material, the joints being filled generally with a cement mortar. In Paris the granite slabs are 6 inches in thickness, bedded in the concrete. Flag stones are usually 2 to 3 inches in thickness.

Cinders are laid 6 inches deep and are then flooded and tamped. These sidewalks are apt to be dusty.

Gravel walks are laid 3 to 4 inches thick on a good subsoil. Where the soil is poor it is excavated and the space refilled with crusht stone, clinker, or screened gravel of large size. The total depth may be as much as 8 in, the wearing course being 0.25 to 0.5 inch of fine gravel or torpedo sand.

Tar Concrete sidewalks are built on a coarse gravel foundation, the stones being not more than 2 inches in greatest diameter, which is thoroly coated with

a hot coal tar before it is laid. On top of this course is laid the binding course composed of gravel, not exceeding 1 inch in its greatest diameter, mixt with a hot coal tar in an amount of 1 gal to 1 cu ft of gravel. These two courses are tamped and rolled until no further movement of the stone takes place, and are laid so that the total thickness after rolling shall not be less than 2¼ in. The wearing surface is composed of a mixture of sand and coal tar, 75% sand and 25% tar, and is laid on top of the binding course and rolled in so that the finished depth will be ¾ in at all points.

Asphalt Mastic sidewalks are constructed in France as follows: a mixture of natural rock asphalt, Trinidad asphalt and asphaltic oil is laid to a thickness of about 1 in on a cement concrete base about 4 in thick, the top of which has been treated with a layer of cement mortar ½ to 1 inch in thickness. A sprinkling of gravel is spread over the surface while the asphalt is still warm.

The Costs of various forms of sidewalk construction follow: cement concrete, including excavation and a cinder or gravel foundation, varies from about 80 cents to $1.50 per sq yd; brick on a sand and gravel bed, 70 cents per sq yd, Middle States, and $1.10 per sq yd, New England States, including excavation and sand or gravel bed; flagstone, from $1.75 to $3.00 per sq yd; tar concrete approximately 60 cents per sq yd.

Stone Curbs are usually composed of granite, blue stone, limestone, or sandstone. They are 4 to 12 in wide, 8 to 24 in deep, and 3 to 8 ft long. The top and front faces are drest, the latter being given a slight batter to keep wheels away from the top edge. The ends are square drest, and the curbs are so laid that the ends come about ⅛ in apart. Curb stones are most commonly laid on a well compacted sand base.

Concrete Curbs are common, laid usually "in situ" on a sand base. They should be separated from the sidewalk by an expansion joint. Several types of combination concrete curbs and gutters are on the market, practically all of which are laid "in situ" and some of which are reinforced.

The Cost of Curbing is as follows: granite, $1 per lin ft, including cost of setting; concrete curb 8 in wide by 24 in deep, approximately 60 cents per lin ft, including cost of laying.

Gutters are from 1½ to 6 ft wide, some having the same fall as the roadway, with the lowest point next to the curb, and others having the lowest point at the center, thus forming a trough section. In the latter case the depth at the center will vary from 4 to 9 in. Cobblestones, as commonly used, are laid on a 6-in to 10-in bed of sand or gravel. These stones are 3 to 8 in in their longest dimensions, and are laid on a sand or gravel bed with broken joints. The joints are filled with sand, after which the surface is rammed and covered with a thin sand layer. Gutters are also constructed of brick and stone block. In brick, stone block, and asphalt pavements, the gutters are formed in most cases by extending the pavement to the curb. The cost of cobblestone gutters is approximately 75 cents per sq yd.

25. Street Cleaning and Snow Removal

Formation of Dust. The formation of a large part of street dust is due to the deposition of dirt adhering to the wheels of vehicles coming from adjacent earth, gravel, or macadam streets, the leakage of the contents of loaded vehicles both in transit and while loading and unloading, the excrements of animals, and the abrasive action of traffic. Other sources of street dust are mineral matter applied to the surface of streets, the decay of leaves, bark, twigs, and other vegetable matter, dust from manufacturing concerns, and soot and ashes from chimneys. It is always a public nuisance. Under traffic it forms heavy clouds

to such an extent as to obscure the traveled way; when wet it forms a mud which renders footing dangerous to both man and beast, and may cause skidding of wheels.

Methods which have been found applicable to various types of roads and pavements in urban districts are as follows: Earth, gravel, and broken stone roadways are cleaned by gangs or patrolmen with push brooms or by horse-drawn or motor-driven rotary sweepers. Bituminous surfaces, and good brick, bituminous and wood block pavements are cleaned of coarse dirt by gangs or patrolmen during the day and by hose flushing and squeegeeing or by rotary scrubbers during the night. Brick, in poor condition, and stone block pavements are cleaned during the day by gangs or patrolmen and during the night with rotary brushes and hand or machine flushing methods. In connection with all the methods, the dirt is forced to the gutters and is usually removed by gangs with wagons following the machines.

Hand Cleaning is done either by gangs or patrols. In the first-named method, the pavement is cleaned at frequent intervals, while in the latter case each patrolman has a certain definite area to clean every day, his equipment consisting of a push-scraper, push-broom, shovel, and usually some type of can-carrier to collect the refuse in. The material is collected in cans or bags and placed to one side, or is swept into heaps at the side of the street to await the arrival of wagons which cart the refuse to the public dumping-ground. In almost every city of size in Europe may be found a patrol system well organized and highly efficient, but in this country the poor supervision and general indifference given to the matter are usually responsible for the lax and shiftless systems encountered in so many of our smaller cities. Hand sweeping is entirely confined to the day time.

Horse Sweepers are employed in many cases, the work being done generally at night. Such sweeping should always be preceded by sprinkling to ensure the laying of dust. There are numerous combined sweepers and sprinklers, both horse-drawn and motor-propelled, in use in Europe. This treatment alone is excellent on streets subject to light traffic, but on the heavier-traveled thorofares should be supplemented by hand sweeping during the day. A pavement in good repair is essential for best results with a mechanical sweeper. For cleaning asphalt pavements a sprinkler combined with a rotary scrubber is employed with good results. The scrubber is a cylinder fitted with a series of rubber blades.

Hose Flushing is employed to a considerable extent in Europe, and is used to some extent in this country. The material is carried in suspension to the sewer thru the nearest catch-basin. This treatment is particularly efficient in removing all fine dirt, but it necessitates the preliminary removal of all coarse material, which might in time clog the ordinary sewer-pipe. Flushing is accomplished by applying a stream of water to the surface with a broad, sweeping motion. In addition, the pavement is scrubbed with rubber squeegees.

Motor-Truck Flushing Machines. There are various types of flushing machines used on sheet and block pavements which throw the water in broad fan-shaped sprays over the surface, thus washing the dirt into the gutters.

Snow Removal in Urban Districts. Wm. H. Connell describes and classifies the common methods as follow: (1) Plowing the snow to the side or center of the street by means of automobile or horse-drawn plows, after which it is piled and then loaded into vehicles and hauled to dumps, which may be sewer manholes or rivers and in some cases open lots. This general method of disposal should start when the snow begins to fall and plows should be kept continuously at work during and after the storm until all of the snow is removed from the

streets. (2) Panning (supplemental method), which consists of pushing the snow into the sewer manholes by means of a specially constructed form of scraper, usually constructed of iron, which may be likened to a very large snow shovel. (3) Flushing the snow into sewer inlets or manholes (supplemental method). This is done by means of a hose or by running power flushing machines up and down the streets and forcing the snow to the gutter, following with a gang of men brooming the melted snow into the sewer inlets.

Highways Outside Urban Districts. Conclusions from 1919 Report of Committee, Am. Road Builders' Assn. "On main traveled roads snow must be removed to the road surface and for the full width. Methods: (1) Prevent the excessive accumulation of snow wherever possible by the use of snow fences and the removal of the natural causes of these accumulations. (2) Wherever speed is essential and enough equipment can be provided to keep ahead of the storm, plows attached to the front of motor trucks have proved the most efficient method of removing snow. These must be supplemented by local assistance wherever drifts and excessive accumulations cannot be prevented, and wherever snow must actually be moved away. (3) Wherever speed is not so essential and the depth of snow fall is not too great, road machines and plows drawn by horses or tractors are satisfactory. (4) Wherever the fall is great, the snow may be rolled in the outlying districts, and must be removed from the roadway in thickly settled sections, where hand methods are the only satisfactory solution."

MACHINERY

26. Crushing Plants

A complete crushing plant for road-building purposes consists of a boiler, engine, crusher, elevator, screen, and storage bin.

The Crushers are of two distinct types: namely, the gyratory and the jaw crushers. Both types of crushers have some means of regulating the openings so that, by using the proper opening together with appropriate crushing plates, almost any size of crusht product can be obtained. The size of the crusht product is limited by the smallest opening between the crusher plates at the outlet end of the crusher. The gyratory crusher is a more recent invention than the jaw crusher. That the gyratory crusher produces a more uniform product and is a more durable machine are the main advantages claimed for it over the jaw crusher. With the same horse power this type of crusher will generally produce a larger output.

The type and size of crusher to be used depends upon the nature of the rock to be crusht, the size of the product desired, and whether or not the plant is to be permanent or portable. The output of any crusher will depend to a large extent upon the plant arrangement. This latter consideration should be given serious study. It will be found that the smaller the stone is crusht, the less will be the output of a crusher, since just so much more work must be done in crushing the stone.

The Gyratory Crusher is extensively used for permanent plants. Its great weight and height have not made it generally adaptable to portable plants, altho it is sometimes made for this purpose. A description of portable gyratory crushers is given as follows:

Dimensions of each receiving opening in inches	7 by 32	8 by 35	10 by 40
Capacity in short tons per hour	10 to 20	20 to 40	30 to 60
Diameter of ring in inches	1.5	2	2.5
Horse power required	15 to 20	18 to 25	22 to 30
Weight of mounted crusher in pounds	12 000	16 000	18 000
Approximate price on wheels	$1250	$1600	$1800

In the following are given data of gyratory crushers adaptable for permanent plants:

Dimensions of receiving openings in inches	8 by 30	10 by 38	12 by 44	14 by 52
Capacity in short tons per hour	15 to 40	30 to 70	50 to 90	80 to 120
Diameter of ring in inches	1.5 to 3	1.75 to 3.5	2 to 3.5	2.5 to 4
Horse power required	14 to 21	22 to 30	28 to 45	50 to 75
Weight of crusher in pounds	20 900	31 200	45 500	64 800
Approximate price	$1400	$1700	$2300	$3000

Jaw Crushers are largely used for portable crushers. They are placed on a framework which is supported by four wheels. They are designated by the size of the jaw openings at the top. The size of 8 by 16 is very commonly used. The following shows the weights and capacities of several typical sizes:

Size of openings in inches	8 by 16	9 by 18	10 by 22
Capacity in short tons per hour	9 to 14	12 to 20	16 to 25
Jaws set to, in inches	2	2	2
Horse power required	12	15	25
Weight of crusher in pounds	7500	9600	13 500
Approximate price on wheels	$735	$900	$1400

The crushers may be run by gasoline engines or by steam engines, the latter being perhaps more common. The steam engine is generally mounted upon a horizontal boiler, which is in turn placed on wheels so that it can be easily transported from place to place. This last type of engine and boiler is made in sizes capable of developing from 4 to 50 h p and costs about $30 per h p. Gasoline engines, which develop from 10 to 25 h p, cost from $40 to $50 per h p.

Elevators and Screens. The stone as it comes from the crusher is carried by means of a bucket elevator to the revolving screen, which is fixt over the bin. In portable plants the arrangement of the elevator, the screen, and the bins is such that they can be readily dismantled for transportation purposes. The elevators and screens are made in standard sizes, the lengths depending upon the size of the crusher and bin. Unless the elevator is to be housed in, the buckets should be fixt to a chain drive, rather than fixt to a revolving belt, from the standpoint of durability. The prices of screens and elevators with gears and skids depend upon the length and size. A 10-ft screen with gears and skids will cost from $200 to $300. A 16-ft elevator will cost about $300.

The Portable Bins are generally made with three compartments. These bins are made in sizes varying in capacity from 13 to 50 short tons. In some of the more modern types of portable bins, provision is made so that the bin can be raised to a height which will allow teams to pass beneath the unloading chutes. An average price for this type of portable bin is approximately $10 per short ton capacity.

Small Tools. The prices of small tools are as follows: No 2 hand shovels, $6.00 to $9.00 per dozen; No 2 hoes, 4 by 11¼ in, $4.00 per dozen; railroad picks, $6.00 per dozen; pick handles, $3.25 per dozen; 10-tine stone forks, $17 per dozen; 4-tine stone hooks, $9 per dozen; 2-man 12-tooth rakes, $26.50 per dozen; crowbars, 5 cents per lb; stone hammers and sledges, 8.5 cents per lb.

27. Rollers and Scarifiers

Rollers. Two types are manufactured, 3-wheel and tandem rollers. The common size of the 3-wheel rollers varies in weight from 10 to 18 short tons while the tandem rollers vary from 2.5 to 12 short tons. The 3-wheel roller is used to a great extent in ordinary macadam construction, the heaviest size being used in the construction of roads where the stone is either very large or of an extremely hard nature, such as trap rock. The tandem rollers have been mostly used in the construction of sheet-asphalt, bituminous concrete,

brick and wood block pavements. Both types of rollers in this country are commonly run by steam, altho there are some makes which are run by gasoline engine. Rollers in Europe equipped with this latter power have been found to be particularly advantageous, since the roller can be made more compact; no time is lost in waiting to get up steam; the rollers are less noisy; they are smokeless, and capable of much more rapid movement; and they are found to be particularly useful in repairing patches and on maintenance work. Within the past few years the use of the heaviest types of rollers in constructing bituminous concrete pavements has been found detrimental. A 12-ton roller has sufficient weight to do all the work required. The tandem rollers will in the future without doubt be more largely used on this type of work. Successful construction does not require the heavy weight so much as it does a steady rolling, which gradually brings the different particles of stone together in juxtaposition without actually crushing them. The rear wheels of all 3-wheel rollers are provided with holes in which spikes may be inserted for picking up the road. These spikes, however, do not accomplish the same work as a good type of scarifier.

Cost. Three-wheel rollers varying from 10 to 15 short tons in weight cost from $2500 to $3500 f o b at the factory. Tandem rollers varying from 2.5 to 12 short tons in weight cost from $1300 to $3000.

Scarifiers. In the United States most of these machines consist of a heavy cast-iron block on two or four wheels, which holds a series of steel picks. The blocks weigh about three short tons. These picks can be adjusted in the block or the block itself so arranged that any depth desired up to 5 or 6 in can be picked up. The picks are arranged in either a straight line, or in two lines which together form a V. Most of the scarifiers are so designed that it is not necessary to turn them around. This is accomplished generally by having two sets of picks, one set being used when the machine runs in one direction, and the other when in the opposite direction. Scarifiers of this type are towed by a chain hitched to the roller. The arrangement of the picks and the form of the blocks vary, but all of the machines work on the same principle. The scarifiers of Europe are of two types, one of which is similar to the one just described, while the other is attached to the rear of a 3-wheel roller and is a part of the roller. It consists of a framework supporting a small block to which the picks are attached. This pick block is behind one of the driving wheels and the picks are set at such an angle that they are forced into the road by the tractive force of the roller and the weight of the block. The advantages of this type of scarifier are the ease with which it is handled and the saving in time obtained by having the scarifier so attached that it can instantly be put into operation when the roller is traveling in either direction.

A road surface will be much more easily scarified if it is first thoroly watered. The scarifier will rip up the surface, bringing the stone to the top, and allow the dirt and finer particles to go to the bottom. By using a scarifier it is possible to accomplish as much as one hundred times more work in a day than can be done by hand methods.

The price of many of the American makes of scarifiers is about $500 f o b factory.

28. Mixing Plants

Asphalt-Mixing Plants. A complete mixing plant used in the asphalt-paving industry includes elevators, dryers, storage bins, kettles for melting bituminous material, and a mixer capable of mixing the sand and bituminous material, all suitably arranged so that the operations follow one another in such a manner that none of the ingredients of the mixture have to be handled

by hand from the time they are placed in the receiving end of the machine until they leave the outlet end. The above apparatus is installed as a stationary plant, or is mounted permanently on either one or two flat cars as a portable plant.

Bituminous Concrete Mixing Plants. Mixing plants may be divided into four classes: first, cement-concrete mixers; second, cement-concrete mixers with heating attachments; third, dryers, storage bins, and mixers; fourth, dryers, storage bins, weighing devices, and mixers.

Cement-Concrete Mixers. Unheated broken stone has been mixed with tars or heavy asphaltic oils in the ordinary type of concrete mixer. With this type of plant asphalt cements of low penetration at normal temperatures cannot be mixed with unheated aggregates, as it is generally impracticable to coat the unheated broken stone with the hot asphalt cement. This class of mixers should not be used for the construction of bituminous concrete pavements.

Cement-Concrete Mixers with Heating Attachments. There are several different types of this class of mixing plant in current use. In one type the heat, in the form of hot air, is passed into the mixer by means of a large iron pipe, which runs from the fire-box to the outlet end of the mixer. A second type consists of a cylindrical mixer mounted on a four-wheeled truck. Heat is obtained from a hot-air jacket entirely surrounding the cylinder except on the ends and by means of a kerosene torch inserted within the drum. In a third type, hot air obtained by the combustion of oil in air is led from the combustion chamber into the mixing cube. After the mineral aggregate is heated the bituminous cement is added. A fourth method of utilizing concrete mixers is to use a rotary dryer, as a part of the plant, for drying the aggregate.

Dryers, Storage Bins, and Mixers. In several types of plants the aggregate is heated in rotary dryers from which the dried material is transported by elevators to storage bins. In some cases the aggregate is raised to the storage bins before being dried. As required, the aggregate falls by gravity into the mixer. The heat for the dryers and the mixer is obtained by direct heat from fire-boxes or by oil-burning apparatus.

Dryers, Storage Bins, Weighing Devices, and Mixers. In a complete plant for the manufacture of bituminous concrete, the aggregate is carried by bucket-elevators to rotary dryers, where it is dried and the dust exhausted; from the dryer the aggregate is raised to the storage bins by elevators; when required the aggregate is drawn from the bins to a weighing device and from there deposited into a mixer.

Kettles are made in different shapes, mounted on wheels or otherwise, and vary in size from 50 to 1500 gal. The smallest sizes are generally cylindrical in shape. Portable kettles are usually heated by direct fire. Kettles used in asphalt-paving plants are usually heated by means of steam coils.

Small Tools. The prices of small tools are as follows: asphalt or tar rakes, 18-in iron shank, $12.85 per dozen; asphalt mattocks with crucible steel cutter, $9 per dozen; tar-carrying pails, $2.70 each (see Engr.-Contr., Apr. 5, 1911).

29. Distributors

Distributors may be divided into two classes: namely, pressure distributors and gravity distributors. Under the gravity type may be included the Pouring Pots. There are several different makes of pots, all of which are somewhat similar to the ordinary watering-pots, except that the nozle and spout are replaced with other devices by means of which the material is poured onto the road in a sheet rather than in streams.

Gravity Distributing Machines include hand-drawn gravity distributors from which the material flows in the form of a sheet, tanks from which the bituminous material flows by gravity through a hose and nozle onto the road, machines with distributing apparatus consisting of one or more horizontal pipes pierced with small holes from which the material flows in small vertical streams onto the road surface or onto a flash board and from the board to the surface

of the roadway in the form of a sheet. The general practise in Europe in using machines of this type is to follow the distribution by brushing the material into the road. This is done either by hand brooming or by brooms which are attached directly behind the distributor.

Pressure Distributors. The various types of distributing machines of this class may be grouped in the following subdivisions: hand-drawn distributors, n one type of which the material is pumped from the tank through a length of lexible hose to an iron pipe fitted with one or more nozzles, while in another the heated material is pumped into the distributor and applied to the roadway surface by pressure from a tank of compress air; pressure tanks to which are attached hose and spraying devices or horizontal distributing apparatus; and machines equipped with mechanical power-pumps between the tank and the listributing apparatus. Several machines of the last type have been invented n the United States. The distributing devices of all of these machines are alike in having horizontal pipes fitted with nozzles. The machines differ somewhat in the way the pressure is obtained and applied. Pumps, run by a sprocket-drive attachment on the rear axle, by steam and by gasoline, are utilized. Horses and steam-rollers are used for hauling. Some distributors are mounted on motor-trucks.

The Am. Soc. of Mun. Imps. prescribed in its 1918 specifications the following requirenents to secure uniform distribution and to provide for such details as means of control of proper pressure and temperature and prevention of rutting of the wearing course of bituminous macadam pavements during construction: "The pressure distributor employed shall be so designed and operated as to distribute the bituminous materials specified uniformly under a pressure of not less than 20 lb nor more than 75 lb per sq in n the amount and between the limits of temperature specified. It shall be supplied with an accurate stationary thermometer in the tank containing the bituminous material and with an accurate pressure gage so located as to be easily observed by the engineer while walking beside the distributor. It shall be so operated that, at the termination of each run, the bituminous material will be at once shut off. It shall be so designed that the normal width of application shall be not less than 6 ft and so that it will be possible on either side of the machine to apply widths of not more than 2 ft. The distributor shall be provided with wheels having tires each of which shall not be less than 18 in in width, the allowed maximum pressure per sq in of tire being dependent upon the following relationship between the aforesaid pressure and the diameter of the wheel: for a 2 ft diameter wheel, 250 lb shall be the maximum pressure per linear in of width of tire per wheel, an additional pressure of 20 lb per in being allowed for each additional 3 inch in diameter."

30. Street Cleaning Apparatus

The Ordinary Push-Broom is universally used in street cleaning operations. n this country the brooms are about 16 in wide, and the head is filled with split bamboo, rattan, hickory, or steel wire. One edge of the broom-head is sometimes fitted with a steel scraper. These brooms are used for heavy sweeping. For lighter and more thoro sweeping the head is filled with basswood, which s more pliable than some of the other forms of fillings. In Europe hand brooms made out of birch or other twigs are still used to some extent for light sweeping. Push-brooms, similar to those employed in the United States, are in general use. n one form of push-broom the filling is enclosed by a wooden clamp that can be moved up and down so as to make the filling as stiff as desired. The average price of hand push-brooms is about $8 per dozen. A small rotary sweeper on three wheels, pushed by hand, has been used in Europe. A man with this machine can sweep three times as much area as he can with the ordinary push-broom

Rotary Horse-Drawn Sweepers are made to sweep widths varying from 6 to 9 ft. By means of levers operated by the driver the broom can be made to engage the road surface with either a light or heavy pressure. The brooms are filled with rattan, split bamboo, or hickory. A 2-horse rotary sweeper with steel frame will cost about $500. A 1-horse sweeper with wooden frame will cost about $300.

Motor-Truck Sweepers have been used in Europe for several years. In France it was found that altho they could accomplish four times as much work with this type of machine as with horse-drawn types and with a lower operating cost per square yard, yet the method was too costly on account of the charges for sinking funds and repairs.

Hand Pick-up Sweepers. Several types of pick-up sweepers have been designed and used. One of the most successful is pushed by hand, and consists of a rotary brush geared to the wheels. The brush is covered in with a hood and operates on the carpet-sweeper principle, throwing the sweepings into a pan which is a part of the machine. The sweeper will clean at one passage a strip 30 in wide. The cost of this sweeper is about $90.

Squeegees and Scrubbers. The squeegees are made of wood or metal with a rubber edge in widths varying from 12 to 20 in. They cost about $1 each. The rotary scrubbers are built on somewhat the same principle as the rotary sweeper and are attached to a cylindrical sprinkling wagon. As the water falls upon the surface it is pushed toward the gutter by the scrubber. This machine complete costs about $1300. Hand scrapers for use in cleaning asphalt pavements cost from $2 to $4 each, depending upon the size. They are made about 36 in wide.

Bags and Cans. Sweepings may be collected in galvanized iron cans or in bags which are later removed by wagons. Cans of this sort cost from $2.50 to $4.00 each. Bags cost 5 to 8 cents each. A 2-wheel truck for carrying a bag to hold the sweepings costs about $14. Cans for holding sweepings are fixt to a wheel truck in such a manner that they can be attached and detached from the truck by a very simple operation. A dust pan is also attached into which the sweepings are broomed. The pan can be raised by a lever and dumped into the can. The truck is pushed by hand. This machine complete costs about $30.

Horse-Drawn Sprinklers. In connection with street sweeping, sprinkling is necessary to prevent the dust rising. Sprinkling carts of the ordinary cylindrical-tank type, having capacities varying from 400 to 800 gal, are very common. A 600-gal sprinkling wagon costs about $500.

Motor-Truck Sprinklers, some of which have the sprinkling attachments on the front of the machine instead of in the rear, are used in Europe. The iron tanks of the European sprinklers are rectangular rather than cylindrical in shape as in this country.

SECTION 16

HARBOR AND RIVER WORKS

ASSOCIATE EDITOR

REAR ADMIRAL FREDERIC R. HARRIS, C.E.C., U. S. NAVY

FORMERLY CHIEF OF THE BUREAU OF YARDS AND DOCKS OF THE NAVY AND GENERAL MANAGER, U. S. SHIPPING BOARD EMERGENCY FLEET CORP.

Wm. M. Torrance, M. Am. Soc. C. E., assisted in compiling data and supervising preparation of drawings.

M. J. McPike and M. Kaufmann prepared drawings.

* Chas. W. Staniford, Chief Engineer, Dept. Docks and Ferries, N. Y., furnished some of the drawings and data in these articles.

Lieut. H. B. Overesch, Jr., C.E.C., USN., and Lieut. H. D. Rouzer, C.E.C., USN., assisted in compiling the data and securing illustrations for the revision of this section. Mr. Joseph Michaelson assisted in the preparation of the discussion of length of sheet piling on page 1730.

HARBORS

1. General Information

A Harbor is a refuge for ships, a port or haven. From the very earliest understanding of the term, it was a sheltered arm of the sea in which vessels could be built and launched. and taken for repair, or seek refuge in time of storm. One of the requisites was a good anchorage or holding ground. Such cargo as was carried by the vessel was transported to the shore by smaller craft or carried to the vessel by hand. Natural harbors are those which, in themselves, are usable without resort to engineering works of improvement. Primitive harbors were almost always of this character. With the increase in size and draft of vessels most of the so-called natural harbors have required works of extension and improvement. As a distinctive term, a natural harbor may be considered as one located on an estuary or an enclosed bay. Artificial harbors, in a more restricted sense, are those requiring the construction of extensive engineering works, such as breakwaters for protection of the shipping from wave action, or where shallow or otherwise unsuitable areas have been excavated and deepened and other improvements made in order to make them available for the purpose intended.

Prevailing usage fails to distinguish clearly between the term " harbor " and " port." When to a harbor is added terminal facilities, the harbor becomes a port. A haven of refuge for shipping from storm and the elements would not be a port unless to the usage made of this shelter there are also added the facilities for loading and unloading the vessels and re-shipping or supplying the necessary cargo by land-drawn and water-borne supply lines and feeders. R. S. MacElwee suggests as a definition, " The harbor may be defined as consisting of the water ways and channels as far as the pier head lines, the port to include everything on the landward side of those lines, that is, the piers, slips, wharves, sheds, tracks, handling equipment, etc.," and suggests that this distinction, while technical and novel, tends to mark off distinctly the lines of the jurisdiction of the Federal Government as against that of the State and municipal authorities. This technical restricted definition would appear to have advantages, but it is believed the term port should be considered the general one and includes the harbor while the harbor does not include the port.

Design. Harbors are usually located by force of circumstance over which the engineer has little or no control. This is especially so with natural harbors where the local geographical advantages and growth of population have resulted in the need for, and location of, harbors irrespective of the existence of better natural harbor facilities at points not far distant. The best natural harbors are probably, by reason of the very facilities they offer, often centers about which important interests and activities grow. In cases where the engineer has some voice in the selection, a thoro survey should be made of the neighborhood, including the foreshore and the depths of water in the vicinity. Borings and soundings should be taken to ascertain the character of the ground, both as to anchorage and as regards the readiness with which it will lend itself to economical dredging or deepening operations, should such be necessary. In an important harbor the depth of water should be sufficient to meet the requirements of the maximum draft of vessel likely to use the harbor, allowance being made for over-depth for the pitching and surging of vessels under wave action and the drag or set of vessels when underway. Borings on land should also be made to indicate probable subsurface conditions with a view to future location of the necessary harbor works. Observations should be made as to the meteorological phenomena, such as prevailing winds, frequency of

storms, height and force of waves, establishment of mean high and low water and range of tide, direction and velocity of prevailing currents, evidence of silting and of littoral drift.

The large ports and harbors of the world, especially the older ones, were undoubtedly located to afford shelter and protection not only from the elements, but from the enemy and to protect the shipping while laid up from destruction and ravages of raids which were frequent in ancient, medieval and comparatively recent times. This condition was common in the Mediterranean and in the North Sea; consequently we find many old ports some distance up rivers, probably located as far up as the vessels of these times could be navigated. The facility with which the river and its tributary branches could be used as a water highway by light draft craft for transporting cargo undoubtedly had an important influence, as water transportation had many advantages over the possible land transportation conveniences available in those times. As a consequence we find the large European ports, such as London, Liverpool, Antwerp, Hamburg, etc., river ports to which, with the change in times and the increase in size of vessels, the sea had to be brought by continuous expensive harbor and river work in order that they might retain their supremacy as ports, or others which have disappeared or are no longer ports, as for example Paris.

On account of the facility with which land transportation, especially rail, can now be handled, the newer ports, especially of the United States, are located on the seacoast or on estuaries, probably explaining the reasons for the location of river and sea ports. This same condition has caused the development and construction in European practice of wet docks together with those reasons given in Art. 24 of this Section.

Tides. The tidal day is always of greater length than the solar day, two tides occurring, generally, in each day, high tide being on an average 50 minutes later every day. While the tides on the coast line are produced by the sun and moon, this is not due to their immediate effect on the waters of the sea adjacent to the coast line, but is due to secondary tidal waves, resulting from primary waves in the wide expanse of the oceans. It is calculated that the primary effect of the moon on rise of tide is 1.34 ft, and of the sun 0.61 ft, or together 1.95 ft, or against each other 0.73 ft, the velocity of the primary tidal wave being from 50 to 60 miles an hour. The momentum of this mass moving around the earth, taken in connection with the shoaling of the ocean and configuration of the coast line, explains the very great variation in range of tide found at different localities. The atmospheric condition, by reason of the pressure on the surface of the water, affects the tidal range inversely as the height of the mercury in the barometer. Sudden variations of the height of mercury in the barometer will give a difference of about 0.35 inches for each foot of tidal range for each inch variation in height of barometer. Tidal range is affected considerably by wind, dependent upon location, and characteristics of the coast line, and the force, direction, and continuation of wind

Tidal Changes. Engineering works of improvement in harbors or rivers may result in quite surprising changes in tidal conditions. In the location and construction of harbors and harbor works, it is of the greatest importance to ascertain definitely the data of high and low water and range of tide, for which purpose automatic tide gages should be used. Elevation of mean high and mean low water at the various important parts of the United States can be readily secured from local authorities, or from the U. S. Coast and Geodetic Survey, but in important new harbor work, it is advisable to establish these independently. Altho the height to which the surface of the sea rises and falls at different points along the coast varies considerably, yet there is a mean level to which,

at a certain stage of the tide, the water returns. This is known as mean sea level. Where possible, it is advisable to refer to this datum.

Tidal Prism. This is the volume of water represented by the area of the bay, river or harbor effected by tidal changes multiplied by the range of tide which would generally be the volume of water entering at the flood and leaving at the ebb. Harbor engineers are loath to permit the construction of any works that will serve to change materially this tidal prism, as a decrease in the tidal prism has a direct effect upon the quantity and velocity of the water of the ebb and flood tide and a consequent effect upon the channel depth and direction by reason of the resulting tidal scour.

2. Waves

Wave Height. In the location of harbors and the design of harbor works, it is necessary to ascertain the probable maximum wave action and forces likely to be encountered. The height of wave to which an exposed entrance may be subjected will depend upon the greatest fetch or reach of open sea from the windward shore; for open exposed locations

$$H = 1.5\sqrt{d}$$

where H is the height of the wave in feet, and d is the length of fetch in miles. For shorter lengths of exposure in bays, or harbors, this height is represented by

$$H = 1.5\sqrt{d} + (2.5 - \sqrt[4]{d})$$

Extensive observations closely check the results obtained by the application of these two formulas, first proposed by T. Stevenson, it being borne in mind that in the open sea the fetch is confined to the distance over which the wind acts continuously in one direction, the rotary character of ocean storms restricting the applicable fetch even in the broadest expanses of the Pacific Ocean to a distance of not over 1000 miles.

Formation of Waves. The direction of the wave crest in deep water is at right angles to that of the wind, but, on approaching the shore, it tends to come parallel to the shore line, due to the lagging effect on the wave of the rising bottom. Most waves are caused by the action of the wind, due to the wind blowing over the surface with varying velocity, acting by friction on the surface and by direct pressure on the rear of the wave crest. A confused sea existing during a heavy storm usually changes to a regular swell afterward, resulting in trochoidal seas. Waves formed in this manner in deep water are generally understood to be oscillatory waves, in which the particles of water forming the wave move thru circular or elliptical orbits. This is not strictly correct as, undoubtedly, all storm waves are to some extent waves of translation. Deep water storm waves on reaching shallow water become waves of translation, the friction of the rising bottom on the lower portion of the wave tending to retard this to the point where the front of the crest of the wave becomes steeper and steeper, and finally breaks and becomes a breaker or comber.

Wave Velocity in deep water is dependent upon the velocity of the wind, taken together with its continuity, and the extent of the surface of the sea over which it acts which, in turn, affects the height of the wave and the wave length, and may be given by

$$V = \sqrt{5.123\,L} \text{ for deep water waves}$$

$$V = C\sqrt{5.123\,L} \text{ for shallow water waves}$$

in which the coefficient C is the square root of the ratio of the axes of surface orbits b/a, it being recalled that the shoaling depth changes the orbits from

circular to elliptical, V being the velocity in feet per second, and L length of wave in feet. It is only necessary to use the coefficient C in cases where the depth of water is less than one-half the wave length. The following are values of C:

d/L =	0.05	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45
C =	0.552	0.746	0.858	0.922	0.958	0.977	0.988	0.994	0.997

in which d = depth of water, or distance from the center of the surface orbit to the bottom, and L = distance from a wave crest to the next.

The relation between wave height and length is dependent upon wind, sea and other local complex influences; in general the proportion between length and height may be taken as: 33 for moderate wind and light sea, 20 for strong wind and rough sea, 18 for storm and heavy sea.

The wave pressure varies greatly; pressures as high as 7840 lb per sq ft have been recorded. A series of observations at Skerryvore Rocks and at Tyree gave results: 6 ft swell 3041 lb; 10 ft ground swell 3041 lb; 20 ft heavy sea 4562 lb; strong gale, heavy sea 6083 lb per sq ft.

Wave Energy of a wave of one unit width, with length L and height H is

In deep water, $E = 8\,L\,H^2\,(1 - 4.935\,H^2/L^2)$
In shallow water, $E' = 8\,L\,H^2\,(1 - 19.74\,a^2/L^2)$

in which a is the semi-major axis of surface orbits, H and L are in feet, and E is in ft-lb. This energy is for salt-water waves; for fresh-water waves reduce amount by 2½ per cent.

Values of a in Terms of Wave Height H

d/L =	0.10	0.15	0.20	0.25	0.30	0.35	0.40
a =	$0.91H$	$0.68H$	$0.59H$	$0.55H$	$0.52H$	$0.51H$	$0.504H$

When a wave enters a bay, or arm of the sea, between natural or artificial barriers, its height tends to decrease on account of friction of the shoaling bottom and the retardation due to barriers, and on emerging into open, interior water, further decreases in height due to distribution and the tendency of the wave crests to diffuse parallel to the shore line.

Wave Action. The percentage of wave height above water level is important as indicating the height to which harbor structures may be subjected to direct wave action. Observations indicate that, in general, about two-thirds of height of the wave is above mean water level, and about one-third below. Due to the action of high winds, opposing currents and further unknown causes, deep sea waves may break partially in water of sufficient depth for their free propagation, so that a barrier opposed to them in water of great depth may at times be subjected to the direct action of breaking waves. It is known, however, that waves invariably break on reaching water of insufficient depth. Considering the height of the maximum wave as determined by actual observation, or by application of Stevenson's formula, the ratio of depth of water to wave height in which waves may break will vary from 1 to 2.71, or 1.67 being a mean ratio taken from 134 observations. Where wave action is arrested by barriers, a portion, at least, of the wave energy will be exerted against this barrier. It is important in designing harbor works that such artificial barriers be made strong enough to resist the successive attacks of maximum sized storm waves. Wave force is exerted and transmitted against such barriers in divers ways, some of which are as follows: (a) The force may be static pressure due to the height of the column of water. (b) It may result from the effect of rapidly moving particles of the liquid. (c) It may be due to the impact of floating bodies on the surface of the water hurled by the wave against the barrier. (d) It may result from the rapid subsidence of masses of water thrown against the structure, producing a partial vacuum and causing sudden pressure to be exerted from within. (e) Destruction of the structure may result from the fall-

ing on it from above of large and heavy masses of water thrown up by the wave action.

The interior of such barrier structures is also often affected by forces transmitted thru joints or cracks, by hydraulic or pneumatic pressure. The most destructive effects of waves are exerted at or about sea level. The result of wave action may be apparent at considerable depths, altho diminishing considerably in force and extent. It should be considered in the design of structures subjected to wave forces that the material entering into the structure is, at least, partially submerged and that, therefore, the weight of the mass submerged must be considered. Consideration should also be given to the presence and movement of ice where harbor works are located in colder climates.

3. Breakwaters

Uses of Breakwaters. A breakwater is a work or barrier constructed around or in connection with artificially sheltered harbors in order to protect the interior water areas from the effect of heavy seas, and make it possible for this area to be used for the safe mooring, operating, handling, loading, and unloading of shipping. Breakwaters are almost invariably a most prominent and essential feature of artificial harbors, and are employed to convert an open area or roadstead into a harbor or in rendering more secure and usable harbors that are enclosed and protected, excepting against the sweep of the sea with prevailing winds coming from certain directions. Breakwaters on a smaller and less important scale are sometimes constructed in the interior areas of large natural harbors to protect shipping from wave action under conditions of heavy storms from an unfavorable direction. A breakwater, the protected side of which is used as a quay for wharfage, is also known as a Mole.

Design. There are three general types of breakwaters: First, that in which the exposed face is vertical. Second, partially vertical and partially inclined. Third, inclined. The type to be selected is dependent upon local conditions. Claims in favor of vertical type of breakwater are that the action of deep sea waves being purely oscillatory, the wave force encountered is due to water head pressure, dependent upon the height of waves. As has already been stated, nearly all waves are to some degree waves of translation, and as breakwaters are usually located and constructed in comparatively shallow waters, the wave forces to be encountered are more complicated than those due purely to hydrostatic pressure and, undoubtedly, vertical face breakwaters are subjected to severe wave impact. The combination of the inclined and vertical face often results in the throwing up, vertically, of large masses of water which, in turn, fall on the top of the breakwater directly behind the parapet. In crib breakwaters, with heavy timber decks, structures have often been seriously damaged by such action. In inclined breakwaters there is danger, if these are not carried high enough and surmounted by vertical wall, with heavy storm waves, that these will sweep entirely over the breakwater, resulting in a disturbed effect, and quite an appreciable secondary wave action behind the breakwater. When waves impinge obliquely in the direction of the breakwater, they often accumulate size and energy as they travel along its front. In the design of harbor breakwaters, information should first be obtained as to the direction and force of prevailing winds, character of coastal currents, probable maximum height of waves, character of bottom or foundation and cost and availability of materials to be employed in construction.

Rubble-Mound Breakwaters are a more or less heterogeneous assemblage of rubble, riprap, or cobble, deposited without any particular regard to bond or bedding. This is the simplest form of breakwater and is usually constructed by the dumping of material into the sea from barges or cars run out on trestles

or staging. This operation is carried on until the mound or heap emerges from the water and is carried up a distance above the same, the action of sea and waves being depended upon to give the sides a natural stable slope. It is usual in constructing extensive works of this character to make some attempt at grading materials and to control the slopes, the interior being composed of cobble or smaller riprap and the sea-side of the breakwater of heavier and more massive stone. As the force of the wave decreases with the depth in deep water, the slopes are often steeper and smaller stones are used. Such a structure is often supplemented by placing heavy massive stone or concrete blocks on the sea side, while the slopes and faces above the sea level are roughly paved with blocks of stone or concrete.

Fig. 1

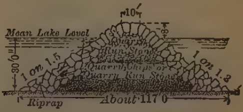

Fig. 2

Rubble-Mound Breakwaters

Figs. 1 and 2 show typical sections of rubble-mound breakwaters, Fig. 1 illustrating the first modification made in the Cleveland, Ohio, breakwater. The earlier breakwater had a complete sand core or hearting; during heavy storms, this hearting was washed out, resulting in the subsidence of the rubble top and eventual disruption. The work was finally built as shown in Fig. 2 with all sand omitted from the core and with rough instead of smooth stone covering. These breakwaters cost about $175.00 a foot. A rubble-mound breakwater of the same general type at Buffalo, N. Y., cost $135.00 a foot.

Timber Breakwaters consist of timber cribs floated out to place and loaded and sunk by being filled with rubble; or are built of close round piles or sheet-piles driven into the bottom, framed, braced and backed up with rock or concrete blocks. Timber cribs of this character are sometimes superimposed on rubble-mound breakwaters. Breakwaters of timber are more or less temporary structures and are principally used in shallow water for unimportant barriers. They have, however, been extensively used on the Great Lakes.

Fig. 3. Timber Crib Breakwater

Fig. 3 shows a typical timber crib breakwater built at Cleveland, Ohio, at a cost of about $175.00 per lin ft. This work was damaged by storms, masses of water projected upward by storm waves fell on the top timber work, breaking the cross members and planking. The work was reinforced by backing the structure with riprap. Somewhat similar timber crib breakwaters at Buffalo, N. Y., cost $151 000 and $165.00 per lin. ft.

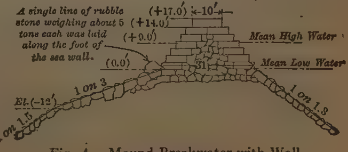

Fig. 4. Mound Breakwater with Wall

Masonry Wall Breakwaters are, in whole, or part, constructed in a regular and systematic manner of coursed stone masonry or concrete with vertical or inclined faces. Such walls are constructed in cofferdam in the dry or under water by divers or diving bells. This character of breakwater is often built from the tide level up surmounting a rubble-mound sub-structure or capping a timber crib.

Fig. 4 shows a low coursed stone wall breakwater surmounting a rubble-mound, at Dog Bar, Gloucester, Mass ; a somewhat similar breakwater at Sandy Bay, Cape Ann, Mass., was considerably strengthened by preventing the large blocks from sliding by fixing steel dowels into the stones on the harbor side against the toe of the course directly above.

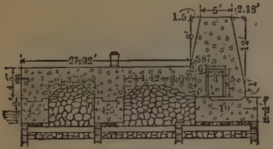

Fig. 5

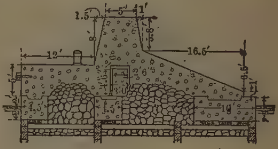

Fig. 6

Timber Breakwaters capped with Concrete

Figs. 5 and 6 show typical sections of the mole breakwater at Harbor Beach, Mich., consisting of a timber crib, capped with concrete blocks. The section shown in Fig. 6 was damaged by storm by having the concrete capping lifted and cracked. The cost of wall and composite wall breakwaters varies widely; the wall breakwater at Dover, England, in 50 ft depth, cost $1733.00 per ft; at Holyhead, a rubble-mound surmounted by a wall in 40 ft of water cost $790.00 per ft.

Reinforced Concrete Breakwaters may be built by means of reinforced caissons built on shore, or in floating structures, launched or lowered into the sea and sunk to place, and settled upon a prepared foundation of rubble or piles, by filling the compartments with stone or sand, or may consist of reinforced concrete piles and sheet-piling banked or filled with sand, riprap or rubble. See Sect. 5, Art. 38, page 565. In the following examples of breakwaters the numbers refer to Fig. 7.

(1) Zeebrügge, Belgium, 1905. Breakwater or mole 6560 ft long, lower course built of monoliths, set in floating caissons of structural steel and plating with concrete lining arches. Lower sections 82 ft long, 24½ to 29½ ft wide, 28 to 36 ft deep. Built in graving dock and floated out. Sills for setting 20 inches deep. Sections sunk at low water by flooding and then filled with concrete. Blocks weigh 1500 to 1600 long tons light and 4000 to 5000 long tons when filled.

(2) Barcelona, Spain, 1906. Section of floating caisson for monoliths for extending the breakwater. Blocks 39 feet long divided into five pockets, which were filled with pre-molded blocks.

(3) Touapsé, Russia, on Black Sea, breakwater 1400 ft long, largest caissons 56 ft long, 21 ft wide, and 21 ft deep divided into 21 divisions, 7 sets longitudinally. Caissons of reinforced concrete. Large boxes weighed 268 long tons when launched and 1600 long tons when filled.

(4) and (5). Talcahuano, Chili, 1908. Breakwater 1750 ft long, section (5), dam (4), each caisson 33 ft long, built of reinforced concrete and filled with sand and stone.

Breakwaters have been constructed employing floating caissons at Bilboa, Bizerta, and Algoma, Wis. See Sect. 5, Art. 38.

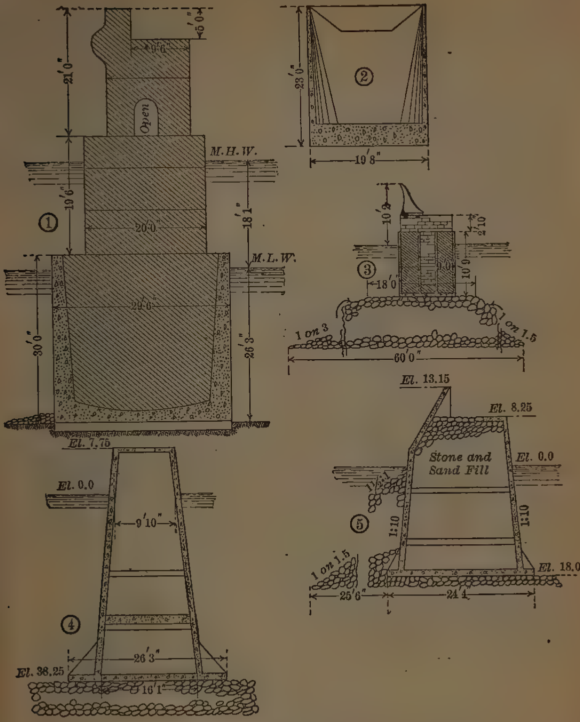

Fig. 7. Reinforced Concrete Floating Caisson Breakwaters

4. Bars. Sea Encroachment

Littoral Drift. The coast line of all exposed foreshores indicates a gradual but continual change, in some locations in the direction of retrogression or washing away, and in other locations in deposition and accretion, the carrying away and depositing of materials being due to wave action in connection with current flow. The breaking of waves on a beach or foreshore serves to stir up loose material and also to break up solid material by direct erosion or by the impact or wearing away, due to the carriage by the water of particles of sand and shingle; the lighter particles of such material remain in suspension long enough for them to be projected some distance along the shore by the resultant of combined wave action and littoral currents. The heavier particles are rolled along

the beach and partake of a zigzag movement, the principal action being generally confined to the reach between high and low water mark. Littoral drift is generally attributable to the prevailing wind direction, altho it is modified by onshore currents. Breaking waves acting on a beach or foreshore by reason of their velocity are carried some distance up the sloping beach, mixing with, and stirring up, the sand and shingle. The wave having spent itself, the water then runs back by gravity, but is met by the next oncoming wave, the returning water carrying in suspension and rolling down the beach some sand and shingle, the oncoming wave by reason of its greatest velocity being at the top or crest is carried over the returning water, the returning water setting up what is known as the "undertow." The material carried down, as the undertow loses its velocity, is in turn carried up again on the beach by returning waves moving backward and forward, as shown in Fig. 8.

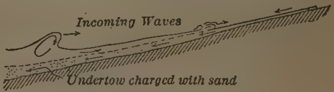

Fig. 8

The general effect of the wind on the foreshore, as shown in Fig. 9, tends to carry this drift of sand and shingle up the beach in a zigzag line. The actual action, as can be readily understood, is far more complex, but the general principle illustrated obtains. The drift varies, being dependent upon the direction and force of the wind, but, in general, the result follows the direction of the prevailing winds of the locality.

Bars. Bars at the entrances of harbors are of four general classes: (a) Natural bars, consisting of hard material not affected by scour or current; (b) Those due to the deposition of alluvial material brought down by river drainage; (c) Casual bars occasionally and irregularly heaped up by storm wave action and afterwards dispersed by similar action, or by one or more currents; (d) Bars consisting of sand or shingle of certain general features and permanent direction, but constantly subjected to alteration by action of winds, waves and varying currents. It is generally concluded that the last given type of bar is that most usually encountered at harbor entrances, and is due, principally, to wave action and the littoral drift engaged in depositing material across the mouth of the outfall channel and the constant tendency of the ebb and flood currents to remove and disperse the same. The result of such drift action and harbor ebb current is shown in Fig. 10, which is typical of the conditions that have affected the entrances to interior bodies of water on sandy coast lines.

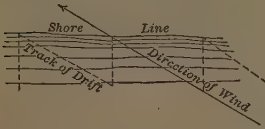

Fig. 9

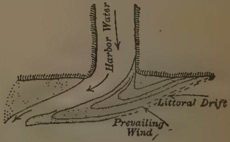

Fig. 10

Influence of Coast Line on Formation of Bars. Where the bed of the sea decreases in depth rapidly, the drift moving along the coast line is less readily carried into the channel by flood tide and is more readily transported by the ebb tide to deep water. Under such conditions bar formation is unlikely. Harbor

entrances on precipitous foreshores of rock materials are not likely to bar formations. Prominent projections.of the coast line on the side from which the flood tide sets in causes the current to run around it with velocity sufficient often to prevent depositing of drift and formation of bars at harbor entrances.

5. Foreshore Protection

Sea Walls, Dikes or Bulkheads are constructed along the shore line to prevent encroachment of the sea by direct wave action, and, as in the case of breakwaters, may consist of loose rubble-mounds or heaps, masonry wall work, usually, however, supplemented with timber, steel, or reinforced concrete sheet-piling driven into the beach and strengthened by wales, guide and brace piles, fascines and mattress work held in place by piles and loaded with rock. The character or massiveness depends on the location and wave forces the work will be subject to. In following notes of sea walls the numbers refer to Fig. 11.

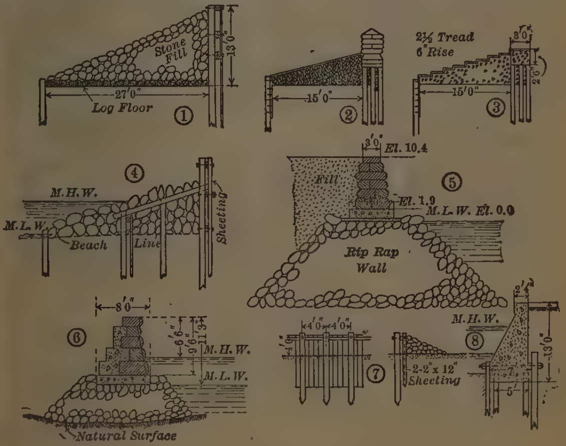

Fig. 11. Sea Walls

(1), (2), (3), (4), Coney Island, N. Y. Section of sea wall.

(5) Governor's Island, N. Y. Sea wall, 1901–1911. Average cost $19.45 per lin ft. Average cost of wall and riprap $47 per lin ft. Average settlement 0.8 ft, maximum settlement 2.4 ft.

(6) New York, Brooklyn Parkway, 1913. Masonry wall. Cost $27.50 per lin ft. Riprap foundation, 40c. per ton.

(7) Atlantic City, N. J.

(8) New Orleans, La., 2650 ft wall, fill behind wall 8 to 12 ft deep, piles 50 ft long, expansion joint every 50 ft, cost of wall, $26 per lin ft, filling 11 ½ c. per cu yd.

Effectiveness of Sea Walls. In many instances large sums of money have been expended on sea wall protection with entirely unsatisfactory results. In exposed locations subjected to high wave action, with a sea current along the beach, on which the sea wall is constructed, the action of the waves, together

with the current, will gradually, but continually, carry the beach material away until the foundation is exposed and undermined and the work destroyed. The most carefully constructed massive works of this character will not endure under such conditions.

Groins are built out from the shore line perpendicular to, or making an angle with, the same. They are generally constructed perpendicular to the direction of the current or drift. Their object is to cut off and prevent the carrying of beach materials along the foreshore. They need not be of massive construction, and usually consist of close piling, or sheet-piling driven between guide wales and piles, or horizontal courses of plank held between vertical timbers or piles driven into the beach. They should be built so as to offer the least resistance to wave action, follow closely at a few feet height the general slope of the beach, and extend from high to low water. When of more massive and stronger construction on a steep beach they should, if built out below low water, extend out into water of depth so that wave action will not seriously disturb bottom conditions, such as would result in scour and undermining and the destruction of the outshore end. When built in this way they are also known as Spur Dikes or Jetties. Groins should cut off the lateral sweep of waves. The distance between groins should equal their length and may be 1¼ times the length. In following notes, the numbers refer to Fig. 12.

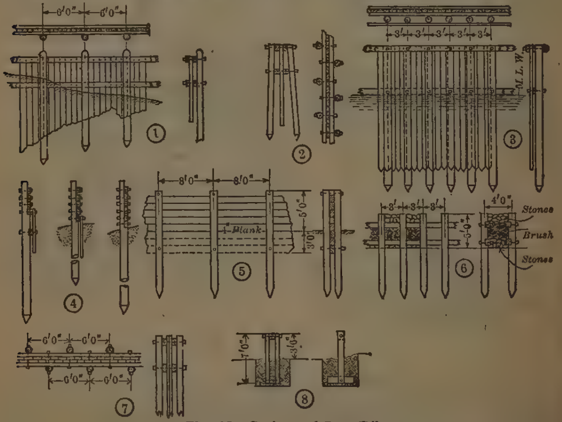

Fig. 12. Groins and Spur Dikes

(1) New York, N. Y., foot of Bay 22nd, Brooklyn. Wales 5 x 10, sheeting 4 in.

(2) Bath Beach, N. Y., Sheeting 3 in, 11 ft long. Top wales, 6 x 6, lower wales, 6 x 8 in.

(3) Coney Island, N. Y. Wales 4 x 10, 4 in sheeting 22 ft long.

(4) Telewana Park, N. Y. Horizontal planking 3 x 10, wales 4 x 8, sheeting 3 in, 6 ft long, piles 15 to 20 ft long.

(5) Atlantic City, N. J. Planking was put in sand as lateral deposit, raised beach, all lumber creosoted.

(6) Atlantic City, N. J.

(7) Asbury Park, N. J. Placed, 1908; successful up to 1914. Beach protected and extended.

(8) Type of low groin adopted by E. Case on English coast with entire success.

Groins of reinforced concrete have been extensively used on the English coast, consisting of grooved reinforced concrete piles and horizontal slabs added as beach rose in height. On the Holland coast spur dikes consisting of brush piles covered by pavement of stone have been successfully used, length about 350 ft.

Principle of Action of Groins. The object of groin construction is to confine the action of the breaking waves on the beach to moving the sand and shingle composing the same up and down locally in the confined space, and at the same time prevent the current along the beach from carrying this sand away to other locations, the beach current being compelled to seek a path outshore of the extremity of the groins at a depth where the wave action will be insufficient to stir up a sandy bottom, so that it may be carried away by the beach current. On the other hand, this current will carry, in suspension and along the bottom, sand or shingle from more distant points not protected by groin construction, and deposit this in the pockets formed by the groins resulting in beach accretion, as indicated in Fig. 13.

Fig. 13

The windward accumulation will be more pronounced, the deposit on the leeward side being materially reduced by eddies caused by the lee side of the outer end of the groins; as the pockets between become filled up, it becomes necessary to raise the height and extend the groin seaward. In most instances it is possible by this method to considerably add to the foreshore where, previous to the work, it was being steadily and continuously carried away. Groins are advantageously employed in connection with sea wall protection.

Dunes. Beside the retrogression or deposition of materials by direct water action of breaking waves, coastal currents and littoral drift, the air currents or wind frequently have a direct effect ot considerable importance, as is evidenced by the erosion, carrying away and deposition of sandy beach materials in the building up and constant movement of dunes. Such action may often become of so important a character in connection with foreshore protection as to require stabilizing.

On the Holland coast this is accomplished by resorting to planting of coarse grass and the placing of brush to protect the sand surface from wind action and also to catch the flying particles of sand and artificially build up dunes or embankments at predetermined places.

6. Channel Regulation

Variation in Channels. In bay or estuary harbors on coast lines subject to appreciable tidal ranges, it is quite frequently the case that the ebb current in finding its way to the sea has a tendency to scour out a channel for itself in the line of least resistance, water from the sea entering the harbor at flood tide, eroding for itself a different channel-way, sometimes across the channel-way of the ebb tide, with a consequent inclination to fill up this channel. The influence of littoral current and drift at the entrance of such harbors, together with that of gales and storms at intervals, often seriously complicate the problem of maintaining navigable channels. However, there is a constant tendency toward an equalization of forces looking to the establishment of more or less fixed channel-way. The navigable channel need not necessarily follow the natural channel eroded by the ebb or the flood tide, but may be established by crossing a series of deep pockets, availing itself, in whole or part, of either or both tidal channels. For methods of marking channels, see Art. 11.

Dredging. Such navigable channels are often established and maintai by excavating shoal reaches between natural channel-ways and deep holes, by straightening out and making more direct the natural channels, by c thru bends, and across bars. A description of the different processes of exca ting under water will be found in Sect. 6, Art. 43. Dredging operations of t character are frequently sufficient in themselves, altho, to some extent, nec sary as a continuous operation for maintenance of channels. In other ca dredging operations are necessary in conjunction with other works of chan control and regulation.

Jetties. In cases where there is considerable littoral drift, resulting in formation of bars across harbor entrances, or formation of bars from depo of sediment, jetties are built out from the harbor entrance into deep water. the construction of jetties, attention must be given to the natural conditi or inclination of the channel to establish itself in a certain direction, with a vi to not unnecessarily disturbing the equilibrium of forces. Where a heavy litto drift is constantly forcing to leeward, the outflow of water should be direct into the sea by a curved channel having its convex side presented to the dir tion from which gales are prevailing, a single jetty of curved section being us on the windward side of the channel. In such construction it will often be nec sary to extend the jetty seaward from time to time, as the foreshore is bu up on the windward side of the jetty; under some conditions such a je would be likely to carry the drift beyond the entrance into deep water, a not require seaward extension.

Converging Jetties run parallel with the general direction of the ebb tide a are carried out from the land and converge, leaving a comparatively narr opening. Jetties of this type tend to guide and restrict the outflowing ti controlling and directing the scouring effect by increasing the velocity. T windward jetty serves to cut off the littoral drift, the leeward jetty assisti the windward jetty in directing the force of the ebb tide to scouring out t drift brought into the channel-way by flood tide. Jetties of this charac often, from time to time, require outshore extension into deep water or the assi ance of dredging. Diverging jetties bring the entrance to a more natural co dition, and afford a better approach for navigation, but have a tendency, ho ever, to scour out a deep hole in the inshore entrance-way.

Design and Construction. Jetties are usually constructed of mounds heaps of large rubble in a somewhat similar manner to the construction of mou or heap breakwaters. The material is usually carried up slightly above t elevation of high tide. In estimating the quantity of material to be used, it is to be borne in mind that considerable is lost thru settlement in soft bottom, besides which, an excess of material must be allowed as the action of the waves will tend to wash down the stone to flatter slopes than would ordinarily obtain. From time to time, after completion, stone will have to be added to insure a high enough elevation to keep cross currents at high tide from sweeping beach drift over the jetty into the

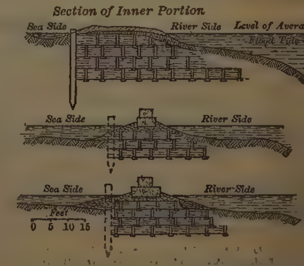

Fig. 14. South Pass, Mississippi River Jetti

channel. Fascine and mattress work with rubble loading is employed in jetty construction. Jetties are also built of wall work and also of reinforced concrete.

A jetty built in 1913, at Shark River Inlet, N. J., consists of two practically parallel walls curved with concave side toward the south, the beach sands drifting toward the north. The jetties consist of a row of 16 inch reinforced concrete sheet-piling, with counterforts at 10 ft intervals, and with a braced reinforced concrete superstructure;

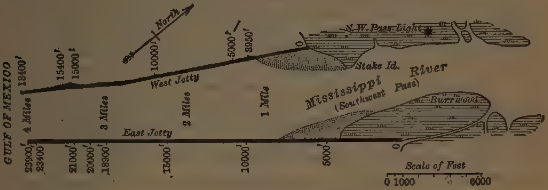

Fig. 15. South West Pass, Mississippi River

the pockets are filled with sand, the toe or apron is protected with riprap. Fig. 14 shows typical sections of jetties at the South Pass of the Mississippi River, and Fig. 15 a general plan of the jetties at South West Pass of this river.

RIVERS

7. Character and Description

Origin. Rivers owe their origin to the natural drainage or flow of water from the land to the sea, the development of their beds and their direction being due to the character of the soil, natural obstructions, inclination to follow the path of least resistance, and to certain modification in these characteristics due to influences, in some cases passed, traceable to the breaking up of the Glacial Period. Their final formation and direction are the results of erosive action of the water, as balanced by soil resistance, resulting, in the cases of most older rivers, of an established equilibrium within certain limitations between the contending forces and the regimen as existing.

Sources of River Water are, in all cases, derived from tidal or rain water, the tidal water entering at the lower end, or mouth, and being directly due to the great primary or secondary ocean tidal waves, which, at high tide, pass up the estuary and the river, raising the level of the water and causing a flow of water up the river, and during the period of low water the process is reversed. The quantity of water passing up the river, due to such tidal influences, is, of course, on the average, the same as the quantity flowing out on the reverse tide. The supply of fresh or rain water coming into the river at its source and constantly augmented by smaller supplies from branches and rivulets and the drainage from the banks along its course, travels solely in one direction from the source to the mouth and is subject to considerable variation in quantity and duration.

Tidal Rivers. Nearly all rivers emptying into a tidal sea are affected by tidal influences for some distance up from the mouth, depending principally upon the range of tide and the slope or fall of the river. At the crest of the tide, the salt water of the sea, by action of gravity, flows up the river; the sea water being denser than the fresh river water, the flow has a tendency to take place

by moving under the less dense fresh water and lifting this up. On the trough of the tidal wave the flow is reversed, causing a continual oscillation in and out, the quantity of the ebb tide being augmented by the fresh water of the river. The volume of the ebb is under normal conditions always in excess of the volume of the flood, this condition being reversed at rare intervals by the occurrence of heavy onshore gales. The method of action of the tide is, that as the flood tide begins to make up the river, the current is at first slowed up, then entirely checked, and then reversed, banking up and preventing the flow and escape of the fresh river water into the sea. On the turn of the tide, the tidal water and the stored accumulated river water flow out into the sea, the greatest velocity occurring at about half flood or half ebb. At the periods of reversal, or of slack water, a short time elapses with no current existing. Contrary to the conditions generally prevailing directly on the coast line, the duration of ebb tide in rivers is longer than that of the flood tide, the difference depending upon the character of the river and the quantity of fresh water flowing down the river as compared with the volume of tidal water entering the stream.

Non-Tidal Rivers are rivers emptying into tideless seas or lakes or the upper reaches of tidal rivers beyond the effect of tidal action. The rise and fall of such rivers are entirely dependent upon the precipitation of rain on the areas drained by such rivers and their tributaries, the melting of snow and ice in such areas or as modified by the characteristics of the surface of the ground, growth of vegetation, and the peculiarities of the stream itself, such as depth, width, and slope.

8. Flow of Water in Rivers

Velocity of Current. The direction of flow and velocity of river water is due solely to the effect of gravity dependent upon the level of the surface of the water in the river. The difference in such level in any given length is termed "slope" or "fall." The particles of water at high level exert a pressure on those below them; these, being free to act in any direction, are pressed downward, forward, and upward toward the lower level, the whole mass being thus set in motion generally in the manner indicated in Fig. 16.

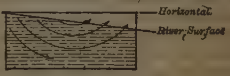

Fig. 16

The particles which come in contact with the bottom and banks of the stream are retarded by friction, not moving with the same freedom as the particles in the center of the stream section. Particles in contact with the bottom and side are also deflected from their true course causing disturbances in the stream action. As the stream moves forward the particles describe orbits, varying in dimension with the section and depth of the stream; in large deep streams, the orbits being larger, the disturbing elements are less potent, the mean velocity being that obtaining in open channels as given in Sect. 9, Art. 15, and may be obtained more directly by

$$V = C\sqrt{2\,R.\,F}$$

in which F equals the fall per mile in feet, R the hydraulic mean depth in feet and C a coefficient of varying value, as follows:

For small streams of about	50 cu ft per sec	$C=0.65$
For larger streams of from 200 to 300 cu ft per sec		$C=0.75$
For tidal rivers of	1000 cu ft per sec	$C=0.85$
For tidal rivers of	10 000 cu ft per sec	$C=0.95$
For tidal rivers of	100 000 cu ft per sec	$C=1.00$
For tidal rivers of	1 000 000 cu ft per sec	$C=1.50$

Transporting Capacity of Water. All rivers are charged with alluvial matter carried by them in suspension, the turbid condition of many rivers during periods of heavy flow illustrating the extent of the work being carried on by them in the transporting of material. In addition to the materials actually carried in suspension, heavier and larger particles are transported by being rolled along the bottom of the stream. The sources of materials carried in suspension are the disintegrating effect of frost, breaking up and loosening of soil materials, the wash and erosion of rain, and the scour or eroding effect of the stream upon its banks. Under normal conditions the sectional area of the river is sufficient to provide for a velocity which will not cause undue erosion, the natural bed remaining in a state of equilibrium. However, any agencies which tend to increase such velocity tend to cause erosion with increase of sectional area and eventual decrease of velocity to the point of equilibrium. With a constant variation of volume of water flowing in rivers, detritus is brought down at one time and deposited, is again taken up and transported further down stream, and so on. See discussion of Experiments by Grove K. Gilbert in Professional Paper 86 of U. S. Geological Survey, 1914; abstract in Eng. News, Sept. 10, 1914.

In a tidal river, the soil material carried by the stream is carried back and forth by the tide; the volume of ebb being greater than the flood, it is eventually slowly carried out to sea, or is deposited on the shores of the river mouth or estuary forming salt marshes. In non-tidal rivers, as the velocity of the current slackens on approaching and emptying into the sea, the material carried in suspension is deposited at the mouth of the river forming deltas. The delta of the Mississippi River is a prominent example.

If a stream is loaded to its full carrying capacity it will tend to flow within the confines of its bank and the bed without further erosion; in some rivers upward of 2 percent in weight of the total volume of water passing along the channel is solid matter. The ability of a stream to carry material is dependent upon the square of the velocity as modified by the depth. Refer to Sect. 9, Art. 17.

Erosion and Scour. A non-tidal river with its flow constant in a down-stream direction has an inclination to flow in a sinuous or meandering course. The particles of water moving in circular orbits or paths tend to impinge against one bank or the other, and on account of the lack of uniformity of the character of soil materials forming the banks, there is a constant tendency to erode or scour on one side or the other. A curved direction having once been assumed, the tendency is to increase the curvature, as illustrated in Fig. 17.

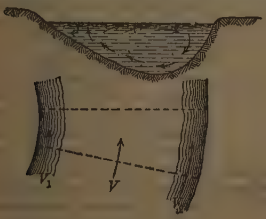

Fig. 17

The stream velocity is V. On account of the curved direction of the stream, the centrifugal force will tend to increase the velocity near the concave bank to V_2, and to decrease the velocity on the convex bank to V_1; the increased velocity on the concave bank, together with the dynamic pressure, due to the centrifugal force, will tend to deepen the stream bed at this side of the stream and erode and scour out the bank, these same forces tending to broaden a river at the bend by decreasing the mean hydraulic depth. The usual condition of a stream is illustrated in Figs. 18 and 19, the first showing a slight reverse bend, and the second a more considerable one.

The current in each case being close to the concave bank, has a tendency to scour out on this side deep channel-ways with consequent steep banks. Where material is carried

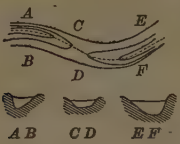

Fig 18

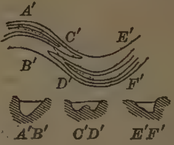

Fig. 19

in suspension the decrease in velocity on the convex side permits the deposition of detritus and the formation of flats, as illustrated in Fig. 20 and, eventually, with the growth of the meandering effect of marsh land.

In some streams the bends become so great that the bights approach each other and a natural cut-off occurs, the bends soon taking the form of crescent lakes. The intersection having once occurred, the new channel is rapidly eroded as the shortest path and the one of least frictional resistance, the meandering effect is more prevalent with less velocity than in torrential rivers in which the increment due to centrifugal force is proportionately less. As the navigable distance is often naturally shortened by such cut-offs, they have been made by dredging; this should only be done after careful investigation as to water height and the consequent velocity thru the cut-off; experience has shown that the shortening of the river course by this means often results in scour and bank caving.

Fig. 20

Channels and Bars. In non-tidal streams the flow being constantly in one direction, the regimen of the stream flow is closely fixt, the flow, quantity and velocity varying with the precipitation of rain so that, within reasonable limitations of time, the location and direction of channels and flats are likely not to vary greatly. In tidal streams the conditions are different and more complex, the variation in fresh water flow being materially complicated by tidal flow as regulated and controlled by the extent and direction of storms. Fig. 21 illustrates the condition often obtaining at or near the mouth of tidal streams, the reversal of current due to the ebb and flood resulting in two or more variable channels with consequent formation of bars, very often shifting in character and extent.

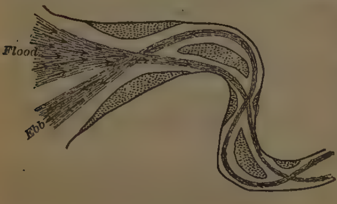

Fig. 21

The width and sectional area of channels in non-tidal rivers and in the upper reaches of tidal rivers bear a certain fixt relation to the drainage area and to the consequent quantity of water discharged. The width and depth of the tidal reaches of a tidal river do not appear to be so fixt, altho the channels once fixt are usually maintained by the tidal flow. Any cause that tends to obstruct the free flow of tidal water and the propagation of the tidal wave is detrimental to the maintenance of the

channel condition and frequently leads to shoaling. It is important to observe this effect in the design and construction of works of proposed improvement.

9. Training Works

Dredging. As with harbor work, the improvement of rivers, while often attempted by dredging, is not always effective as a measure of permanent improvement and usually entails continuous maintenance operations. Channels may be straightened out by cuts across bars and flats and the navigable distances along rivers decreased by excavating between the bends of meandering rivers. Dredging for the improvement of tidal or non-tidal rivers is principally useful in connection with other improvement works for stream regulation and control, and as a regular operation to maintain adequate depth and width of channels, slips, and basins.

Training Walls, also called dikes, are employed to direct the flow of the current in rivers with a view to the establishment of more favorable and fixt channels and often, also, to prevent scour and the erosion and carrying away of river banks. In the navigation of rivers it is important that the curvature of the channel should be of such radius as to permit the ready handling and movement of ships, this depending upon the depth of water and the size of ship to be considered. For large ships, if possible, it should be not less than 2500 feet. Single or double walls may be employed, the selection depending on the object to be accomplished. Two parallel walls may be used in a river flowing thru a broad alluvial valley, in a wide bed and with an inclination to meander, the walls confining and directing the current flow, keeping the space between them open by sluicing and scour. The slack water area inshore of the training walls will tend to shoal and fill up. Such wall work in rivers is similar to and in many respects merely an interior continuation of jetty work at river mouths or harbor entrances.

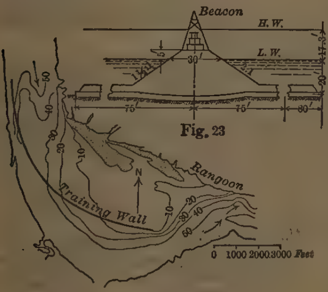

Fig. 22. Training Wall, Rangoon River

At Rangoon, India, 1907, the Rangoon River (Figs. 22 and 23) was cutting out the concave river bank just above the city, causing formation of sand bars and shoaling of water on the opposite side, and on being deflected by a prominent point opposite the city was scouring out and undermining the foundations of wharves and piers. The training wall built was 2 miles in length and consisted of brushwood mattress 3 ft thick, covered with a weighting layer of rubble, a rubble-mound wall surmounted by a concrete wall filled with rubble. Range of tide 20 ft with 5 to 7 mile river current. Wall cost, average, $470 per lin ft. River has scoured out new channel along wall and area behind wall has filled up.

Construction of Training Walls or Dikes, as with jetties, may be of loose rubble-mound construction, with or without a surmounting masonry wall, or may be of timber, timber close piling, timber sheet-piling, steel sheet-piling, or reinforced concrete. In the employment of rubble-mound walls, considerable material will have to be used that will afterward be buried in the bottom, for

as the wall is built and extended, the scour of the stream at its end will tend to deepen the channel at this point, leaving deep holes to be filled with stone as the wall work is carried forward. Training walls should be carried up to the elevation of high tide, and when curved should be given easy curves so as not to cause sudden changes in the direction of channel currents. The area in back of the training wall eventually becomes filled up with sediment deposited by the stream in the slack water. A typical section of a loose rubble-mound dike in use on Arkansas River is shown in Fig. 24, the rubble being deposited on fascines or brushwood mattress. Fig. 25 shows a typical solid, pile brushwood and stone dike in use on Arkansas River.

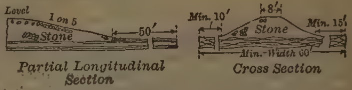

Fig. 24. Stone Dikes, Arkansas River

Spur Dikes, also called Spur Jetties, may be employed to regulate and direct the current of a river by contracting flow area and causing scour and lateral deposition of material behind or in between dikes. The influence of the spur dikes is similar to that of the groins employed in foreshore protection work, as described in Art. 5. Spur dikes are sometimes employed in connection with longitudinal dikes or training walls, or such longitudinal walls or bulkheads may be constructed connecting the end of the spur dikes after the space between them has become filled up with deposit.

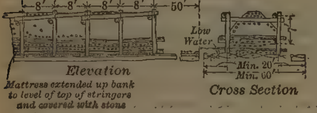

Fig. 25. Solid Pile Dike, Arkansas River

Fig. 26 illustrates the improvement of the Upper Mississippi River by the employment of spur dikes which are built out perpendicular to or making an oblique angle with the direction of the current.

Permeable Dikes, instead of entirely cutting off or diverting the current flow, merely slacken and retard it. They consist of open-work construction, usually of timber piles and cribbing with rubble weighted brushwood mattress work hurdles. The velocity of the current being retarded behind or between such dikes, material in suspension is deposited and the area is filled up, the dikes themselves eventually become buried in a hydraulic fill dam of their own creation. On account of the initial increase in velocity at the contracted area of the dike itself, the fascine or mattress work is built with an apron on each side of the work to prevent scouring and undermining.

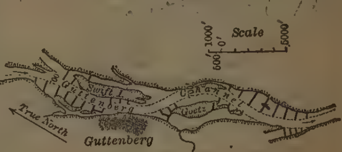

Fig. 26. Spur Dikes, Upper Mississippi

Fig. 27 illustrates the employment by the Chicago and Northwestern Ry. Co. of permeable dikes on the Missouri River at Blair Crossing. The river, as shown in (1), was following a cut-off and threatening the Blair bridge. The work was done in 1913. Permeable dikes were constructed across this cut-off, forcing the river into the old channel. (2) shows a section of the 2-pile dike; the main dike employed a 5-pile section.

Bank Revetment is effected, when practical, by sloping the bank to stable slopes, protecting them from scour by brush mattresses, riprap, or block paving, timber planking, piling and sheet-piling. Such work is necessary, not only on rivers to protect banks from erosion due to the flow and velocity of the current, but at tide level to protect against wave action and wash of passing vessels. See Sect. 11, Art. 16.

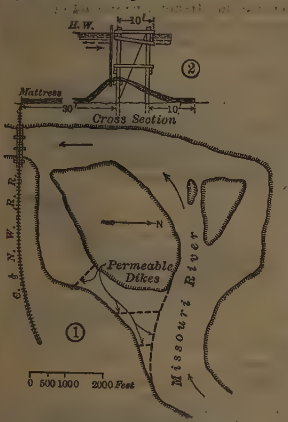

Fig. 27. Permeable Dikes, Missouri River

In Fig. 28 (1), (2), (3), (4), (5), (6), (7), show typical methods of revetment on the Arkansas River. (8) and (9), typical methods Upper Mississippi River. (10), typical methods, the Missouri River.

The standard revetment consists now of grading the bank on a slope of 1 : 3, laying a woven willow mattress 86 ft wide from 3 ft above low water and over the river bed, ballasting and sinking it, and paving the bank from the inshore edge of mattress to the top of bank. If the paving (riprap) fails by erosion, a substantial reinforced concrete revetment is placed extending from the top to almost low water and from there a system of connected concrete flexible blocks about 24 in square, extending beyond low water. This protects the bank and weak point of willow mattress. Cost per lin ft $8 to $10.

10. Flood Control

Overflow. The causes which contribute to a river overflowing its banks are naturally found in exceptionally heavy precipitations of rain and in the melting of snow and ice in the early spring over the area of its watershed, the origin usually being in the more precipitous upper reaches of the stream. Under normal conditions, floods of this character are to be expected periodically and have in certain cases been of considerable assistance in enriching the flat agricultural lands on either side of the stream by the depositing on them of rich alluvial matter brought down and deposited as the river water recedes after the period of flood. This natural regimen is sometimes disturbed by a change in the condition and character of the vegetation and forest growth over the drainage area; the cutting of timber, removal of forest underbrush, and the placing of land under cultivation, serving to increase the rapidity of the run-off, with the possible result that periods of rainfall which would not have ordinarily caused serious floods, under the change in the natural condition of the drainage area may have a tendency to hasten the drainage and outflow of rain water into the river. The conservation of forest growth, especially on the high lands where river tributaries have their source, has been advocated as a measure to reduce rapidity of run off and consequent flood, and at the same time by the retarding or storage effect increase the flow at low stages. Forest growth, undoubtedly, does exert a useful regulating effect on flow and resulting floods, but such effects are materially changed and even reversed by altitude and frost, especially by snow and ice. The effect of forestation on flood would appear to be a local problem, as it can hardly be asserted as a general proposition that changes in such forest areas produce well-marked effects on river floods.

Levees are embankments of earth built up on the sides of rivers to prevent the overflow of the banks. They should be built up two or three feet higher than the highest water recorded in that vicinity. In their design and construction, consideration should be given to the fact that the confining of the stream between the side levees will serve to decrease the stream area during flood flow, and probably entail increase in velocity and in elevation of the highest water over and above that recorded before the construction of the levees. The side

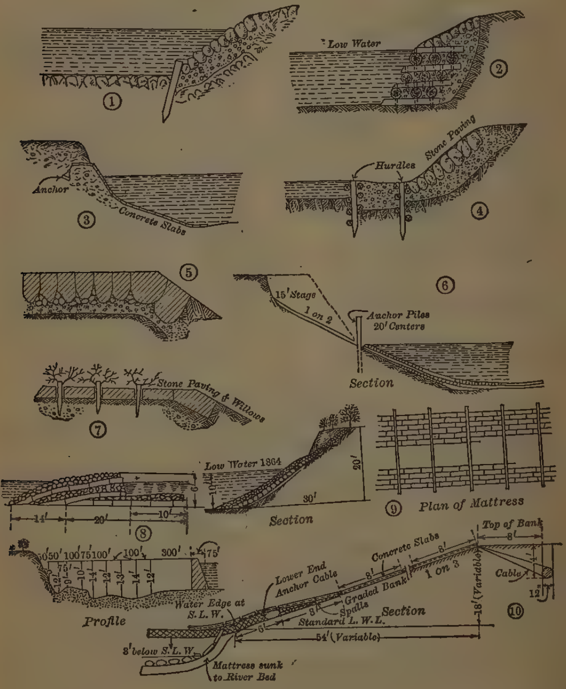

Fig. 28. Revetments

slopes are dependent upon the character of the soil and vary from 2: 1 to 4: 1 The top width of the levee should be sufficient so that in case of settlemen or unusually high water, the crest of the levee may be raised by additiona embankment or by placing of bag extensions. Refer to Sect. 6, Art. 41, Leve Construction, and Sect. 17, Art. 19.

Fig. 29 shows typical sections for various heights of levees employed on the Mississipp

River. Revetment work is employed to protect levee slopes where river conditions are such as to indicate the necessity for such work.

The Dikes of Holland perform a duty somewhat similar to that imposed on river levees, protecting the low lands from inundation by the sea. This system of dikes consists of the natural sand dunes, artificially built up sand dunes, and embankments. The rivers outflowing along the coast line have levees constructed along their banks. These sand dunes are protected against wind erosion by a growth of coarse grass and reed, which

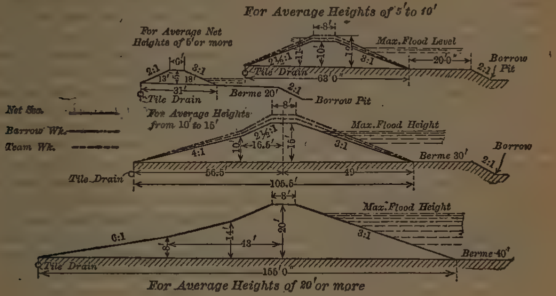

Fig. 29. Mississippi River Levees

also serves to retard and hold the blowing sand and build up the dunes, fresh grass being planted on top of this. Where subject to wave action, the slopes are protected by fascine and mattress work, weighted with basalt or concrete blocks; short timber piles are driven to pin and hold down the work and help to break the force of the waves. In localities where lateral currents occur, spur dikes are built out perpendicular to the main dike.

Flood protection walls may be employed in connection with, or to replace, levee work. Such walls, consisting of two reinforced concrete walls backfilled, were employed at Portsmouth, Ohio. The walls were fitted with flood gates which are closed when the elevation of the river reaches a dangerous height, the sewage discharge from the city is then pumped instead of flowing thru the wall. 6500 ft of wall was built at an average cost of $6 per ft.

Navigation. Most rivers at high stages usually afford the necessary facilities for navigation restricted within the known and expected local requirements. The low stages of rivers often make navigation impossible without the assistance of engineering works. At such low stages with the fall in stream velocity and in the quantity of water discharged, bars extend diagonally across the river, especially at bends, blocking the fairway and making the passage of vessels difficult or impossible. With sudden rises, new channels are eroded thru such bars, varying much in direction and location. Formerly in the Mississippi, when this river carried a large local river traffic, it was customary at New Orleans to hold frequent conferences between pilots of ascending and descending steamboats in order to learn and ascertain the latest changes of channel. Rivers, especially during freshets, bring down large quantities of drift logs, developing snags or sawyers, which tend to obstruct navigation, raising barriers and sand bars and changing the channel conditions; it is important that such snags be removed as soon as possible.

Reserve Basins or Reservoirs. Under favorable conditions, river floods may be somewhat controlled by the construction in the upper reaches of basins

or reservoirs, consisting of large areas with impounding dams, it being contemplated to hold in reserve in these reservoirs the excess flood volume, this to be released during the periods of low stages, and thus to increase artificially such low stage flow with a view to establishing an average flow. The fundamental principle involved is a sound one, but, usually, natural difficulties are encountered that render impractical the obtaining of the desired results. The problem involved, for successful application for such works for flood control, requires special and careful study of local conditions, the areas available for reservoir sites, value of land likely to be submerged, and the existence of suitable sites for dam construction. The plan has been tried on the upper Mississippi River, the region being remarkable for the number of small lakes. A large Indian reservation presented conditions unusually favorable. Five reservoir lakes were immediately available and additional ones possible and in prospect. The watersheds of the five reservoirs constituted 11.8 per cent of the whole area above St. Paul, and 21.5 per cent of that above Minneapolis. The actual result to navigation on the Upper Mississippi system was an average increase in low water depth at St. Paul of about 14 inches. When the release of water was specially regulated, 22 inches increase was obtained; these figures are based on a record of 20 years, during which period the total outlay, including construction and operation, was about $1 500 000. From this it is concluded that, as a general proposition, such reserve reservoir work, while instrumental in controlling flood discharge and assisting navigation, is of use principally in connection with other engineering work of improvement. The difficulty of regulating the discharge from such storage reservoirs can not be over-estimated. The release of reservoir water may be necessary and beneficial to one section, and have quite the opposite effect on other sections served by tributaries or branches which, due to local severe precipitation, are experiencing local floods.

Canalization is a method employed to considerable extent in Europe for improving the navigable condition in rivers. It has been applied to the Ohio River below Pittsburgh for a distance of about 1000 miles. In 1875 this project, by means of 45 movable dams, increased the minimum navigable depth to 6 ft, and in 1905, by 54 movable dams, to 9 ft. The total fall of the river in this distance is 424 ft, of which 26 ft are at the falls near Louisville, around which a canal has been constructed, for use at low water stages. Refer to Sect. **11**, Art. 16, Canals. The employment of dams and canals and canal locks is well suited to such projects where the local conditions are favorable.

11. Signals and Lighthouses

Buoys. Buoys are employed for demarcation of entrances, interior channelways, and for the location of dangerous shoals. They are placed at intervals at either side of the channel-way, the port and starboard boundaries being indicated by the shape and color of the buoy. Buoys must be moored to heavy cast iron mushroom anchors or frequently large blocks of concrete are used with heavy iron eyes cast therein. Dependent upon the range of tide, the buoy is secured to an anchor by a length of cable two or three times the maximum depth in which it is to float. In channel demarcation the distance between buoys varies with the character of the channel, as to its width and straightness. In the interior of harbors mooring buoys are frequently provided at various fixt locations so as to enable vessels to moor without resort to ship's anchors. In harbors of restricted area, at times two buoys, one for bow and one for stern, are provided for mooring. Buoys are used for location of wrecks in outer harbors or in the open sea; also to indicate cable crossings.

Beacons are fixt signals or structures used for means of alignment or for indi-

cating changes of direction. Frequently prominent objects or land marks, natural topographical features, or prominent structures, are used as beacons.

Channel Lighting. The location of channels is often fixt for night use by luminous buoys lighted by means of oil or gas, or the range is fixt by two illuminated points, afloat on buoys or fixt on shore, or one afloat and the other ashore, the change in direction being shown by a similar line or range.

Sound Signals. Light being impractical and useless during heavy mists or fogs, resource is had to sound or warning signals, a bell or whistling buoy being used for this purpose. In deep water where there is always some wave motion, bell buoys depend on this motion to actuate balls or pendent clappers. Whistling buoys depend on the taking in of air and its expulsion as the buoy rises and falls, or the bell may be struck or the whistle sounded by compressed air or gas carried in a tank that is regularly recharged. Sound transmitted thru the air often gives a misleading idea of locality, so that resort is had to submarine sound signals which can be heard a great distance, and from which the direction can be identified.

Lightships. At locations where, on account of the natural conditions, it is impractical to locate and maintain lighthouses, or at locations where luminous buoys would not be striking enough in character, necessary light for the assistance of navigation is placed on light-ships. Signals of this character are more certain and reliable than are light buoys exposed to strong currents in heavy seas. The principal requirements are staunch construction and steadiness under severe storm conditions.

Lighthouses. See Sect. 5, Art. 42. Dangerous promontories, points, and bars are marked by lighthouses, especially at entrance to bays and harbors. The lights are fixt, revolving, or flashing, for purposes of identification. When a navigator has identified a light and knows its height above sea level, the distance at which it first becomes visible at sea is known. Let H be the height of light, h the height of the observer above sea level, both in feet, and D the distance from the vessel to the light in statute miles. When the light is seen exactly on the horizon, then

$$D = 1.32\,(\sqrt{H} + \sqrt{h})$$

If the distance in nautical miles is required, 1.32 is to be replaced by 1.15. For example, if the height of the light is 100 ft, and the observer is 25 ft above the water, he sees the light on the horizon when he is 19.8 statute miles or 17.2 nautical miles from the lighthouse.

The following statements regarding the lights of lighthouses and the structures themselves have been kindly furnished by J. S. Conway, Deputy Commissioner of the U. S. Lighthouse Service.

(1) **Intensity.** Lights are of classes heretofore known as "orders," based on the focal diameter of the lens, as "first-order," "second-order," etc., and miscellaneous smaller lights. Recent practice substitutes the candlepower of the light in place of the now more or less misleading term "order."

(2) **Ranges of visibility,** two classes: the geographical range of the light due to its height above sea level, and the luminous range due to the intensity of the light emitted by the illuminating apparatus.

(3) **Character** of the illuminating apparatus, three classes: catoptric or reflecting, dioptric or refracting, and catadioptric, in which the "lens" is provided with both reflecting and refracting media. The latter type is the most in use.

(4) **Characteristics** of the light, such as Fixt, Flashing, Occulting, Fixt and Flashing, or other combinations for distinguishing purposes. Fixt lights are liable to confusion with neighboring private lights and should be avoided if practicable. Fixt

combined with flashing, and lights with prolonged flashes should be avoided for the reason that the "fixt" and "prolonged" rays emitted by the lens are weaker than those of the "flashes," giving a misleading characteristic at a distance. Multiple lights, except for minor lights, are now considered obsolete, because they largely increase the cost and are less distinctive than flashing lights. Lights of alternating colors should be so designed that the white and colored rays are of equal intensity.

(5) **Arcs of visibility,** two classes: single lights illuminating a large arc of the horizon and two lights in range illuminating a limited arc for purpose of marking narrow channels and passages. Often plates of red glass are introduced in the lantern so that the sector of rays passing through them will cover an outlying danger such as a reef, rock, or shoal, or to indicate the edge of a channel.

(6) **Attendance,** two classes: Watched and Unwatched lights.

(7) **Fog-signals,** four classes: the ordinary bell struck by hand or machinery and submarine bells struck by machinery, also whistles, reed horns, and sirens blown by compressed air. Some of the whistles and sirens are sounded by steam.

(8) **Materials.** Almost all the usual materials of construction have been used in building lighthouses in the United States Lighthouse Service: stone masonry, brickwork, reinforced concrete, framed timber, structural cast iron, structural steel, cast iron plates, steel plates and piping.

(9) **Arrangement.** Light stations situated on land sites usually consist of the light tower, oil house, fog signal building, keepers' dwellings, workshop, water supply and drainage systems, boathouse and ways, barn, and the usual outbuildings, roads and walks, altho, owing to the restricted area of some sites, one or more or all of the buildings may be combined in one. On submarine sites the whole station is practically confined to one structure.

(10) **Foundations.** For land sites, the foundation for a closed tower of masonry, or metal work, is usually a single block of concrete resting upon the foundation soil. Occasionally these blocks are placed upon a timber grillage supported by piles for sites upon low or marshy land. In all cases the block is extended so as to bring the unit pressures within the bearing power of the soil. Occasionally a skeleton structure is placed upon a single foundation block, but usually each column or leg of the tower has its individual block. Where the site is subject to overflow, the buildings are sometimes grouped together, raised upon braced columns and connected by a system of galleries.

For submarine sites, the foundation may consist of a cylindrical cast iron or sheet steel caisson filled with concrete, or a masonry pier. Cast iron caissons are in general use on the Atlantic Coast. When placed upon a ledge of rock, the latter is usually leveled up with concrete bags if below low water, or with tools if exposed, and the ledge or rock is then heavily ragbolted to the concrete filling. For soft bottom, the best method of procedure is to float the caisson out and sink it by the pneumatic process. Both timber and metal working chambers have been used and the depths from the cutting edge to high water have varied from 19 to 85 feet. Other foundations, consisting of timber cribs and concrete blocks, used in fresh water, have been placed either directly on good existing bottom, or upon a layer of small rock usually 3 or 4 ft thick deposited upon the soft or dredged bottom prior to floating the crib out. These timber cribs are usually filled with stone and terminate about 2 ft below low water level, the concrete blocks are then placed to the height of the deck.

(11) **Forces.** Structures upon land sites are exposed to wind pressures, and occasionally to waves in addition. Those upon submarine sites are exposed to wind, wave, currents, and ice. The usual procedure in determining the stability of tower is to locate the common center of effort of all the forces acting upon the structure to overturn it and so proportion the weights of the entire structure (the buoyancy of the water must be taken into account for submarine structures) that the resultant of the active forces and the net weight falls so far within the outer edge of the base that there is compression over its whole surface if the foundation soil is compressible. In seeking for this result it is proper to include the lateral resistance of the soil when the structure penetrates it for some distance for the reason that it is often heavily compressed by a large deposit of riprap and offers good support. The maximum unit pressures both vertical and lateral must not exceed the bearing power of the soil. In case the foundation is rock,

the resultant must fall so far within the outer edge of the base that the maximum unit pressure does not exceed the compressive strength of the materials in contact.

The wind, wave, current, and ice pressures assumed should be the maximum in each instance, as lighthouses are commonly exposed to severe gales and flows of ice. It has been the practise to assume wind pressure for flat surfaces at 60 lb per sq ft, allowing ⅔ of this figure for rotundity. Maximum wave pressures of 6000 lb per sq ft on flat surfaces are assumed, based upon Stevenson's experiments, the force of the wave being greatest at its crest and diminishing to zero at its base. The pressures exerted by currents vary with their rate of speed. The pressures due to ice have been assumed at 30 000 lb per sq ft for a field of melting ice, one ft thick, striking the pier and crushing its way past.

(12) **Superstructures.** The superstructures of all towers, whether separate or combined with other buildings, have certain features in common. There is a main entrance door at the base, a flight of winding stairs, broken by landings in high structures leading to the service room, which in the larger lights is usually separated by an airlock from the watchroom above, the latter supporting the lantern. Occasionally in large lights and usually in small ones the service and watchrooms are combined. The pedestal of the illuminating apparatus usually rests upon the watchroom floor, but in the small lights the lantern floor supports it. The clear glazed opening of the lantern is just sufficient to pass the horizontal rays from the illuminating apparatus, and if the latter is of a revolving type, showing flashes or occultations, the newel post of the tower serves as a weight shaft for the clock. There are railed galleries outside both lantern and watchroom. The tower should be thoroughly fireproof and isolated in this respect from the other buildings. For calculating the strength of closed and skeleton towers the manner prescribed for chimneys and viaduct bents is employed with the exception that great stiffness and rigidity must be provided, as vibrations are detrimental to the proper working of the lamps and clocks of the illuminating apparatus.

QUAYS

12. Design

Definition. Wharves are landing places or platforms built out, into, or on to the water for the berthing of vessels. Wharves parallel to the shore are generally known as quays, and their protection walls as quay walls; wharves built into the stream or fairway perpendicular or oblique to the shore are generally known as piers.

Quay Walls, or bulkheads, are used for wharfage for retaining and protecting embankments or retaining filling. Their proper design and cost are largely dependent upon local conditions and the use to which they are to be put. The character of the foundation and the depth of water to be provided are important factors in the cost and design. Some data on design are given in Sect. 7, Art. 13.

Data on Design. It is important to observe the character of the foundation on which the wall is placed; whether the wall may be built directly on rock or hard-pan, or on a floating foundation on timber piling or grillage work. In the latter case, information must be secured as to the prevalence of marine wood-borers, and, if present and active, precautions must be taken to protect the exposed timber work by creosoting or other preservative or protective methods. Quay walls are designed in a similar manner to retaining walls with the difference that on the water side they are subject to the water pressure varying with the height of the tide, and on the land side to the earth and contained water pressure, with a proper allowance for surcharge. The contained water on the land side of the wall will usually stand higher than the tide water, especially at low tide.

The Combined Pressure of water and earth upon a wall is needed in making a design. Let w_1 be the weight of a cubic foot of water, w_2 the weight per cubic

foot of the submerged earth, ϕ the angle of repose of that earth, and h the heigh of the vertical wall. Then, for one foot in length of the wall,

$$\begin{aligned}
&\text{Water pressure} &&= \tfrac{1}{2} h^2 w_1 \\
&\text{Earth pressure} &&= \tfrac{1}{2} h^2 w_2 \tan^2 (45^\circ - \tfrac{1}{2}\phi) \\
&\text{Combined pressure} &&= \tfrac{1}{2} h^2 (w_1 + w_2 \tan^2 (45^\circ - \tfrac{1}{2}\phi)) \\
&\text{or, Combined pressure} &&= \tfrac{1}{2} h^2 W
\end{aligned}$$

To find W the weight per cubic foot, w_1 of sea water is taken as 64 lb, and w may be found experimentally by taking samples of the earth as near as possib in its natural compacted state, and ascertaining its weight submerged in se water, or may be fixt theoretically in approximate terms by taking the weig of the original material, such as limestone rock, granite, slate, and other materia less the weight per cubic foot of water multiplied by the percentage of soli material per cubic foot, that is, 100 percent less the percentage of voids in th material.

Combined Weight W of Sea Water and Earth, lbs per cu ft
(Equivalent Liquid Pressure)

Slope of repose of earth	Weight w_2 of Submerged Earth, lbs per cu ft							
	40	44	48	52	56	60	64	68
½ : 1	66.2	66.4	66.7	66.9	67.1	67.3	67.6	67.8
¾ : 1	68.4	68.9	69.3	69.8	70.2	70.7	71.1	71.[illegible]
1 : 1	70.9	71.6	72.2	72.9	73.6	74.3	75.0	75.[illegible]
1¼ : 1	73.2	74.2	75.1	76.0	76.9	77.9	78.8	79.[illegible]
1½ : 1	75.4	76.6	77.7	78.9	80.0	81.2	82.3	83.[illegible]
1¾ : 1	77.5	78.8	80.2	81.5	82.9	84.2	85.6	86.[illegible]
2 : 1	79.3	80.8	82.3	83.9	85.4	86.9	88.4	90.[illegible]
2½ : 1	82.3	84.2	86.0	87.8	89.7	91.5	93.3	95.[illegible]
3 : 1	84.8	86.9	88.9	91.0	93.1	95.2	97.2	99.[illegible]
3½ : 1	86.8	89.0	91.3	93.6	95.9	98.2	100	102
4 : 1	88.4	90.8	93.3	95.7	98.1	101	103	105
5 : 1	90.9	93.6	96.3	99.0	102	104	107	109
6 : 1	104	108	112	116	120	124	128	132

This table gives the combined weight W, or the values of $w_1 + w_2 \tan^2 (45^\circ - \tfrac{1}{2}\phi$ the weight w_1 being taken as 64 lb per cu ft for sea water. It should be noted that t submerged weight of the earth will be dependent on both character of original soil ro and on the extent to which the soil is compacted, the angle of repose becoming great as the soil is more compacted. See table A, page 689, for values of angles of repo corresponding to various slopes.

It will be unusual in practise to find conditions where a combined weight W in exce of 90 lb per cu ft should be used. The total pressure in pounds against a linear fo of a vertical wall h feet in height is found by multiplying W by $\tfrac{1}{2} h^2$.

Some observations have been made at various depths on the weight "in situ" of so immersed in sea water, and, as should be expected, they show wide variation.

The Overturning Moment is the product of the total equivalent liqu pressure on the rear side of the wall, and one-third the height, less the produ of the water pressure on the sea side of the wall, by one-third its depth. In d docks, canal locks, masonry quay walls or bulkheads, the height to be tak would be the distance from the top of the fill down, while in walls with timb or other relieving platforms the height would be from the bottom of t platform. When the bulkhead or wall is founded on viscous or plastic so the depth or height to be considered will not necessarily be the height of the wa but may extend some distance below the depth of water at the sea face.

Weight of Soils immersed in Sea Water

Material	Pounds per cu ft		
	Max.	Min.	Average
Gravel and marl	..	42.0	62.9
Gravel and sand......	73	42.0	62.4
Sand................	66	42.0	58.3
Gravel, sand and clay	80.9	51.2	70.0
Stiff clay............	64.8	38.4	47.8
Stiff clay and gravel...	70.3	44.8	52.6

Practise and Custom. It is too frequently the case in the design and construction of wharfage work to be guided entirely by the accepted custom of practical wharfbuilders. It should be remembered that the same fundamental principles apply here as to other engineering structures. If the wall is a gravity structure, the safe bearing capacity of the foundation soil must be considered, it being remembered that the submerged part of the structure loses dead weight to the extent of the buoyancy effect of the water displaced by it.

Where piles are employed, their safe bearing capacity should be obtained by driving test piles and either applying a test load or making observations of weight and drop of hammer, penetration when bringing up, and use these data in connection with one of the well-known pile driving formulas, the pile structure being examined as a column, and, if of timber, due allowance made for character of material used, the creosoting of timber reducing the strength and safe carrying capacity of the pile. If capped with timber, consideration should be given to the safe bearing power across the grain of the timber used. In wharf work under conditions generally obtaining, timber piles 14 inches in diameter at butts, with the usual framing, should not be counted on to give more than 18 tons carrying capacity per pile. If creosoted timber, not more than 15 tons. The safe bearing capacity of reinforced concrete piles is frequently taken at twice this, but is, of course, dependent on the pile section and the driving of the pile. In reinforced concrete piling the bearing capacity at the top of the pile is reduced by the weight of the pile. In a reinforced concrete pier built in Havana, Cuba, piles 20 inches square, and up to 85 ft long, were used, and gross bearing capacity of 40 tons per pile allowed, or net capacity of 25 tons, 15 tons being allowed as the weight of pile. When employing batter, brace, or spur piles, this bearing capacity should be somewhat reduced, as the driving effect of the pile driver hammer will be less effective, on account of the inclination and consequent friction on the leaders or guides.

Expansion Joints. In long quay or sea walls or bulkheads, expansion joints at intervals of about 50 feet, are necessary in order to avoid unsightly shrinkage and settlement cracks. It is desirable to so design these as to permit irregular vertical movement in adjoining sections, but to lock these sections so as to prevent a horizontal break. A simple and effective joint of this character is made by casting one or more "V" or grooves in the end of one section, and coating this with pitch or tar, or

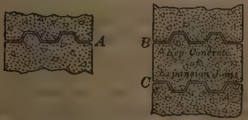

Fig. 30. Expansion Joints

the end of two adjoining sections may be built in this manner a few feet apart and the space filled up. The two methods are shown in Fig. 30.

For joint *A* tar is applied with brush to side first concreted. For joints *B* and *C* tar is applied with brush to body concrete after forms are removed and before key concrete is placed.

13. Foundations.

Sheet-piling. When sheet-piling is employed in quay walls or bulkheads in connection with or without relieving platforms, the sheet-piling will act as a simple or partially fixt beam supported where driven into the bottom and at its anchorage or fastening at the platform. Due precautions should be taken to see that the sheet-piling is driven deep enough into the bottom to secure a proper hold and to guard against being pushed out, for which purpose it must be driven to a depth so that the passive resistance of earth will take the bottom reaction. In reinforced concrete sheet-piling, steel can be placed accordingly, but in any case sufficient reinforcing steel must be placed on both faces so that the pile will be strong enough to be lifted and handled while being placed in the work. It is usually advisable to lift the piling at two points so that the negativ and positiv bending moments are equal, and to fix these points by casting gas pipe section or eyes in the piling.

A too frequent cause of failure of walls or bulkheads is the pushing out of the bottom or toe of the sheet-piling, or, in very soft material where sheet-piling is not long enough, the running out or mudwave effect underneath the bottom of the sheet-piling.

Method of Computing Depth to which Sheet Piling should be Driven, size of piles, struts or tension of tie backs.

In Fig. 30*a* the problem is shown in its simplest form.

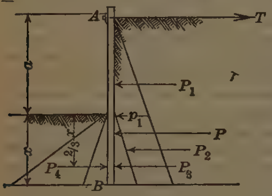

Fig. 30*a*

AB is a sheet pile driven to depth x into the soil and a the known height above the soil to which it is retaining earth, assume it is held at *A* by a strut or tie *T*. P_1 is the known active pressure above the outside soil. p_1 the intensity at the level of the soil, p the increment of intensity per unit of depth for active pressure above or below outside soil. kp the increment of intensity per unit of depth for the passive pressure below the outside soil. $P_2 = p_1x$; $P_3 = \frac{1}{2}px^2$; $P_4 = \frac{1}{2}kpx^2$; $P_1 = \frac{1}{2}pa^2$ or $P = P_1 + P_2 + P_3 = \frac{1}{2}p(a+x)^2$.

Take moments around *A* and $P \times \frac{2}{3}(a+x) = P_4(a + \frac{2}{3}x)$.

Which is an equation with one unknown quantity x. Also $P_4 + T = P$ or T tension in tie or compression in strut $= P - P_4$.

Fig. 30*b* shows the usual trench sheeting, the two struts at *D* and *C* take the place of the tie, *T* in Fig. 30*a* and under these conditions $P_4 + S_1 + S_2 = P$, and from this the size of sheeting and depth to which sheet piling is to be driven can be determined, and also the dimensions of struts and wales. Sheet pile *AB* being considered as a beam loaded as shown in *ABF*. The same analysis as above is applied to the general type of sheet pile bulkhead, Fig. 30*c*, where *AB* is the sheet pile *MN* the elevation of water. The triangle *ALM* indicates the earth pressure above tide level while *MLIB* indicates the total active pressure

of submerged earth and water below tide level on the land side. *MHB* indicates the total water pressure on the water side, and *EGH* the total active soil pressure on the water side and *EHF* the total passive pressure. Superimposing the active

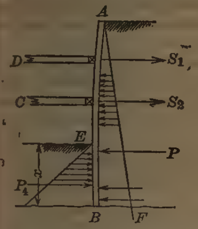

Fig. 30*b*. Length of Sheeting and Dimensions of Braces

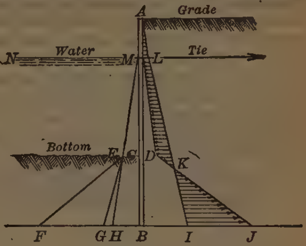

Fig. 30*c*. Bending Moment and Shear on Sheet Pile

and passive pressure on the water side on the active pressure on the land side *AMDKL* represents the intensity of the forces outward. *KIJ* represents the intensity of the active and passive forces inward which with *T* equals the outward forces. From this may be constructed the moment diagram and the size and details of the sheet piling actually desired.

Fig. 30*d* is the general case of a platform wall with surcharge, the length and size of the sheet piling may be determined as follows:

Find the known active force P_1 extending from the relieving platform to the level of the outside soil. Find the intensity p_1 at the level of the outside soil. Find p the increment of intensity per unit of depth for the active pressure below the outside soil. Find kp the increment of intensity per unit of depth for the passive pressure below the outside soil. Then $P_2 = p_1x$, $P_3 = \frac{1}{2}px^2$ and $P_4 = \frac{1}{2}kpx^2$. Take the moment of all the forces below the platform about the point O, giving

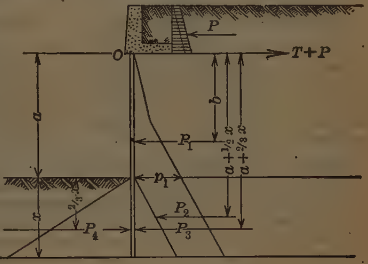

Fig. 30*d*

$$P_4(a+\tfrac{2}{3}x) - P_3(a+\tfrac{2}{3}x) - P_2(a+\tfrac{1}{2}x) - P_1b = O;$$

$$\tfrac{1}{2}px^2(a+\tfrac{2}{3}x)(k-1) - p_1x(a+\tfrac{1}{2}x) - P_1b = O;$$

$$\tfrac{1}{3}p(k-1)x^3 + \tfrac{1}{2}ap(k-1)x^2 - \tfrac{1}{2}p_1x^2 - ap_1x - P_1b = O.$$

An equation with one unknown x. Solve for x. Then determine P_2, P_3 and P_4 and $T = P_1 + P_2 + P_3 - P_4$.

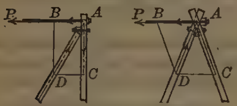
In applying this method the table of equivalent liquid pressure in article 12 page 1728 may be employed. kp the increment of intensity of passive pressure

is dependent upon the character of soil bottom and must be obtained by experiment or experienced inspector.

Brace Piles, when driven with opposite inclinations, are subjected to a pull in one case and a push in the other, and connection should be made accordingly. It is too frequently the case that brace piles, tho provided for in ample number and of sufficient bearing capacity, have weakened and improper connections, so that the full lateral effect is not secured from them.

A quay wall or bulkhead can be anchored against the thrust or horizontal pressure by dead-men or anchors buried in the embankment some distance back and below the plane of rupture made by the angle of repose, or by anchors of brace piles. Having determined the amount of this thrust, the anchorage can be readily designed.

Such anchorages are shown in Figs. 31, 32, 33. In Figs. 31 and 32, the amount of horizontal thrust is represented by A B, A D would be the push or bearing



Figs. 31, 32. Pile Anchorages

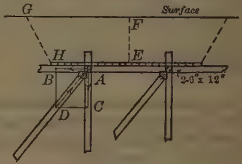


Fig. 33. Pile Anchorage with Platform

on the brace pile, and A C the uplifting effect or pull on the vertical pile in Fig. 31, and inclined pile in Fig. 32; Fig. 33 is an anchorage in connection with a relieving platform, or might be used separately as anchorage for a bulkhead or wall. A C is the uplifting effect, but the actual pull or uplift on the vertical pile shown is decreased by the weight of the soil or backfill surcharge on the platform, represented by $E\,F\,G\,H$.

Effective and Ineffective Anchorage details of brace or anchorage connections are shown in Figs. 34 and 35. Fig. 34 shows five typical brace pile anchors for a quay wall or bulkhead. Fig. 35 also shows five typical cases of improper brace or spur, pile details or connections. Some of these have been taken from actual work, Fig. 35 (1) and (2) having been discovered and sketched only after the failure of the work by the outward movement and overturning of the wall. It will be noted that in these two cases the bearing or thrust in the brace pile is

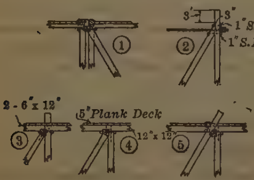

Fig. 34. Effective Pile Anchorage

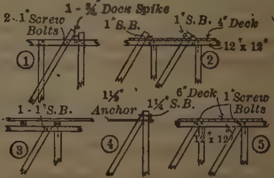

Fig. 35. Ineffective Pile Anchorage

entirely taken by the bending in two 1-inch screw bolts and one ¾-inch dock spike. These, apparently, held for some time, but, being submerged, even this

upport was greatly weakened by the corrosion of fastenings. In Fig. 35 (3) nd (4) depend entirely upon the strength in bending of one screw bolt, as does 5), except that the deck planking directly above the piles furnishes an additional bearing. In designing work that will be submerged, or kept partially o, if the work is to be considered permanent, it is important, in so far as posible, to avoid entire dependence upon iron or steel fastenings. Galvanizing as been attempted with indifferent success, and, in one or two instances, exruded brass has been used for fastenings. As far as possible, work of this charcter should be detailed for dependence upon the fitting of timber joints and the ise of wedges, dowels, and treenails. The general practise in engineering design hould be applied to obtain dimensions of caps and stringers, thickness of plankng or decking, bearing surface in contact, and other details. Liberal allownce must be made, however, for the weakening of aged water-logged timber r the deterioration of timber by rot, when exposed to successive wetting and lrying out; and in reinforced concrete construction to the possible disintegrating ffect of concrete when submerged in salt water, especially when subject to the ction of frost.

Safe Bearing Capacity of Groups of Piles. As stated in Sect. 6, Art. 23, he bearing capacity of piles is dependent upon the support at the bottom of he pile; if the pile penetrates a short distance to hardpan or rock, the strength f the pile as a column must be considered; when the pile penetrates some disance into soft materials, the bearing capacity depends upon the skin frictional esistance. It would be well, however, to note that the skin frictional resistance s the means by which the load on the pile is transmitted thru the pile and thru vertical cone of earth, of which the pile is the center, to the subsoil at the plane f extreme penetration of the pile, the bearing capacity of the soil also being ncreased by being compacted by the driving of the pile. For this reason the safe earing capacity of one pile is no criterion for fixing the safe bearing capacity of number of piles driven closely together, as in the latter case the cones of resisance overlap and the bases of these cones at the bottom of the piles will, in cases f a group of piles driven closely together, each be required to carry the load, at east in part, of several piles. While the bearing capacity of the subsoil at some listance beneath the surface, as at the foot of long piles compacted by pile drivng, will safely carry considerably higher loads than the same character of subsoil t or near the surface not compacted, there is, nevertheless, a limitation which an be readily exceeded by placing piles too close together, expecting them to arry considerable loads. It is inadvisable in pile foundations, for harbor work, o place piles closer together than 2½ ft to 3 ft. It will be seen that at 2½ ft enters, in carrying loads of 18 tons each, the interior piles of a large group vill subject the subsoil to a load of approximately 3 tons per sq ft.

Anchorage or Pull on Piles. Where brace piles are used for anchorage of uay walls or bulkheads, or in connection with pier work, as previously stated, he bringing into play of these brace piles to resist lateral movements frequently esults in an upward pull on some inclined or vertical piles. As a general rule, iles driven some distance into the soil and dependent upon skin friction for heir carrying or bearing capacity can be safely counted on as giving an anhorage effect or resistance to pulling equal to the estimated bearing or carryng capacity. Experience in pulling up or attempting to pull up piles driven n harbor work fully confirms this statement. Observations made on piles 55 to 5 ft in length, driven in 23 to 35 ft of water, indicate that a pull of from 20 to 5 tons was necessary, in many instances tops of piles pulling off before the piles vere moved. This resistance to up-pull is dependent upon the skin friction of he pile or actual mechanical anchorage in the case of types of concrete piles

with enlarged bases, which, in turn, is dependent upon the weight submerged in water, of the cones or pyramids of soil engaged by the pile and having their small ends or apex at the bottom or foot of the pile and the enlarged bases at the river or sea bed. Hence, the anchorage effect in a group of piles driven closely together, will be less than the sum of the anchorage effect of a like number of single piles, because the anchorage is entirely dependent upon the weight of the mass of earth engaged by the group of piling and in no case should be expected to exceed the weight of the affected inverted prism of soil to the bottom of the piles of the group. The effective weight is, when below tide level, of course, the submerged weight of the soil, for which refer to Art. 12.

14. Timber Quays or Bulkheads

Inexpensive and Temporary Character. When work is to be of a more or less temporary character and of inexpensive type, timber is largely employed, often, where necessary, treated by one of the preservative processes. In harbors where marine wood-borers do not exist or are not active, timber work below mean tide level, where always kept wet, will last indefinitely and can be employed in the foundation and other parts of permanent harbor work.

Creosoted Timber. Available information shows that the life of creosoted timber, submerged in water where marine wood-borers are prevalent, varies a great deal and this is due to differences in quantity and quality of the oil used and to the method of treatment. A variation in quantity of 10 to 24 lb per cu ft is frequently employed. Short leaf pine, on account of its structure, readily takes more oil per cubic foot than pitch pine, and, while not possessing the same strength, is, in many instances, a better material to use where creosoted lumber is required.

Yellow pine piles treated with 16 lb of creosote per cu ft, after being in place in Charleston harbor 12 years, show no evidences of having been attacked by marine wood-borers. In some of the other South Atlantic and Gulf ports, where the marine wood-borer is very active, there are examples of creosoted timber piles that have not been seriously damaged by the marine wood-borers, and have been in place over 20 years.

Examples of various timber quays are shown in Fig. 36, the numbers referring to the brief descriptions given below.

(1) Garrison Ave., Bronx River, New York City. Front close piling filled with riprap.

(2) Harlem River, New York City. Three inch sheetpiling backed with riprap. Anchor bents 10 ft centers.

(3) Echo Bay, New Rochelle, New York. Close piling backed with riprap. Bents 6 ft 6 in centers.

(4) Oak Point, New York.

(5) Hudson River, New York. Riprap embankment. Bents of platform 10 ft on centers.

(6) Astoria, L. I., New York, Astoria Light and Power Co. Crib filled with rubble, pockets 8 ft square formed by logs.

(7) Hudson River, New York, Interboro Rapid Transit Co. Slope paved with riprap. Bents 5 ft centers.

(8) Harlem River, 171st Street, New York. Three inch sheetpiling, backfilled with riprap. Guide piles 5 ft centers, two anchor piles every 10 ft.

(9) Rockway Inlet, New York, Barren Island. Bents 10 ft centers, one brace pile to each.

(10) San Pedro, Port of Los Angeles, California. Live load allowed 500 lb per sq ft. Piles creosoted, bents 15 ft centers.

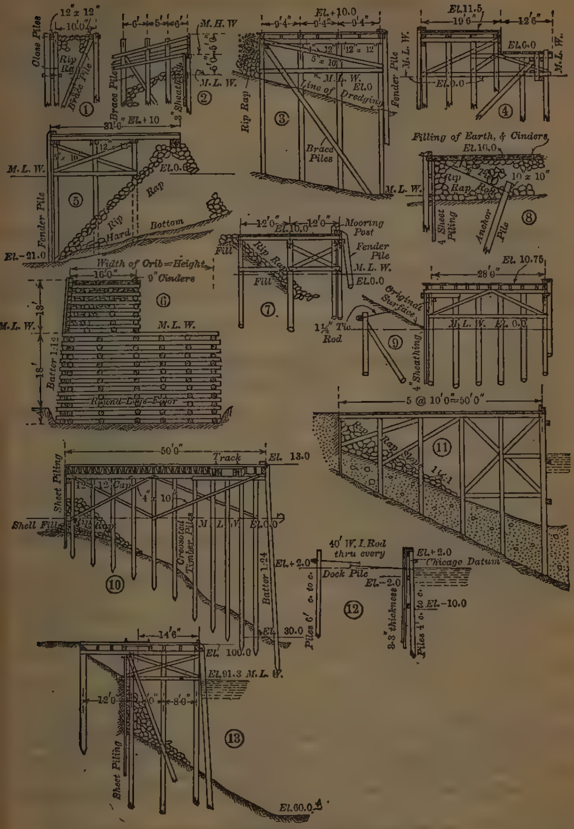

Fig. 36. Timber Quays

(11) Missouri River, Kansas City, Mo. Timber and piles creosoted. 526 ft long. Cost $43 per lin ft.

(12) Chicago, Ill. Standard Sheetpile bulkhead. Sanitary District.

(13) Navy Yard. New York, 1912. 200 ft long. Cost $38 per lin ft. Platform with 6 in sheetpiling. Bents 10 ft centers.

15. Masonry, Concrete, and Timber Quays

Foundations. In the construction of quays or bulkheads of more permanen character where rock or hard unyielding foundation can not be readily secured timber piling and grillage work are often employed for the foundations or ma be carried up to mean tide level, the work being surmounted by a masonry o reinforced concrete structure.

Riprap in locations where it can be secured in quantity and at a low cost i extremely valuable as a Quay wall material, for the foundations of the wal the protection of slopes, filling behind the wall, and for the underwater part c the wall itself. On account of the voids the material in mass submerged doe not weigh more than earth fill and stands at a much steeper slope, less than on 1.

Essential Details of various precedents are given in the following state ments, the numbers referring to Fig. 37.

(1) Savannah, Ga. Standard Fuel Supply Co. 1912. Twelve inch reinforced concret wall on timber piles, 15 ft 6 in centers reinforced concrete deck slab. Live load 600 lb Cost $50 per lin ft.

(2) Brooklyn, N. Y. Gowanus Canal. Timber platform, with concrete wall on pile and riprap.

(3) Chicago, Ill. Proposed plan for bulkhead wall alongside Long Pier.

(4) San Diego, California. 1912. 2675 ft long. Cost $124 per lin ft. Concrete in cased piles 7 ft centers.

(5) Iloilo, P. I. 1912. Cylinders 12 ft centers. Reinforced concrete on timber piles Cost $70.35 per lin ft.

(6) Chicago, Ill. Long Pier bulkhead.

(7) Charleston, S. C. 1911. 4000 ft long. Untreated timber piles, sheetpiling an concrete wall. Reinforced concrete sheetpiling, 3 ft wide, to protect timber work fror marine borers. Cost $35 per lin ft. The cost of an alternative design, having a rein forced concrete wall, was $36 per lin ft.

(9) New York (South Brooklyn), N. Y. One of several types of wall used by De partment of Docks and Ferries.

(10) Boston, Mass. Northern Avenue. 1911. At Commonwealth Pier. Lengt 645 ft. Cost $106.70 per lin ft.

(11) Schenectady, N. Y. N. Y. State Barge Canal. (12) Amsterdam, N. Y. N. Y State Barge Canal. (13) Utica, N. Y. N. Y. State Barge Canal.

(14) Providence, R. I. Fields Point. Bents 4 ft centers, two brace piles to each bent Sheetpiling 6 in and 8 in.

(15) New York, N. Y. Central R. R. of New Jersey, Bronx Terminal. Bents 8 f centers, two brace piles to a bent, sheeting 6 in.

(16) Boston, Mass. U. S. Navy Yard. (17) Norfolk, Va. U. S. Navy Yard. 191c Timber platform, surmounted by concrete wall on reinforced concrete sheetpiling, 5 ft long. Similar wall faced with granite ashlar, built at New York Navy Yard, 1912 Cost $180 per lin ft. Bents, 5 ft centers.

(18) Berlin, Germany. Spree Canal. (19) Neufahrwasser, Commercial Railroad Germany.

16. Masonry and Reinforced Concrete Quays

Foundations. Where the foundation is of rock or unyielding material, qua walls built up of large stone blocks, concrete blocks, or concrete monoliths, ar permanent and effective. In localities where granite is readily procurable a a reasonable price, this type of wall can not be improved upon both as to per manency and cost. With less satisfactory foundation conditions, especiall where marine wood-borers are prevalent, reinforced concrete piles or column are effectively used. In masonry walls the underwater work, if of blocks, is usu

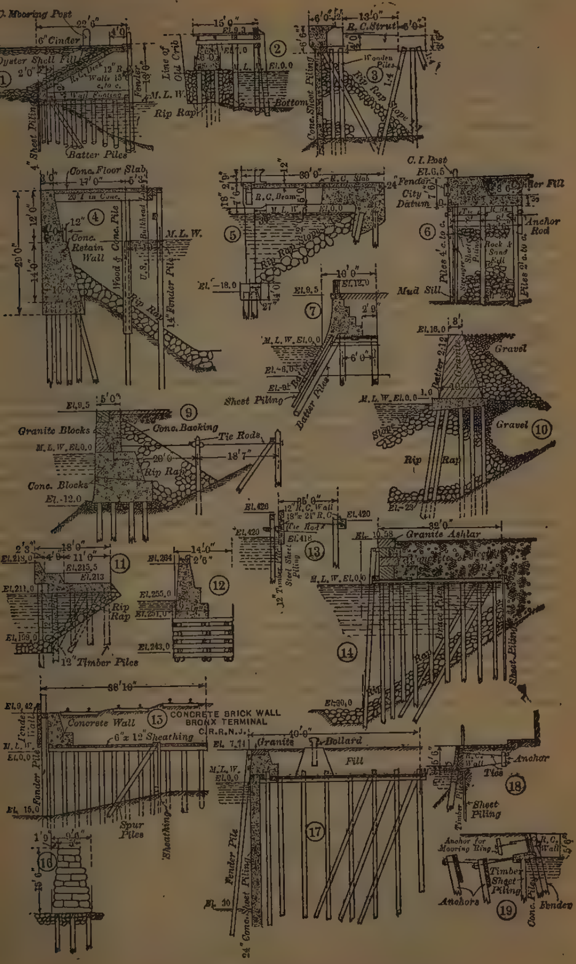

Fig. 37. Masonry, Concrete, and Timber Quays

ally laid by divers to elevation of low water. Where monolithic concrete block are used these may be premolded and lowered to place by heavy derricks, th foundation being prepared by the use of riprap and broken stone or concret bag work. Concrete or stone masonry walls are also built in the dry in coffe dams, or use is made of reinforced concrete or timber floating caissons or boxe built on shore, launched, and sunk in place by filling.

Essential Details of various precedents are given in the following state ment, the numbers referring to Fig. 38.

(1) Key West, Fla. U. S. Navy Yard. Reinforced concrete piles and deck. Ben 10 ft centers. (2) Albany, N. Y. State Barge Canal. (3) Los Angeles, California, 191 Reinforced concrete piles and deck. Cost $170 per ft. Bents 20 ft centers; anchors, vertical, 4 brace timber piles. (4) Nantes, on Loire, France. Reinforced concrete. (Spandau, Germany. Municipal Quay. (6) Nantes, France. (7) New York, N. Y. Po Morris, Bronx, N. Y. C. & H. R. R. (8) Oakland, California. 2005 ft long. (9) Bo ton, Mass. Fish Pier. Wall around Pier 6. Cost, about $260 per ft. (10) Baltimor Md. Proposed design. Est. cost, $50 per ft. (11) Portsmouth, N. H. Navy Yar Loose coursed granite laid by diver. A type of wall used along New England Coas 1907–1912. 320 ft. $308 per ft. (12) New York, N. Y. 116th Street, Department Docks and Ferries. (13) New York, N. Y. Cedar Street. Department of Docks ar Ferries.

The Department of Docks and Ferries of New York City has for many years em ployed large premolded concrete blocks for Quay wall construction. With rock found tion within 40 ft of surface, if material over rock is soft, it is dredged off and rock cleane and the wall based on bag concrete brought up to level by divers. Upon this successiv tiers of concrete blocks are laid up to low tide level; above this, granite ashlar, backe with mass concrete, is used. The blocks weigh from 25 to 95 tons. Where the foundatio is such that piles can be driven to clay, sand or other firm bottom, soft material is exc vated to 30-ft depth, piles driven and cut off 15 ft below low water and given lateral resis ance by an embankment of riprap and gravel brought up to tops of piles. Upon the piles a single tier of concrete blocks is laid, each weighing 80 tons. A granite ashlar wa facing with concrete backing surmounts the blocks. Where the bottom is soft, the wa is provided with a relieving platform. In some walls in soft bottom, settlements high as 4 ft have occurred, which were remedied by adding courses of granite. Th blocks are handled by scows and set in place by a 100-ton or a 40-ton crane. Cost h varied greatly from $100 to $750 per lin ft.

Quay walls, in which monoliths are employed consisting of floating caissons, in a sim ilar manner to their use in Breakwaters, see Art. 3, have been constructed at Zeebrugg Belgium; Rotterdam, Holland; Norresundby, Denmark; Talcahuano, Chili, and hollo reinforced concrete boxes at Passau on the Danube. At Antwerp, Belgium, a quay wa was constructed using caissons launched and floated to place and then sunk by fixin over their upper part a pneumatic caisson or diving-bell handled by two floats, the se tion being then filled with concrete.

17. Failures of Quay Walls

Movement and Settlement of quay walls and their eventual failure in who or part are not uncommon, even in well-designed walls or bulkheads where amp provision has, apparently, been made for the outward thrust; it is not unusu to find after work has been started evidences of settlement at the toe and irre ular outward movement at the top. This may, in some cases, be accounted fo by the slight settlement of the foundation under the front of the wall on accoun of the concentration of load and the outward thrust at that place and also i walls where timber platforms or anchors, employing brace piles, are used, t the slight movement allowed in the bringing up of bearings and connection In most instances, this will not continue to any great extent, and may be co rected in so far as appearance goes, by resetting the coping. On walls or bul heads having ornamental copings or balustrades, it is often advisable to post

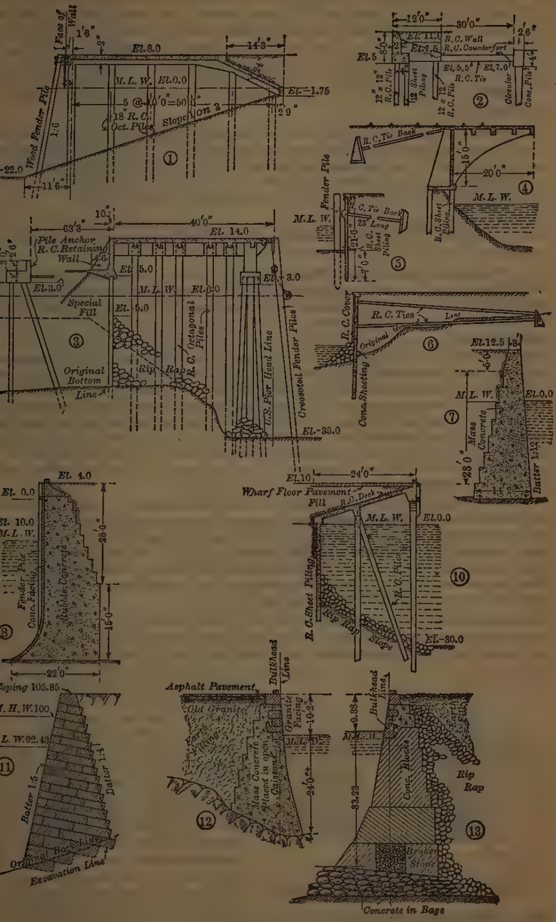

Fig. 38. Masonry and Reinforced Concrete Quays

pone the placing of these until a short time after the wall or bulkhead has been built and has had an opportunity to take its set. In gravity masonry walls, a not infrequent form of failure, or partial failure, is the moving or sliding out, in mass, of the wall on its base. It is customary, where possible, to lay the foundation and upper courses of masonry at an inclination to overcome this.

Examples of Failures and the corrective measures successfully applied in some instances:

(a) An outward movement was observed during the construction of The Fish Pier wall in Boston Harbor, the wall resting on an inclined riprap bed, laid on clay overlaying hardpan and rock. The movement was arrested by driving piles directly in front of and at the toe of the wall and constructing in the rear of the wall a relieving platform. 400 ft of wall were involved; the cost of repair was about $90.00 per lin ft.

(b) A section about 300 feet long of a masonry and timber platform wall built at the New York Navy Yard, failed by outward movement and overturning, the cause being, undoubtedly, improper brace pile connections, and as referred to in Art. 12.

(c) A somewhat similar wall in Washington, D. C., built on a very narrow platform without brace pile ties, moved outward 10 ft when the backfilling had only been carried to mean tide elevation. When repaired, by constructing a timber relieving platform with adequate brace piles, backfilling was carried to grade and no further movement of importance found.

(d) A wall in Charlestown, S. C., harbor, 4000 ft long, was located on a salt marsh; the river silt of increasing compactness and density extended to a depth in excess of 90 ft below tide. The depth of water at face of wall varied from 0 to approximately 8 ft. The support for the wall consisted of a timber platform and brace piles with sheet-piling driven at an inclination. Filling of river silt was placed behind the wall by hydraulic dredging. In two locations the filling material blew out underneath the sheet-piling, pushing out the bottom of the sheet-piling. This was corrected by loading the toe of the wall with riprap and, in some instances, by driving heavy vertical sheet-piling inside and back of the wall platform.

(e) A platform bulkhead built in New York Harbor, consisting of a timber platform with sheet-piling on the inside with brace piles at 5 ft intervals, with 15 ft depth of water at the sheet-piling, and 30 ft depth along the face, gave evidences of outward movement when the depth of water was increased by dredging to 34 ft. This was corrected by placing 2 in round steel anchors every 20 ft and carrying these back 40 ft inshore of the sheet-piling to anchors of timbers, dead-men, and piles, and placing riprap along the slope decreasing the depth of water at sheet-piling to 12 ft.

(f) A wall built at the Navy Yard in New York, about 1885, of gravity type consisted of heavy granite blocks, with massive counterforts, laid by divers on a timber pile foundation and of granite ashlar work above tide level. It was designed at a time when the draft of the vessels did not exceed 20 ft. With the increase in draft of vessel, the basin directly in front of this wall was dredged out and, finally, to a depth slightly in excess of 30 ft. A somewhat similar wall in another locality failed by outward movement and overturning. The wall in question moved outward and gave every indication of early failure. It was repaired by the method indicated in Fig. 39, the ashlar work being stripped off to low water, sheet-piling driven directly in front of the wall, and this tied back in turn by timber ties to a platform in back of the wall provided with vertical and brace piles, the space between the face of the wall and the sheet-piling filled with riprap, and a new wall built directly atop of the sheet-piling, and the work backfilled.

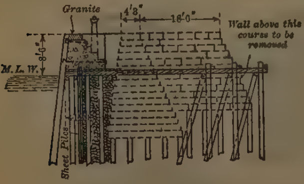

Fig. 39. Quay Wall Repair, New York

(g) A crib wall in D., L. & W. R. R. yard, Hoboken, N. J., the top of which had given way and needed renewal, was repaired at a cost of $13.21 per ft, as shown in Fig. 40.

(h) A seawall built on a timber platform, the protective face of which under water consisted of 3-lap, 2-in yellow pine treated with creosote, began to fail on account of the destruction of the wood by the teredo. Eight-inch grooved and tongued reinforced concrete sheet piles were driven and a reinforced concrete face put on top of this and the structure tied back by tie rods. The work will cost about $85.00 a linear foot in 1919 as shown in Fig. 40a.

Fig. 40. Quay Crib Repair, Hoboken, N. J.

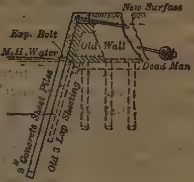

Fig. 40a. Wall Repair, Hampton Roads, Va.

There are numerous other examples, especially of walls or bulkheads constructed to retain filling that have failed by the outward movement of sheet-piling at the toe or bottom, or by outward movement at the top, and overturning on account of insecure and insufficient anchorage.

The increase in the depth of harbors, due to the increased draft of vessels, has, in instances, rendered insecure wall structures designed with sufficient strength and stability for the conditions existing when they were built.

LANDING PIERS

18. General Information

Pier and Bulkhead Line. In the interior of harbors and on navigable rivers, two lines are usually established in the United States by the National government, or, outside of this jurisdiction, by local port authorities. The bulkhead line is the line to which solid, or solid filled structures may be built. The pier-head line is the line fixing the boundaries of the fairway to which wharf or pier structures may be built, but when so built must be of open construction, permitting the flow through them of the full sweep of the current or tide, such open construction being in the nature of pile or column bents. It is usually permissible, if desired, to make the structure from mean-low-tide up continuous or solid.

Length and Width of Piers. Piers should be of at least sufficient length to berth the longest ship likely to use them, and hence should project out into the stream a short distance beyond the bow or stern of the ship to protect the hull of the vessel from collision by passing navigation or floating ice. Piers are often built long enough for berthing two or more vessels on either side. Allowance should be made in determining the length of piers for the growth in dimension of shipping. The width of piers is largely dependent upon the use to which they are to be put, altho a safe minimum width, in order to secure lateral stability by bracing, would be fixt by the depth of water and the length of the pier and the character and size of the vessels to which it will be required to afford wharfage. Piers to be used for the berthing of vessels, but not to any extent for the discharge, handling, or storing of cargoes, should be not less than 40 to 50 ft wide. For piers in shipbuilding, and repair yards, carrying standard gage rail-

road track, and for heavy crane track service, requiring the handling of bulky material, 75 to 100 ft which is frequently used. For commercial pier work and in an important port where the largest ships are likely to be berthed, and cargo handled and re-handled, widths of 100 to 250 ft are used, while in the same character of piers, in connection with railroad terminals carrying one or more lines of standard gage railroad tracks and provided with sheds for handling and storing of cargo, widths of piers in excess of 200 ft are often used. No fixt rule can be given for the length of piers. Local conditions and the value of property must control. If piers are designed long enough for two or more vessels to lay alongside, the traffic congestion incident to handling and rehandling cargo at the entrance to the pier must be considered. As the width of piers, or transit shed erected on the pier, should afford storage space for at least one cargo outgoing or incoming, that is, considering whether a one- or two-story shed is used, the cargo capacity of the vessel at the pier and the necessity for aisles or passage ways thru the storage space, and for road ways and railroad tracks to take in and bring out cargo, must be considered. There has been a tendency to increase the width of piers at cargo handling terminals.

The width of piers for handling incoming and outgoing cargo is directly related to the quantity of cargo to be accumulated on the pier for loading or the quantity to be landed in unloading while awaiting transfer and distribution. At a properly laid-out terminal vessels should be promptly loaded or unloaded. In determining the proper width the cargo carrying capacity and length of the largest vessel likely to use the pier should be taken. For man handling 5 ft high would appear to be the highest economical height of stowage; while 40 cu ft can be allowed for a cargo ton, or with passageway, etc., allow 12 sq ft of pier or wharf per cargo ton. With mechanical stacking and handling this could be decreased or the width of piers can be decreased by using two decked transit sheds, altho in that case one deck is generally employed for incoming and the other for accumulating outgoing. On account of the increase in sizes of vessels and the importance of space for accumulating cargo in advance and discharging without delaying vessels, the tendency is to construct wider piers. The New York City pier and waterfront congestion is undoubtedly due largely to too narrow piers for the size of vessels using these.

Width of Slips. The berthing space or slip between two piers should be wide enough to readily accommodate two vessels, one lying at each pier, and also give room for the entry or departure of either. Sufficient space should also be provided for loading and unloading by barges or lighters on the off pier side of the vessel. The greatest beam of the largest ships is now about 100 ft, so that in slips where the largest vessels are to be accommodated the width should not be less than 250 ft, and it should preferably be more than this.

Depth of Water at Wharves. In former years the amidship, hull section of wooden ships was such that the maximum draft required was not necessary directly in front of quays or piers, but with the advent of steel hulls of practically rectangular amidship section, with bilge keels, the maximum draft is required directly in front of the wharf to be occupied, unless the vessel is kept off by spur shores, or floats, in which case there is a loss of space in the slip and inconvenience in the placing of gangways and the handling of cargo.

At the first-class piers on the Atlantic Coast 40 ft appears to have been recently fixt as the desired depth for port approach channels. One or two notable examples exist of transatlantic liners which have a depth of approximately this at full load. It is doubtful that the tendency to increase full load draft design of ocean-going vessels will continue beyond this 40-ft limitation.

On the Atlantic Coast, in the important harbors, where possible, a usable depth of not less than 35 ft should be provided, as some of the larger vessels in commercial use, when fully loaded, have a draft in excess of this. Provision should be made for this usable depth at extreme low water by allowing additional depth for silting up, and to provide for movement on account of wave action.

Naval vessels seldom have a maximum displacement draft in excess of 30 ft. An allowance, however, must be made for over-draft, especially in case of injury, such as the flooding of compartments.

Direction of Piers. In the prevailing American practice, piers are built out perpendicular to the shore line and to the direction of the channel. Some advocate placing piers obliquely, urging that the task of bringing vessels into and out of slips is thereby rendered easier. This is, of course, dependent upon tidal and current conditions. In a tidal harbor with the ebb and flood of the tides, this would be so under one of the two conditions of the tide, but it would be more difficult, or impossible, to bring vessels in or out with the reverse condition of current.

Laying Out of Wharf Work. The location of piles or columns in bents are usually fixt by batten ranges placed on shore, the spacing being laid off on two bases, a short distance apart, parallel with the bents, and the distance out to bents determined by similar ranges on adjoining structures, or by steel or cloth tape lines measuring out from a fixt base, the piles being held in place by stay-lathing or temporary braces below the cut-off or finished grade. The elevation of cut-off is given by level and carried from the given point by straight edge and checked by instrument. Piles are cut off below water, by divers using a hand saw, or by using a horizontal circular saw operated from the surface.

Piers in Deep Water. When piers are laid out so that for the entire length or at the outer extremity they are in water of considerable depth, resort is sometimes had to raising the bottom, into which the piles are to be driven by making embankments of riprap. In pile piers, if placed after the piles are driven, there is likely to be a settlement in the structure due to the weight of the riprap or cobble. This method of construction has been employed along the New York City waterfront, and in the case of the New York Central pier, at Watt Street, resulted in a settlement of nearly 2 ft. Riprap embankments, under water, are also used to give the pier lateral strength, especially where the piles can not be driven deep enough into the bottom to insure good holding. The raising of the bottom by embankments of riprap or cobble is also resorted to to strengthen the pier laterally and especially to support the piling, which would otherwise involve consideration of the carrying capacity of such piles as an extremely long unsupported column.

19. Design

The Live Load carrying capacity of piers and quays depends largely on the use to which they are to be put, and ranges from 250 to 1200 lb per sq ft. The minimum should be used for piers intended solely for berthing light traffic and the support of oil and water mains, and the maximum for especially heavy work, such as the handling and storage of ordnance, armor plate, and heavy machinery. In commercial wharves, 600 lb per sq ft should be used for piers, and 750 lb for quays. The foundations are to provide for this live load and dead load of the structure itself. The foundation for standard gage railroad track, or heavy crane tracks, shed or building foundations, require special treatment as in other engineering structures.

Prevailing Practise. In pier design it will be found that details frequently have to conform with established rules fixt by local authorities. Where this is

not the case, the deck or slab should be designed to carry full live load and dead load, the stringers, rangers or beams to carry full live load and dead load. Caps or girders, 80 percent of live load, and full dead load. Piles or columns 75 percent of live load and full dead load. For other structures such as sheds, railroad tracks, and special work, design in conformity with general building practise.

Timber Pier Framing is largely done by the methods used in ship framing. Pile caps, if not in one piece, are usually scarfed at such locations as to break joints in adjoining bents. In substantial work piles are usually tenoned and caps mortised. Frequently clamps are substituted for caps, these consisting of two timbers, the pile being shouldered out on each side to receive them. String pieces or rangers are either butted over caps and drifted, or spiked, to the cap, or the joint occurs in the middle of the bay, the timbers being fish-plated. In heavy and important timber piers, the deck system usually consists of heavy planking with somewhat lighter wearing sheathing laid diagonally to the direction of traffic over it. Out-shore corners on piers are usually rounded and heavily reinforced. In harbors where floating ice is prevalent, especially in tidal rivers, the bays at the outer end of the pier are made of double width, and the pile or column bents at either side protected between tides with steel or iron plates. The fastenings used are, in general, similar to those employed in timber, ship, and bridge work, and are frequently galvanized. Piers are often built with a slight crown at the center to facilitate drainage.

Fender System. Wharves, when used for berthing, are protected by fenders fitted so as to be readily removed for repair and replacement. The fender system is made up of vertical fenders or fender spring piles and horizontal wearing ribbons. The outer ends or corners of piers are usually protected by heavy clusters of fender piles, or by separate pile clusters or dolphins. In reinforced concrete and masonry piers the fender system is often arranged on an elastic system with sufficient spring to save the main structure from the shock of vessels coming alongside. For this purpose the spring of the vertical and horizontal timbers is employed, or groups of heavy car springs used. Frequently such fender systems are assisted or replaced by floating fenders, rolling logs or spars of single or made-up timbers sometimes served with old hemp line and fastened at the ends with lines or chains fixt to the side of the piers or quays.

Fender System. In addition to the fenders employed it is sometimes customary to construct dolphins or clusters of piles along the side of a pier to breast off vessels with. Such dolphins are also used without the pier for mooring purposes while vessels are awaiting for pier or berthing space or being loaded or unloaded by lighters.

Moorings. Piers are provided with mooring posts or bollards, bitts, and cleats, one for each 50 ft length of berth, the inshore and outshore moorings for bow and stern lines to be heavy bollards or posts fitted with horns or pins. Typical details of mooring fittings are shown in Fig. 41. When vessels are berthed alongside of quays, it often becomes necessary to spur them off so that at low tide the bilge keel will not rest on bottom slopes. Spur shores of heavy spars are used for this purpose, one end resting against the vessel's side, and being supported from it by lines or chains, the other end resting on wheels or rollers on the wharf platform, and made fast by lines or chains to bitts or mooring posts. The same object is accomplished by placing floats in between the vessel and the wharf.

Accessibility of Wharf Platforms. In harbors where the range of tide is only moderate in extent, the platform elevation of main piers and of second floors of pier sheds are usually so fixt that access may be had to cargo openings in sides of ships, for placing and transfer of cargo, by portable gangways. Where

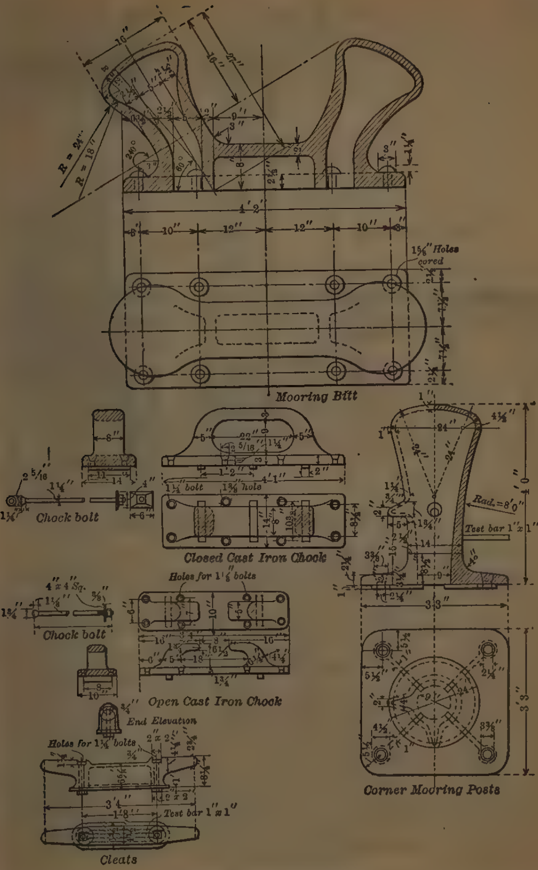

Fig. 41. Mooring Fittings

there is considerable range in tide, piers are sometimes built on two levels, the low one used at low tide, and the upper one at high tide, or inclines are built on the sides of the wharf, and sometimes these are provided with drop or adjustable gangways. A detail of such a gangway, in use at Philadelphia, Pa., is shown in Fig. 42.

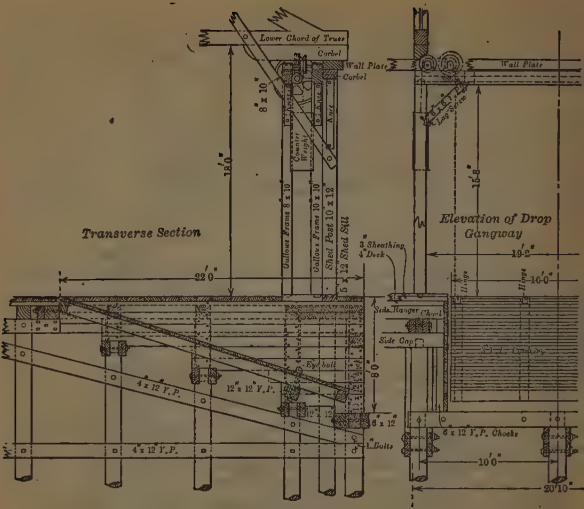

Fig. 42. Drop Gangway, Philadelphia

Ocean Piers are generally built for passenger service, landings or recreation purposes. Ocean piers have been constructed for commercial purposes in locations where natural harbors were not available or convenient. Piers of the recreation type are found at resorts near populous cities, and are very often constructed of steel or iron piles or columns with steel and timber superstructure. The piles or columns are made up of pipe, or structural shapes, iron or steel disks or sections of screws being fixt to the lower end. The piles are put into position, with the aid of water jets, an attempt being made to place them sufficiently deep so that the sand surrounding them will not be disturbed and washed away by wave action. These iron or steel piles or columns, when made of pipe, offer a minimum resistance to wave action; the requisite lateral stiffness is usually secured by cross bracing of steel rods. Piers of this character have also been built employing reinforced concrete piles surmounted by a reinforced concrete deck system. Ocean piers of the commercial type have been constructed on the southern coast of Cuba and in South America; in some cases, instead of being continuous piers built out into the sea, they consist of a detached platform or pier in deep water, the cargo being handled to and from the shore by means of overhead cableways.

20. Life and Cost of Piers

The Life of Piers is entirely dependent upon the location of the work and character of construction employed. Timber piers built in harbors where marine wood-borers are not active will last indefinitely below mean tide, but above this are subject to rapid deterioration and decay. Under such circum-

stances the life of a timber pier, in its entirety, could be probably fixt at 20 years. There are instances of work of this character requiring extensive repair, amounting to replacement, in 15 years, while in other cases piers after a life of 25 to 30 years are still in use. C. W. Staniford, Ch. Eng., Dept. of Docks and Ferries, New York Harbor, gives the following facts in Trans. Am. Soc. C. E., Vol. 77, 1914:

Description	Percentage of total original cost	Renewal required
Sheathing	12	Every 6 yrs
Backing log	1.8	" 8 "
Fender chocks, including vertical cheating	4	" 10 "
Fender piles	4.7	" 12 "
Decking	11.3	" 15 "
Bracing	7.1	50% in every 20 yrs
Rangers and caps	24.4	50% " " 20 "
Piles, above mean low water	34.7	33⅓%" " 20 "

From the above it is derived that the average life of the entire pier is 21.6 years. The timber piles, however, below mean tide elevation, which are still in good condition, can be made use of by building a new superstructure above and resting on them. Climatic conditions, the care with which the construction work is performed, and the character of timber employed will materially modify length of life. Timber piers, with creosoted piles, in ports where marine wood-borers are active, may have a length of life between 15 and 25 years. In timber piers with reinforced concrete decks, the length of life is dependent on the length of life of rangers and caps, and, when of substantial construction in a locality such as New York Harbor, can be taken as 30 years. Masonry, reinforced concrete, masonry and reinforced concrete on timber foundations or platforms where marine wood-borers are not prevalent or active, have practically an indefinite length of life, altho under some conditions there is a possibility of deterioration of concrete work immersed in sea water requiring extensive repair and renewal. It seems safe, however, to fix the length of life of this character of structures at 60 years. Untreated, unprotected timber in harbors where marine wood-borers are prevalent and active, are destroyed rapidly, in some instances the piles being entirely eaten away and destroyed in two or three years.

Costs of Piers. The data available as to the cost of piers are likely to prove extremely misleading. These costs are, of course, dependent upon details of construction, character of foundations, live load carrying capacity for which designed, the character and cost in the particular location of the material employed, availability and cost of labor and appliances. For general estimating purposes, for the cost per superficial foot of different types of pier work, in American ports, the following may be taken, the range between the maximum and minimum being dependent on location, foundations, and detail of design. These costs do not include auxiliary structures, shed foundations, railroad track foundations, subways, galleries, or other structures:

	Cost per sq ft
Untreated pine timber piers	\$0.75 to \$1.20
Creosoted pile untreated timber superstructure piers	\$1.00 to \$1.50
Untreated timber piers with reinforced concrete deck	\$0.90 to \$1.45
Creosoted timber with reinforced concrete deck	\$1.15 to \$1.75
Untreated timber platform with concrete cross-walls or reinforced concrete columns and deck	\$1.40 to \$2.00

	Cost per sq ft
Creosoted timber piles with reinforced concrete columns and deck	\$1.70 to \$2.35
Reinforced concrete piles and timber system and deck	\$1.70 to \$2.55
Reinforced concrete piles and deck and deck system	\$1.90 to \$2.75
Timber platform to low water and solid fill above	\$1.50 to \$3.00

On reinforced concrete deck piers there should be added to the above figures, if asphalt wearing surface is to be placed, from 10 to 16 cents per sq ft, and if creosoted wood block wearing surface is to be placed, 20 to 28 cents per sq ft. On filled piers, in addition to this, add 8 to 12 cents per sq ft for concrete base. It is to be noted that on the last type of filled platform pier, the enclosing wall structure representing the principal cost of the structure, the width of the pier would be a controlling feature in the cost. No cost can be given for solid filled piers, that is, piers enclosd by one of the various types of quay walls, as this cost will depend entirely on the cost of the wall and the width of the pier.

Cost of Piers. The cost herein given as is the case with cost generally is that obtaining previous to the years 1914 and 1915. These are probably no criterion, even, for the cost obtaining at present, and likely to obtain. Increase in the wages of labor, cost of materials, and various other economic reasons have disturbed cost so that during the year 1918 on the Atlantic coast the cost of wharf work has increased, two, three and in cases four times. In consideration of this condition the tabulation to be given hereinafter as to annual charges and capital cost has value only as a comparative measure of estimate for different types, wherein it undoubtedly still holds.

Annual Charges or Capitalized Cost. The first cost of construction of pier work is not the sole or true criterion of cost, as this should be considered with the probable length of life, cost of repair, and insurance risk.

Undoubtedly the proper method to make comparison is to consider the annual charge representing the interest on first cost, cost of sinking fund to replace, cost of repair and insurance, and, if desired, capitalize this.

While the insurance rate would apply to the first cost of the pier itself, the character of construction will also affect the rate on cargo handled and stored on the pier, and the type of construction would be of importance to the pier user, emphasizing the need of adopting a fire-resisting type of construction for piers on which valuable cargo is to be handled or stored. In planning wharf work, the considerations affecting first cost may often outweigh the apparent advantages of a lower annual charge. Irrespective of the financial problems, it is difficult or impossible to fully foresee future requirements, and it is frequently the experience that port improvements become obsolete and require extensive changes or must be removed, in which case the advantage is apparent of having selected a design of low cost and one readily torn down.

In preparing the table, p.1749, the following governing conditions have been taken: Live load, 600 lb per sq ft. Pier platforms 10 ft above mean low tide level, 5 ft range of tide, 30 ft depth of water, length of piles required, 70 to 75 ft to top; 65 to 70 ft, low water platforms. Yellow pine piles 15 tons bearing, creosoted, 12 tons bearing, concrete piles, 25 tons bearing and dead weight of pile. Uniform unit prices applied to quantities in each case and are prices prevailing in the Port of New York.

Types 1, 2, 3, 4, 5, and 9 .... 10 ft bays.
Types 7, 8, 10, 11, and 12 .... 5 ft bays.
Types 6 .... 15 ft bays.
Types 1 to 9, piers 70 ft wide, 700 ft long.
Types 10 to 12, piers 200 ft wide, 1000 ft long.
Types 1, 3, 5, 6, 7, 8, 10, and 11, for harbors in which marine wood-borers are not active.
Types 2, 4, 9, and 12, in harbors where marine wood-borers are active.

Data on Costs and Annual Charges for Piers

Type of piers	Cost per sq ft Dollars	Cost per sq ft with asphalt top Dollars	Cost per sq ft with asphalt and concrete base Dollars	Average length of life Years	Annual charge per cent Int. 5% Sinking Fund 5% Repair, Insurance	Annual charge Cents per sq ft
Piers 70′ wide, 700′ long						
(1) Timber piles and top......	1.633	.....	.....	20	12.02	12.42
(2) Timber top, creosoted piles	1.42	.....	.....	20	12.02	17.10
(3) Reinforced concrete deck and timber piles........	1.177	1.317	.....	30	8.51	11.21
(4) Reinforced concrete deck and creosoted piles......	1.596	1.737	.....	20	10.02	17.39
(5) Timber piles and platform concrete column and deck	1.421	1.561	.....	60	6.53	10.19
(6) Timber piles and platform, concrete cross wall and deck............	1.545	1.685	.....	60	6.53	11.00
(7) Timber piles and platform, concrete ret. wall filled..	2.109	.....	2.35	60	6.1	14.34
(8) Timber piles and platform, concrete ret. wall, granite faced..............	2.452	.....	2.692	60	6.1	16.42
(9) Reinforced concrete piles and deck...............	1.812	1.952	.....	60	6.53	12.75
Piers 200′ wide, 1000′ long						
(10) Timber piles and platform, conc. ret. wall filled......	1.653	.....	1.893	60	6.1	11.55
(11) Timber walls and platform, conc. ret. wall, granite faced................	1.793	.....	2.043	60	6.1	12.40
(12) Solid filled surrounded by timber platform, conc. wall, reinf. conc. sheet piles..................	1.643	.....	1.883	60	6.1	11.49

Types 10, 11, and 12, show the decrease in cost per square foot, of these three types of piers (the first two being similar to Types 7 and 8, 70 ft piers), when piers are made wider.

The tabulation is subject to material change in the order of costs and annual charges, dependent upon location, cost of material and labor, purpose for which pier is intended, and various other factors.

21. Timber and Timber Composite Piers

The Temporary Character of timber piers which, apparently, serves as a reason against their extensive use, in many instances loses much of its force in view of their low first cost, simplicity in design, and short length of time in which they can be built. Furthermore, in localities or harbors where a comprehensive and well-planned port improvement project has not been developed, the wharf work is often laid out and constructed to serve the immediate purpose, to be later torn down and rebuilt on new lines. The growth in

importance of many American ports has been so rapid, and unforeseen, that no attempt at port planning in the past could have adequately provided for the future. The unprecedented and unforeseen growth in the size of vessels has also made necessary far-reaching and sweeping changes in port facilities. For these reasons timber piers of temporary character were as serviceable as more permanent piers, it being easier and less expensive to remove them to make way for other more extensive work. The timber pier has played a not unimportant part in the rapid growth and expansion of American harbors. The engineer in planning pier work when considering cost, is hardly justified in employing a permanent structure of a probable life of 50 or 60 years, when it is apparent that the wharf work will long before that time require extensions and improvements amounting to rebuilding.

While timber wharf construction in American ports has played the part indicated in the development of such ports, and has made it possible to materially re-arrange and re-build without excessive cost, this very condition has brought about a more haphazard construction with very little serious and comprehensive planning for port problems and construction of port facilities. It is to be regretted that pier or transit sheds are frequently used in American practice for long storage periods and cargo is not expeditiously brought to and taken away from vessels. Vessels frequently lie at and monopolize wharfage space when they might as well be at anchor in the stream or be laid up at dolphins and thus make available wharves for other vessels awaiting for loading or unloading cargo. As an illustration the area devoted to wharves at the port of New York is several times that devoted to similar purposes at ports such as Hamburg, Liverpool and London, all of which ports have in recent years handled about the same quantity and value of incoming and outgoing cargo.

Composite Piers, in localities where the under-water timber work will not be attacked by marine wood-borers, are practically permanent structures and, as a rule, are economical in first cost.

Crib Work may be employed for pier construction on a yielding or rock foundation. The crib consisting of round or square timbers is built in courses with pockets filled with riprap or rubble, in soft ground the crib being sunk to place on a prepared foundation of piles cut off to grade, on a level bed of broken stone or gravel, or directly on the bottom. On rock the crib is built up to rest and fit on the ledge, the contours of which have been previously determined by soundings.

Essential Details of various precedents are given in the following statements, where the numbers refer to Fig. 43.

(1) Philadelphia, Pa. 1912. Pier 5. 657 ft long; bents 10 ft centers. Live load 500 lb, inner 400 ft, 300 lb outer. Supports 40 ton crane track and standard gage track. R. con. top on timber piles. Cost $2.78 per sq ft inner end; $2.34 per sq ft outer end.

(2) New York, N. Y. Navy Yard, Pier 3. 1905. 520 ft long. Timber piles below water; 35 ft depth of water. Cost $2.80 per sq ft.

(3) New York, N. Y. Dept. Docks and Ferries, West 77th St. Timber piles and framing to mean tide elevation. Reinforced concrete walls, 12 in thick; 10 in reinforced concrete deck.

(4) Norfolk, Va. Proposed Old Dominion Terminal. Untreated timber piles. Surrounding wall with 16 in 45 ft long reinforced concrete sheet-piling. Wall bents, 4 ft centers; pier bents, 8 ft centers. This type of construction to bulkhead line; open creosoted timber pile pier to pier head line. Estimated cost $2.10 per sq ft.

(5) Norfolk, Va. Proposed alternate plan, Old Dominion Terminal. Cost $2.05 per sq ft.

(6) New York, N. Y. Navy Yard, Pier 2. 1901. Timber low water platform, filled

and banked with riprap, supports coaling plant. Length of pier 500 ft. Cost $2.85 per sq ft.

(7) New York, N. Y. Navy Yard, Pier D. 1912. Timber pile platform to low water; 34 ft of water. Piles 55 to 60 ft long. Granite ashlar faced surrounding wall. Paved creos. W. B. pavement. 2 standard gage and one 50 ton crane track entire length of pier. 440 ft long. Live load, 600 lb per sq ft. Cost, $3.25 per sq ft.

(8) Hoboken, N. J. D., L. & W. R.R. Terminal, Pier 1. 1909. 958 ft long. Bents 10 ft centers; 12 in caps; 6 in deck. Cost, $2.76 per sq ft.

(9) and (10) New York, N. Y. Navy Yard. Alternate designs, (10) adopted. Two

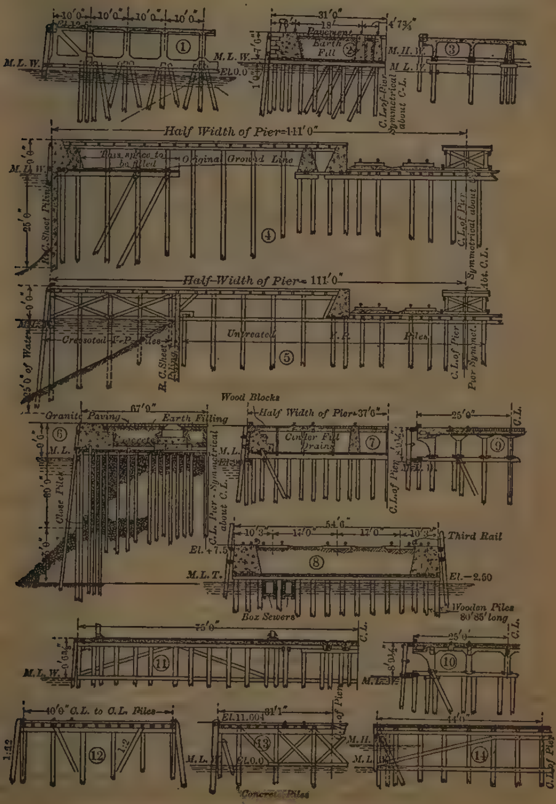

Fig. 43. Timber and Timber Composite Piers

piers, each 500 ft long. 1913. Timber piles and grillage below mean tide level. Piles 85 ft long, depth of water 35 ft. Reinforced concrete columns and deck system, columns premolded and set. Piers carry 2 lines of standard gage track, subways, and piping. Paved in center, creos. W. B. pavement. Cost, $2.08 per sq ft.—(9) Mushroom system, and (10) Beam system.

(11) New York, N. Y. Dept. Docks and Ferries. Typical construction at present in use. Untreated timber structure with 10½ in reinforced concrete deck with 2¼ in asphalt pavement.

(12) Puget Sound, Wash. Navy Yard. Timber approach wharf. Cost, $0.92½ per sq ft.

(13) Charleston, S. C. Navy Yard, Pier 4. 1905. 650 ft long. Reinforced concrete piles, 16 in square. Timber braces, clamps and deck system, 8 x 16 top clamp; 6 x 10 low water clamps; 3 in deck; bents 10 ft centers. Live load, 500 lb per sq ft. Creosoted timber pile fenders. Cost $2.10 per sq ft. Similar approach wharf 45 x 920. 18-inch reinforced concrete piles 40 to 50 ft long. 10-inch reinforced concrete deck. Cost, $2.00 per sq ft. Similar construction employed in Railroad terminal pier, Brunswick, Ga.

(14) Philadelphia, Pa. Clyde Line. 1900. Pier 556 ft long; bents 10 ft. Timber piling, bracing, deck system.

22. Masonry and Reinforced Concrete Piers

Filled-in Piers consist of walls similar to Quay walls of masonry, or of the platform type, the interior being filled with earth; when properly built they are permanent and unyielding and require little or no repair work, other than that due to the settlement of the filling usually occurring only during the first few years of use. Such settlement prevents the pier from being paved or kept level during the period of settlement. They can only be employed inshore of the "Bulkhead Line." On account of the cost of the surrounding wall work, narrow filled piers are not economical, except possibly at times when pier work is located on flats, in shallow water, or on high land, and the approach channels, slips or berths alongside require excavation or dredging, so that this dredged material can be used for filling.

Reinforced Concrete Piles and Cylinders are employed in pier construction where marine wood-borers are active, for economy in locations where the cost of timber piles is too high, or where the character of the pier foundation is such as to require the use of cylinders.

Essential Details of various precedents are given in the following statement. The numbers refer to Fig. 44.

(1) Balboa, Canal Zone. 1911. Lumber pier; live load, 400 lb per sq ft; length 706.6 ft; bents 30 ft centers. Hollow concrete cylinders built in 6 ft sections of 1 : 2 : 4 concrete, provided with steel cutting edge shoe; sunk to rock by jetting and interior excavation, filled with 1 : 3 : 5 concrete.

(2) Olongapo, P. I. U. S. Navy Yard, Pier B, 332 ft long; bents 12 ft centers; reinforced concrete cylinders, 6 ft; reinforced concrete deck. Cost $2.60 sq ft.

(3) Boston, Mass. Pier 6. 1912. 1200 ft long; 300 ft wide. Surrounding wall of courses of split granite 2 to 3 ft high, laid by diver. Cost $1.90 sq ft.

(4) Puget Sound, Wash. U. S. Navy Yard, Pier 8. 397 ft long; bents 16 ft centers. Live load 400 lb sq ft. Cylinders 3 ft diameter at top, 6 ft at bottom, shell 4 in thick, 23 to 52 ft long; sunk to hardpan by interior excavation. 2 standard gage tracks full length of pier. Cost, $3.25 sq ft. In the same location a similar designed pier No. 4, 490 ft long; cylinders 42 in diameter, 11 ft diameter at bottom, 43 ft long. Cost, $3.53 sq ft. This was constructed by placing wooden shells, sinking these by interior excavation, sealing bottom with tremie concrete and filling with concrete.

(5) Havana, Cuba. Pier No. 1, 660 ft long by 162 ft wide, bents 20 ft centers. A similar pier No. 2, 680 ft long, was built, and a quay 800 ft x 80 ft. Reinforced concrete piles 16 in, 18 in, and 20 in square. Water 20 to 40 ft deep. Soft bottom. 12 in rein-

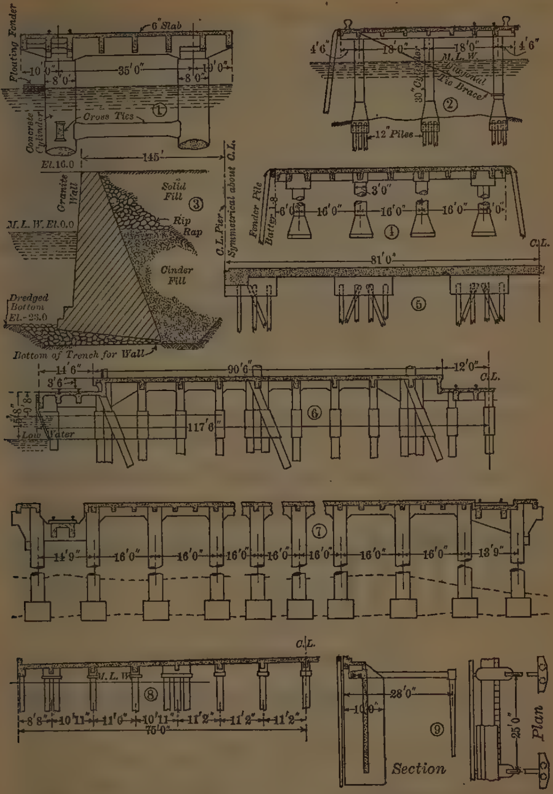

Fig. 44. Masonry and Reinforced Concrete Piers

forced concrete deck, deck live load 250 lb per sq ft and shed load. Cost, $3.35 per sq ft.

(6) Halifax, N. S. Pier No. 2. 1913. 686 ft long. 24 in sq reinforced concrete piles, 45 to 77 ft long; reinforced concrete brace piles cambered 2 to 5½ in. Special cement employed with minimum of aluminum to resist salt-water action. Bents 18 ft centers; rock foundation 68 to 52 ft below surface; area under pier filled by dredging to increase lateral stability. Piles loaded 80 to 90 tons each, test load 120. 1 : 2 : 4 concrete. Piles protected against ice between tides by timber sheathing. Live load 1000 lb sq ft.

(7) San Francisco, Cal. Pier 28, 677 ft long; bents 15 ft centers. Creosote W. B.

pavement, 31 ft wide down center, remainder of pier asphalt. Car springs fender employed. Type of construction general in this harbor, which is best given by a brief abstract of specification: "The excavation for the cylinders shall be made inside of steel caissons which shall be driven into the hard bottom and sealed. The steel caisson shall be of such strength and rigidity as to resist external pressure, and of such size that they may be withdrawn without injuring cylinder bases. The forms shall be wood stave forms of the diameter indicated. After the steel caissons have been set in place and the excavation made, as hereinbefore specified, the wood stave forms and reinforcement shall be set in place in the exact location shown on the plans. The concrete shall then be deposited thru a tube or bottom dump bucket. Under no circumstances will the placing of any concrete be allowed in or under water." Cylinders are sunk 12 to 14 ft below dredge line, and where bottom is soft, timber piles are driven to support the concrete. Cost of this pier was $3.20 per sq ft. Cost of Pier 26, $3.16 per sq ft. Piers 30 and 32, $2.52 per sq. ft. Pier 39, $3.57 per sq ft.

(8) Baltimore, Md. Broadway pier. Reinforced concrete piles, 16 in sq; 8 in reinforced concrete deck. Bents 10 ft centers.

(9) Baltimore, Md. Piers 4, 5 and 6, filled piers. Surrounding wall consists of flattened steel cylinders 25 ft on centers, sunk, excavated and filled with concrete. Reinforced concrete sheet piles between, anchored by reinforced concrete anchors and piles. Cylinders 27 ft in length, built up in sections of 4 ft. Cylinders driven, excavation made by jet and pumping. Cost of surrounding wall $97 00 per lin ft. Cost of piers, $1.57 per sq ft.

Two examples of piers of widely different types constructed during the period of the war in 1918 and 1919 are herewith shown.

Fig. 44*a* shows Pier 4 at Norfolk, Va, 1919, 1000 ft long. Interior untreated pine piling, 4-ft centers live load 900 to 1200 lb per sq ft. 350 long ton fixed tower revolving

hammer head crane, see Fig. 91*f*, inclosed space by 60 ft concrete reinforced sheet piles 40 ft depth of water at mean low water, range of tide, 3 ft. Cost $7.47 per sq ft.

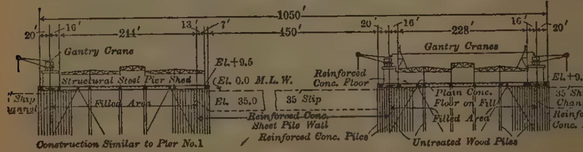

Fig. 44*b*. Shipbuilding. Filling Out. Navy Yard, Norfolk, Va.

Fig. 44*b* shows two piers for general loading and unloading of cargo of miscellaneous character built 1919, 1328 ft long. Filled center surrounded with reinforced concrete sheet-piles, interior untreated piles, exterior concrete piles.

23. Pier or Transit Sheds and Warehouses

Shelter from the Weather is provided on piers used for the loading and unloading of cargoes, by the construction on the piers of sheds, one or two stories in height, the floor area covered by the sheds being devoted to the handling and distribution of incoming and outgoing cargo and used for the storage of this cargo for a short time. Warehouses are usually provided on shore for goods to be stored for periods of more or less lengthy duration. When such warehouses are for the purpose of storing dutiable articles, remaining under custom seal until called for, and the custom imposed paid, they are known as Bonded Warehouses. Pier sheds are constructed of timber framing and siding with roofing covering of appropriate roofing material; timber framing with corrugated sheet metal siding and roofing; structural steel framing with corrugated sheet metal siding and roofing; of reinforced concrete and other combinations of materials. On open pier construction, lightness of construction within safe limits is essential, and the tendency is to make such structures fire retarding or resisting, especially where quantities of valuable cargo are handled. The width of the shed is, in most cases, made nearly the same as the width of the pier, a narrow space being provided on either side for string pieces, location of mooring posts and bitts, and for handling lines. The outshore end of piers is usually left open so as to permit of ready handling of the bow and stern lines of incoming and outgoing ships.

Pier or Transit Sheds are of one or two story, dependent upon local conditions and practice and the availability of water front and value of the same. On account of the conditions, pier or transit sheds should be capable of affording floor space for the storage of the cargo of incoming vessel or the accumulation of cargo ready to be placed in an outgoing vessel. Two-story sheds permit of a narrow pier width, or the second story is utilized for passenger traffic. That the two-story pier sheds apparently are preferred in the American practice is witnessed by the newer piers in New York, Philadelphia, and Boston. One-story sheds are preferred in European practice.

Railroad Tracks, when carried out on piers, are as a rule run either directly thru the center of the pier, or at the sides of the pier. Tracks are laid in a depression, so that the level of the car platform will be at or about the level of the pier deck, or are laid on the deck level. When railroad tracks are run on the side, they are not usually covered by the main pier shed. When run in the center, the pier shed is designed so as to afford proper head room and ventilation for the locomotive gases.

Details of Construction of Sheds are generally the same as those followed in building construction it being often customary to give the sides of the shed a slight inclination inwards or "tumble-home." The second floor in two-story sheds is sometimes given a slight crown and the lower chords of roof trusses a camber. Openings should be provided at frequent intervals in the sides used for berthing, or should be made continuous so as to afford ready access to the various ship hatchways and side openings. Doors may be either swung from the top and counterweights employed to facilitate ready and rapid opening and closing, or slide horizontally on overhead trackways. (Various folding cargo doors and metal rolling shutters are also used.) When continuous openings are provided, several lines of overhead tracks are placed, so that the door leaves may be rolled by one another. When the siding of the shed is of light sheet metal, on either structural steel or timber framing, it is advisable to protect this on the inside to a height of about 6 ft by cargo battens placed at a slight distance from the inside of the siding.

Lighting and Ventilation. In wide sheds the lighting arrangements are of considerable importance; natural light is provided by a continuous or series of skylights, or by monitors constructed in the roof, or by both methods. The employment of monitors also affords opportunity for ventilation, but is likely to permit leakage in heavy driving rain storms. Circular sheet-metal ventilators of various types may be employed on the roof ridge spaced 50 to 100 ft apart. As occasions frequently arise where the loading and unloading of vessels and handling of cargo must be done at night, proper artificial lighting is important, for which the practise is similar to that obtaining in general building lighting.

Miscellaneous Appliances. There have been many disastrous pier fires, so that adequate fire protection and service systems are important adjuncts to properly constructed pier sheds. Piers, if of timber or timber composite, being highly inflammable, the fire insurance rate on the structure itself and on cargo stored is an item that can properly be fixt in the annual charge and capitalized cost. Important commercial structures should have installed modern fire alarm and indicator systems, automatic sprinkler systems, preferably of the dry pipe type, and fire service mains, laterals, risers, connections and fire hose on reels or racks readily accessible. If local fresh or salt water pressure lines are not available, elevated storage tanks, with pumps and overboard suction connections, must be included in the equipment of the pier shed. If water mains are carried out on piers, precautions should be taken to prevent freezing by means of proper insulation, or by draining the lines when not in use.

Essential Details of various precedents are given in the following statements, where the numbers refer to Fig. 45.

(1) Havana, Cuba. Pier No. 1. 1913. Reinforced concrete pier shed. Live load, second floor, 400 lb per sq ft. Cost, $3.00 per sq ft. One of two piers and an 80 ft wide quay structure composing waterfront terminal, all similar in construction with ornamental street frontage. Freight entering is divided into three classes; first class consisting of soap and food-stuffs; second class, light hardware and machinery—both handled on first floor; third class, crates, bales, and merchandise, handled on second floor. Elevators and escalators provided from first to second floor and above. In another structure, third floor provided with refrigerating plant of 30 000 cu ft capacity.

(2) New York, N. Y. 33d St., South Brooklyn, Dept. Docks and Ferries. Bays, 20 ft.

(3) Halifax, N S. 677 ft long. Reinforced concrete structure, with expansion joints transversely every 90 ft. Live load, second floor, 500 lb per sq ft.

(4) San Pedro, Cal. Port of Los Angeles, Pier A, Shed No. 1. Timber construction.

(5) San Francisco, Cal. Pier 28. Bays 30 ft. Structural steel frame with reinforced concrete roof 2¾ in thick, covered with 5-ply roofing. Siding of reinforced concrete. Wire glass employed. Cost, $1.12 per sq ft. Pier 26, cost, $0.97 per sq ft. Piers 30 and 32 include steel girder runways and rails for inside cranes and outside ship towers. Cost, $0.87 per sq ft. Steel rolling doors employed in these sheds, cost per sq ft of shed being: Pier 26, $0.27; Piers 30–32, $0.22 each per sq ft. Piers 26, 30, 32, timber sheds with steel columns.

(6) San Pedro, Cal. Port of Los Angeles, Municipal Pier No. 1. Bays 20 ft. Equipped with side uprights for cargo handling.

(7) New York, N. Y. Typical pier, Chelsea section, Dept. Docks and Ferries. Swinging lift doors, provided with counter-weights. Uprights at sides of shed equipped for cargo handling.

(8) Jersey City, N. J. Pier No. 9, D., L. & W. R. R. Steel frame. Reinforced concrete roof, siding and floor. Cost of shed, $2.00 per sq ft, including column footings. Cost of quay and platform, $2.25 per sq ft.

(9) New York, N. Y. Dept. Docks and Ferries, Recreation Pier, E. 24th Street. Bays 20 ft. Typical example of recreation piers constructed in this harbor.

WET AND DRY DOCKS

24. Wet Docks

Definition. Docks may be divided into two general classes—harbor docks and repair docks. The former, known as Wet Docks, are enclosed, or partially enclosed basins, usually provided with locks and entrance gates, similar to canal locks. They are sheltered basins for the receiving of shipping, so arranged that the water in the dock may be kept at more or less constant level to facilitate the loading and unloading of cargo.

Use of Wet Docks. Their usefulness is apparent in harbors where there exists a considerable range of tide, and especially wherein under low tide conditions the approach to the harbor itself is not navigable for deep-draft vessels. They also have a special field of usefulness in harbors or rivers where considerable silting up takes place, the dock area being kept free of such silting by keeping out turbid river or harbor water and often by supplying water to the dock basin from other sources. This type of structure, in its restricted sense, is rarely found in American practise, altho it is employed in some South American ports.

The reasons given for the use of wet docks are undoubtedly not the only ones that have occasioned their appearance in European practise, as otherwise they would undoubtedly have before this been employed in American ports where a considerable range of tide is involved. They have undoubtedly been resorted to in order to retain the maritime commerce of river ports, where the increase in draft of vessels has become greater than the normal navigable depth of the river. The wet dock has been developed as the instrument by means of which Old World ports have retained maritime supremacy.

Design of Wet Docks. It is apparent that in wet docks, where entirely enclosed and provided with entrance gates, as the surface of the water is to be kept at approximately a constant elevation, the sides and bottom of such a basin must be practically impervious, or arrangements must be made to replenish the water lost by leakage. This is especially so in all seas having a considerable variation in tide, and a consequent appreciable difference at times in the height of water in and outside of the wet dock. Where the basin is located in a practically impervious soil, such as clay or clay soils, and many kinds of rock, these conditions are generally provided for. For this reason, a thoro exploration of the subsoils in locations where wet docks are projected is of the greatest importance. In locations where the subsoil is readily water bearing, the bottom must be blanketed with clay puddle or a masonry lining placed. The dock walls can be treated in a manner similar to that described under Quay Walls, in Art. 12; the walls, however, of dock basins being at times subjected to external hydrostatic pressure in excess of that to which they would be subjected if located on open basins. This is, usually, not a serious matter, as the combined earth and contained water pressure, together with the passive resistance of the earth backfill, will be found sufficient to provide for this condition.

Locks and Lock Gates. The condition governing the design and construction of these is, in all respects, similar to that found in canal work. Information on this subject will be found under Canals, in Arts. 17 and 19, of Sect. 11.

25. Marine Railways

Definition and Description. Repair docks may be marine railways, lift docks, graving docks, or floating docks. Marine railways are inclined slips or ways, extending out some distance into and under the water, and running up on the foreshore a sufficient distance so that the vessel when hauled out will be entirely clear of the water. A platform or cradle moves on these ways, usually

on nests of rollers, and is hauled out of the water by means of chain or wire rope cable. Racking and pawls are usually provided, so that if the hauling device should break, the cradle and vessel will not slip back into the water. It is apparent that even without considering the feature of range of tide, the application of this type of repair dock is limited to vessels of comparatively small size, as in long vessels of deep draft the ways would have to be carried out a great distance under water, approximately twice the length of the vessel to be docked, making the entire length of the ways over 3 or 4 times the length of the vessel to be docked. This condition is sometimes materially improved by use of a collapsible cradle. While there is no reason why sufficient capacity of hauling device can not be designed, nevertheless important considerations would tend to limit this. This type of repair dock is, undoubtedly, valuable and economical for the docking of smaller vessels. Its application, however, appears to be limited. No marine railways have been built in excess of 5000 tons lifting capacity. Fig. 46 shows a marine railway of 2000 tons capacity. Estimated cost, $100-000.00.

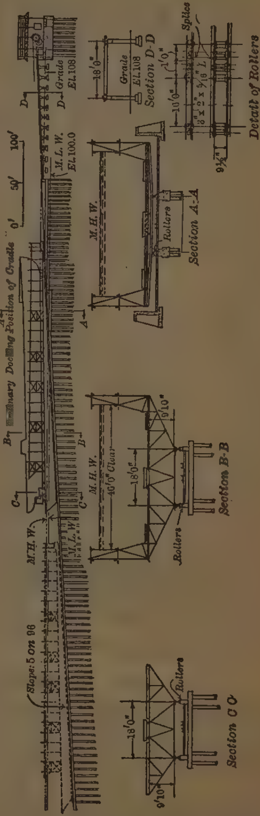

Fig. 46. Marine Railway

Marine Railways were designed in 1918–1919 of 3200 tons capacity; the estimated cost has been $300 000 or nearly twice the cost per ton capacity as that given hereinbefore.

The Foundation should, if possible, be incompressible. In many larger and more important marine railways the ways are built on piling. The intensity of pressure, while not great, is, nevertheless, in the form of a moving load, becoming greater as the vessel hauled out loses its buoyancy. The ways are, in many instances, similar to the ways employed in shipbuilding work, which, however, do not go out under water to the same extent, and besides this, the weight of a vessel when launched is usually considerably less than would be the docking weight of the same vessel.

Ways. The ways are laid at a gradient of between 1 on 13 and 1 on 25, 1 on 20 being the usual slope for large marine railways. The ways consist of

from 2 to 4 rails of iron or steel securely fastened to longitudinal bearers which, in turn, rest on cross-ties bearing on the foundation. The racking to receive the cradle safety pawls is usually placed in the center of the ways between the two central rails, if 4 rails are used. The under-water work is either performed in the dry by the construction of a coffer-dam around the site, or by divers. If no foundation piles are used, the grading must be carefully done, working from over-water battens. If piles are used the underwater portion of the ways is built in sections, floated to place, and lowered onto the foundation by weighting and fastened securely in place.

The Cradle or Platform is usually constructed of timber or structural steel, and is provided with keel and bilge blocks. The cradle is constructed on longitudinal sleepers, placed directly over the longitudinal ways, and provided on the underside with an iron track. The cradle is moved on nests of rollers placed in between the upper and lower lines of track. The rollers are usually of cast iron, double flanged, and held in place by flat bars or links; sometimes the rollers are fixt on the cradle and run on tracks on the longitudinal way-sleepers. In large marine railways, the cradle is built with side frame work, which is used for working platforms. Frequently, cradles, instead of having the same inclination as the ways, are built with the platform horizontal, or nearly so, so that the ship being docked will immediately come to a bearing and not be lifted first by the bow.

Broadside Marine Railways. With a view to overcoming the difficulty as to length of marine railway, they are sometimes built so as to withdraw vessels from the water broadside on.

Power Absorbed in Friction. The power required to raise a vessel is dependent upon the inclination of the ways and the force required to overcome friction. Experiments made on the power absorbed in friction indicates a variation from 3.3 percent to 7½ percent of the weight lifted. On larger and well-designed marine railways, the percentage is in the neighborhood of 4 percent, to which should be added 5 percent for initial friction in starting from rest. Thus in a marine railway having an inclination of 1 to 20, the hauling machinery would have to exert a pull of 14 percent of the weight of the vessel lifted.

Lift Docks are platforms lowered into and raised from the water. This type of structure is of limited capacity and is not now used to any great extent. It is very often employed in connection with pontoons or floating dry docks, hydraulic power being generally employed, applied thru a series of hydraulically operated cylinders placed on both sides of the platform and connected together transversely by girders. A small dock of this type has recently been built in the Island of Curaçao.

26. Graving or Basin Dry Docks

Definition. Basin dry docks, often called graving docks, are basins generally made by excavation in the foreshore of the harbor, having entrance-ways closed with gates or portable caissons and are usually of such dimensions as to be capable of receiving, with sufficient clearance, the maximum sized ship to be docked therein. After the ship is floated into the dry dock, the opening is closed by means of a gate or caisson and the water in the interior is removed by pumping, the ships settling on blocks provided for that purpose. In some graving docks advantage is taken of the fall of tide to reduce the amount of pumping necessary. In nearly all cases the graving dock must be pumped out twice for the docking of the vessel. The dock is usually left unwatered so that when word is received that a certain vessel is to use the dock, the blocking may be arranged to conform with the profile of the keel and the character of the vessel. The

dock is then flooded and the vessel floated in and centered and held in the proper position, the opening closed and the water removed. On completion of the work on the ship, the dock is flooded and the ship removed, the opening again closed, and the water removed from the dock.

Foundations. In large graving docks, water at considerable head must be excluded, and for that reason the character of the subsoil and foundations are of considerable importance in locating structures of this type. A graving dock can, altho at times at a prohibitive cost, be constructed in almost any location, but, where possible, it should be located at a site where sound bed rock will be encountered at some elevation not below the subgrade of the structure or in locations where marl, stiff clay, or mixtures of marl or stiff clay, sand and gravel are encountered. Suitable foundation conditions, other than rock, sometimes result in less expensive and more expeditious construction Fig. 47 shows a half transverse section at the entrance sill of a graving dock on pile foundations.

Graving docks have been constructed in unstable water-bearing soils, but at high cost. With a view to securing a suitable site, or to enable proper precautions to be taken in design and in method of constructions, if selection of a site

Half Section through inner sill, Looking Inboard

Fig. 47. Section of Graving Dock with Pile Foundation

is restricted, an important preliminary step is the taking of exploration borings, operations for which are described in Sect. 11, Arts. 29 and 30. It is advisable, where possible to do so, to secure core borings showing the condition of the soil " in situ " and, in special cases, to supplement these with test pits. See Sect. 11, Art. 31. In water-bearing soils such test pits may have to be made by employing the pneumatic process.

Masonry Graving Docks. In the design and construction of such docks, provision must be made for counterbalancing the hydrostatic pressure by sufficient weight of masonry or other anchorage effect. In porous water-bearing soils, the hydrostatic pressure to be considered will be at least the full hydrostatic pressure due to maximum tide elevation, and under certain conditions, on account of the presence of ground, surface or artesian waters, a pressure in excess of this. Where the dock is located on a solid rock ledge without water-

bearing fissures, this condition will not obtain, altho ideal foundation conditions of this character are seldom, or never, encountered in practise, and it is, therefore, customary on this character of foundation to provide for relieving the water pressure by under-draining the floor of the structure. In some soils, such as tenacious marls or clays, or hardpan, the same precautions may be taken, the walls of the graving dock being designed as retaining or quay walls. In graving docks built in water-bearing soils, full hydrostatic pressure should be expected and provided for. A number of graving docks have been constructed in which the weight of the masonry mass is somewhat less than the uplifting force due to full hydrostatic pressure, their integrity depending upon the friction of the backfill on the back of the side-walls, and, in some cases, to anchorage or pull on foundation piles. In stable waterbearing soils where the uplifting forces are clearly defined, dependence can be placed on the anchorage effect of the foundation piles, where such exist. This anchorage effect, however, should not exceed the submerged weight of the mass of subsoil engaged by piling, as stated in this section, Art. 12. The friction of the backfill on the rear of side-walls being indeterminate at best, should not be given a definite value, and should be considered merely as a factor of safety. In a dry dock completed at the New York Navy Yard in 1912, the anchorage effect against hydrostatic uplift was secured by deep piers with flared-out basis, secured into the floor by a system of anchor rods, the anchorage provided in each being in the neighborhood of 1 000 000 lb, these piers being sunk to position by the pneumatic process.

A masonry graving dock is subjected to three following conditions:

(a) When empty: The bottom or floor is subjected to hydrostatic pressure, usually considerably in excess of the weight of the floor itself. This excess is transmitted to the heavy side-walls by actual or virtual inverted arch action, the abutments of the arch being furnished by the weight of the side-walls taken together with the thrust of the earth and water on the rear of the wall and the passive resistance of the earth itself. When this abutment action is insufficient, reinforcing steel should be provided in the floor.

(b) The dry dock empty with a ship of maximum tonnage in the dock: The conditions are the same as (a), except that there is concentrated at the center line on keel blocks, and on the side blocking, the weight of the ship; for which concentration, where the foundation is somewhat yielding, special provision must be made by distribution of this load by reinforcing the masonry with steel, or the foundation directly under the blocking designed accordingly.

The loading per running foot of dry dock is dependent on the length, depth, and width of the structure and the character of ships to be docked. For war vessels of the largest size weights as high as 90 long tons per running foot should be allowed, as the concentration under machinery and gun turret locations are liable to run this high. For commercial steamers the loads will be less. Under ordinary docking conditions $\frac{5}{8}$ of this load will come on the keel blocks and $\frac{3}{16}$ on each side, docking keel or bilge block. In the work of bottom repair, as blocking is removed, the concentrations are shifted, this, however, only occurring locally over small areas.

(c) Dry dock full of water: Under this condition, the foundation, considered in its entirety, is subjected to the greatest load, consisting of the submerged weight of masonry to tide level, plus the weight of masonry above tide level, the conditions being somewhat altered with the presence of surface or artesian ground water in the soil. Under this condition the thrust on the rear of the wall is due to submerged earth pressure to ground or tide water level, tide or ground water pressure and surcharge of earth pressure above tide or ground water level, and surcharge on wall, reduced by water pressure on the interior of the dry dock. It is often customary to use combined liquid pressure to the coping of the structure and neglect surcharge (Art. 12). Under this condition, very often little or no virtual or actual arch action can be counted on, and the foundations under the side-walls should provide for the weight directly above them, or provisions for distribution made by employing reinforced steel. In yielding foundations, if this is not done, settlement at the side-walls will be in excess of the settlement under the center

f the floor, causing cracks at the toe of the walls, and along the center line of the dry ock. It should be noted, as between Conditions (a) and (c), there is likely to be a comlete reversal of stresses in the floor.

To these three conditions a fourth may be added, that is, of the dry dock while under onstruction. This should be given careful consideration and analysis, the omission of vhich has, in some instances, resulted in damage to the uncompleted structure. Many lder masonry graving dry docks have been constructed of rubble or ashlar stone work, iced with ashlar work. Nearly all of the more modern graving docks are constructed f concrete, unlined, or lined with granite ashlar work, or, as in the case of the graving ock built at the New York Navy Yard in 1912, vitrified brick, in either case caisson or ate seats consisting of granite stone work with radial joints for the bottom and lower arts of the side steps, the contact faces of which are fine cut work, or, at times, rubbed. 'he beds and joints of caisson-seat stone work should not exceed ¼ inch, and, in some ases, are limited to ⅛ inch.

Examples of recent graving docks are shown as follows:

Figs. 47a and 47b show a plan and a transverse section of a group of four dry docks t the Norfolk, Va., Navy Yard. Dry Dock No. 3 was built between 1903 and 1911

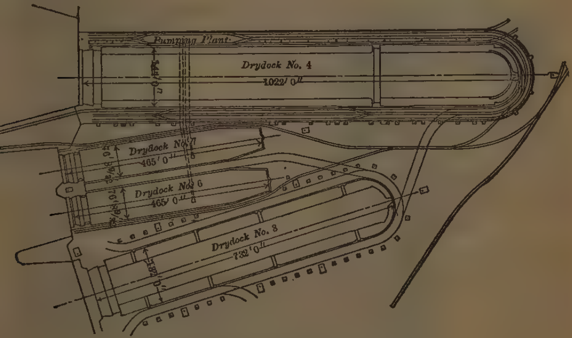

Fig. 47a. Group of Four Dry Docks for Norfolk, Va.

vhile Dry Docks Nos. 4, 6 and 7 are in process of completion; the larger for the Navy nd the two smaller ones for the United States Shipping Board Emergency Fleet Cor-

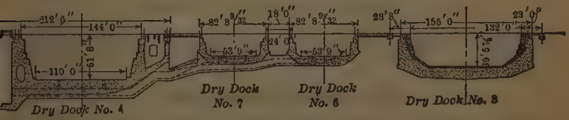

Fig. 47b. Transverse Section of Docks, Norfolk, Va.

poration. Details of all four docks as to dimensions and cost can be found in the tabuation on page 1476, Art. 30. One pumping plant consisting of three 54-in vertical volute umps serves all three of these docks. No. 4 Dry Dock is provided with an intermediate aisson gate seat so that the inner end of the dry dock can be used for smaller vessels on ong time repair work, and the outer portion continue available for docking larger vessels. This arrangement practically provides two docks in one. A similar arrangement is

provided in the Philadelphia Navy Yard Dry Dock under construction and in the Commonwealth Dry Dock at Boston, Mass. These arrangements entail the additional cost of the interior seat, two dry dock caisson gates and independent pumping for the two sections of the dock. The older dry dock of the group, No. 3, as will be noted in Fig. 47*b*, is lined with granite ashlar masonry, while the three new docks are of concrete thruout without other facing or lining. A section of Dock No. 4 shown in Fig. 47*b* is at the pump well. The half-section to the right of the center line is so designed that the dock could be constructed on the natural stable slope of the excavation which was made by drag line in the dry. The floor invert is 20 ft in thickness. The floor of the two smaller docks are 10′ 6″ in thickness. Excavation for these docks is also being made in the dry. Water is kept out of the excavation site by a coffer dam of steel sheet-piling, wooden sheet-piling and earth embankment. Dry Dock No. 4, the large dock, has been completed in about 2 years, while Dry Docks Nos. 6 and 7 will be completed within one year, indicating that this type of dry dock can, under favorable conditions, be constructed as expeditiously as floating docks of similar size.

Fig. 47*c* is a half typical section of a graving dock under construction at the Philadelphia Navy Yard, and is similar in dimensions to that just completed at the Norfolk

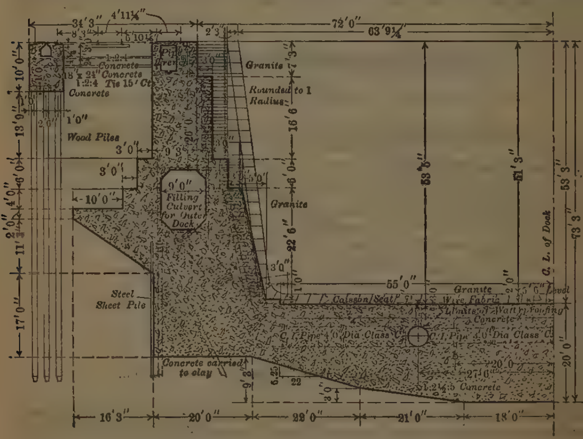

Fig. 47*c*. Half Section Graving Dock, Philadelphia, Pa.

Navy Yard. The steel sheet-piling shown surrounds the entire site at the bottom and was placed to cut off the flow of water in the sand and gravel above the clay sub-soil.

27. Design of Graving Docks

Data on Design. A graving dock should be designed having in mind the three conditions enumerated in the paragraph above, and consideration should also be given to the possible fourth condition. The necessary information having been obtained as to the character of the soil, its probable submerged weight and angle of repose, allowance made for the safe weight of masonry per cubic foot, stress diagrams should be drawn for all conditions. Fig. 48 is such a diagram for Condition (a). In this case the hydrostatic pressure is just counterbalanced by the weight of masonry. The line of pressure does not pass thru the middle-

third at the base of the side-wall or in the center. If on analysis the maximum unit pressure in the virtual arch is not too high, the masonry at the center above the virtual arch may be considered inert, altho it may be desirable to employ reinforcing metal to avoid unsightly longitudinal center line cracks.

Under these conditions the vertical components of the downward forces would be in excess of the vertical components of the upward forces of hydrostatic pressure, this excess being counterbalanced by the soil pressure or passive resistance and would appear as a vertical closure in the polygon of forces (Fig. 48). In analyzing the floor arch thrust in the same way it may be necessary to not only consider the active earth and water forces on the rear of the retaining wall, but the soil pressure or passive resistance that would be afforded to this wall acting as an abutment for the inverted floor arch thrust, from which it will be seen that it is entirely probable in the preparation of the design and in the analysis of the structure and in the making of the stress diagram to insert exterior soil resistance or passive pressure forces.

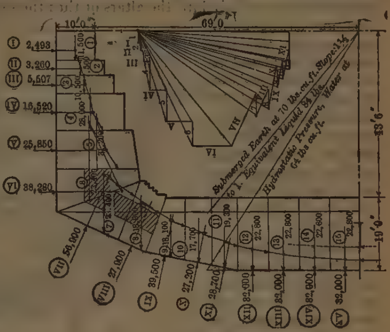

Fig. 48. Stress Diagram

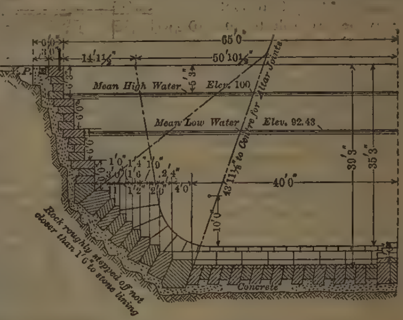
When the weight of the section is in excess of the hydrostatic pressure, the diagram would have to take into consideration the bearing of the structure on the foundation, or soil pressure, which could be considered as equally distributed over the entire area of the foundation. However, in a case such as that shown where the line of pressure was outside of the middle-third at the center, in order to develop longitudinal cracks on the tension side, the floor at the center would have to lift slightly, relieving the soil directly beneath it of pressure and transferring the entire soil pressure to the sides, resulting in raising the line of pressure to within the middle-third as indicated by the dotted line.

Masonry Graving Docks on Rock Foundations. The same considerations govern the design, excepting that provision can probably be made for relieving, in whole or part, hydrostatic pressure; under the most ideal conditions the rock can be excavated out to the rough dimensions of the graving dock, and then lined with masonry, with or without relieving drains. A graving dock built at Hunter's Point, San Francisco, Cal., was built in this way, the excavation being made in impervious serpentine rock, and lined with a comparatively thin layer of concrete. No provision was made for draining. In graving docks founded on ledge rock, the necessary stress diagram should be made for all conditions. Fig. 49 shows a half transverse section of a graving dock on rock foundation.

Altars are provided in the side-walls at convenient heights, the first at elevation of about mean high tide and additional altars at intervals below this. They consist of steps or platforms 2 to 3 ft wide, and are used for the placing of shores to hold upright the vessel being docked, and as a means of access from and to plank stages or working platforms placed alongside the hull.

Stairways and Timber Slides. Stairways are provided for going into and

coming out of the graving dock, two sets on either side of the entrance and at or on either side of the head with intermediate stairways to suit convenience. These are built directly into the altars or thru the side-walls. Timber slides are used for letting down and hauling up material and are placed at convenient intervals in the side-walls on both sides of the structure. In order to simplify design and construction, portable stairways may be provided, leaving the altars clear and continuous.



Half Section thru Body of Dock

Fig. 49. Graving Dock, Rock Foundation

Drainage. The floor is drained by means of either open gutters at the sides or in the center of the floor, or by drainage culverts with drain connections, located at intervals. Where gutters or drains are used the floor must be graded transversely to these, the gutters or drains being given gradients to insure self-cleaning.

Head. The inshore end of the graving dock is known as the Head, as distinguished from the outshore end, or Entrance. Heads are built rectangular, trapezoidal or circular or elliptical, in which case the walls are designed and figured as retaining walls, or are built as simple or compound, circular or elliptical arches.

Timber Graving Docks have, in the past, been extensively employed in American practise, when vessels of smaller size with less draft and of different hull section were constructed for the Merchant and Naval Service. They had the advantage of lower first cost and more expeditious construction and were especially suited for location in stable waterbearing subsoils. The principle of design and construction is different from that obtaining with respect to masonry graving docks and is based upon the partial, or entire, reduction of hydrostatic pressure on the bottom by drainage and the building of the side-walls at a slope approximating the natural slope of the soil, relieving this portion of the structure from the earth thrust. The flow of ground or tide water thru these walls is cut off by a continuous and enclosing wall of sheet-piling driven at the coping or some distance back from it, the timber altars of the side-wall being laid on inclined stringers supported on piles, a sloped wall of puddled clay being laid between the soil and the timber altars. The flow of water onto the floor is cut off or reduced by a continuous enclosure of sheet-piling driven at the foot or toe of the wall or slope and 1 to 3 rows of timber sheet-piling are driven across the entrance, the floor itself consisting of heavy timber planking, fastened to dimensioned caps bolted to the foundation piling, with which the bottom is studded at 3 to 4 ft intervals, additional piles being driven in the center, where necessary, under the keel blocks, and under the probable position of bilge blocks. Three to 5 ft of concrete is placed under the timber floor in between timber caps and piling. In this type of structure a certain amount of leakage or self-draining is expected and allowed for. Among the advantages

claimed are that the sloped sides give better light and ventilation. While this argument, undoubtedly, is of importance as applied to the older types of vessels, it loses its force when steel vessels of rectangular amidship sections, with practically flat bottoms, are considered, as, in both masonry and timber graving docks, artificial light must be employed, under such hulls. The disadvantage of this character of construction is that in order to secure necessary width of graving dock at the height of the blocks, the width at the coping line becomes excessive. Thus, with a vessel 100 ft beam, and 30 ft draft, with allowance for clearance, the width of the timber graving dock at the coping line would have to be nearly 200 ft as against 140 ft for a masonry graving dock, entailing the requirements of a considerably larger area of land, and difficulty in handling materials for building or repair by side-wall cranes. Timber graving docks have a further disadvantage of not being a permanent structure and require continuous and expensive repair and replacement. The surface of the ground around the structure is in a continuous process of settlement due to the percolation of water thru it, and to the washing out by this water of the finer particles of soil. On account of the difficulty of obtaining complete and intact sheet-pile water cut-off walls, frequently extensive washouts and undermining occur in this character of structure.

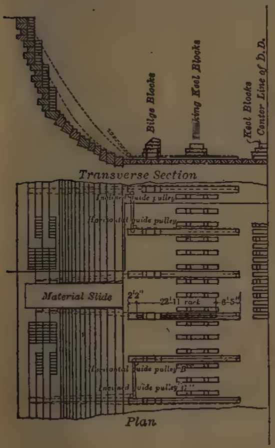


Fig. 50. Arrangement of Blocking

Blocking, Shores, and Fittings. Keel blocks are provided on the center line of the floor and consist of heavy dimensioned hardwood timbers. They should be so laid out as to afford sufficient bearing to avoid undue crushing under the maximum weight likely to be brought upon them. In American practise they usually consist of three or more tiers, placed transversely of the dock on 4 to 2 ft centers longitudinally. Heights of blocks above floor should not be less than 3½ to 4½ ft to give clearance for working under a ship.

In European practise the lower blocks are often of cast iron, sometimes wedge-shape, to permit of ready removal. The lower course is fastened to the floor by anchor bolts, and the upper course, if of timber, by iron dogs. In addition to these blocks, bilge blocks are provided on both sides of the keel blocks, but placed at longer intervals apart. Some of the larger modern ships, especially in the Naval service, are provided with four docking keels, two on either side of the center line, so that in being docked the ship will come to a horizontal bearing on central keel and side docking keel blocks avoiding the expense and delay of holding the graving dock while blocking is being rearranged to fit the hull of the particular ship to be docked. When docking keel blocks are not employed, bilge blocks are used, consisting of several tiers of blocks, the upper one slightly inclined or hinged to the block below and provided with a wedge. These blocks slide on bilge block bearers placed transversely of the dock. They can be drawn in under the ship and against the bilge by means of hauling chains,

cast iron racking being placed on the bearers and adjustable automatic pawls attached to the lower bilge block, holding the block in place when it has been drawn under the ship. These pawls are lifted and the block released when the hauling-back chain is employed. The docking keel and bilge-block bearers are sometimes made of reinforcing concrete, or entirely done away with, the cast-iron racking being fastened directly to the floor of the structure. Fig. 50 shows a half cross-section and floor plan giving position and arrangement of blocking.

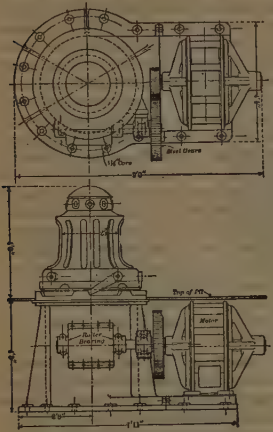

Fig. 51.—Electric Capstan

Shores are used with, or to replace, bilge blocks, to hold a vessel upright when the graving dock is unwatered. They bear against the vessel's side at frames and are wedged against the walls, rest on the altars, or are suspended from the coping by lines, for which purpose small cleats are placed at convenient distances. In order to assist in bringing and holding the vessel to alignment in position over the blocking, brest lines are employed, final adjustment often being made by block and tackle, for which small hand winches are installed at convenient intervals along the top of the dock wall.

Capstans and Bollards. As it is impracticable to place ships in graving docks under their main engine power by tugs, power capstans are very often provided for this purpose. In smaller docks hand capstans are employed, assisted by windlasses on the ship being docked. On large graving docks, power capstans should be provided at the head end of the dock on either side of the entrance and in long structures midway of the length. These should have two speeds, the maximum for slow hauling from 15 000 to 35 000 lb at the capstan barrel, the minimum is used for overhauling lines so as not to permit too much slack and possible snarling. Bollards or mooring posts are

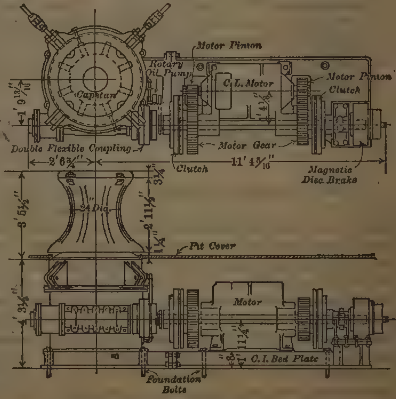

Fig. 51a. Electric Capstan.

placed on both sides at intervals of about 50 ft. Figs. 51 and 51*a* show electric motor driven capstan of the latest type. Fig. 51*a* is designed with barrel height so as to permit the passage over it of the heavy dry dock traveling cranes.

28. Construction of Graving Docks

As graving docks are always located on the foreshore of harbors, the problem of construction has an important influence on design. With the increase in draft of vessels and the necessity for providing for overdraft in case of accident, the clearance depth over entrance sills of graving docks has increased greatly and with it the head of ground or sea water to be taken care of during the construction period.

In certain locations it becomes impossible or impractical, within the range of ready execution, to construct graving docks by any method involving the unwatering of the site. When such cases occur, recourse must be had to a method of construction that will make the unwatering of the site unnecessary. As the method of construction is an important item in graving dock design, it is well worth while illustrating various methods that have from time to time been employed.

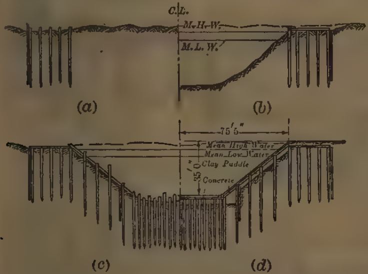

Fig. 52. Timber Graving Dock

The usual course followed in the construction of timber graving docks is illustrated in Fig. 52 where (a) indicates the original conditions of the site. The entire site is surrounded by a wall of sheet-piling, a portion of the round piling being driven previous to excavation, (b) shows the excavation, in part completed, (c) illustrates the driving of the round piling on the side slopes and in the bottom, and of the bottom enclosing sheet-piling, and (d) shows the work completed. This method was generally followed in the construction of two timber dry docks built in the New York Navy Yard, and two similar structures built in South Brooklyn, N. Y.

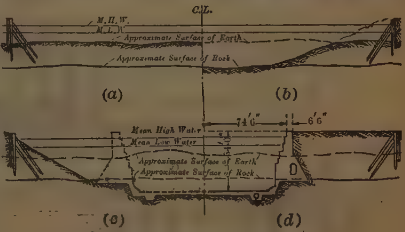

Fig. 53. Graving Dock, Boston, Mass.

Dry dock proposed for the Port of Boston: The contemplated method of construction for this dock is illustrated in Fig. 53. The projected structure is located on ledge rock, covered with a blanket of soil under water. On either side and around the head of the proposed dock double timber bulkheads were placed, filled in with excavated material. The proposed steps of construction (a), (b), (c), (d), are shown, (b) with the space between bulkheads filled and excavation made to ledge rock; (c) excavation in ledge rock; (d) completed structure backfilled. In this design the side-walls are retaining walls, the

floor or bottom is shallow, and is to be under-drained, so that the underside of the floor will not be subjected to hydrostatic pressure.

Naval Dry Dock at Charleston, S. C., was located on a salt marsh, with underlying,

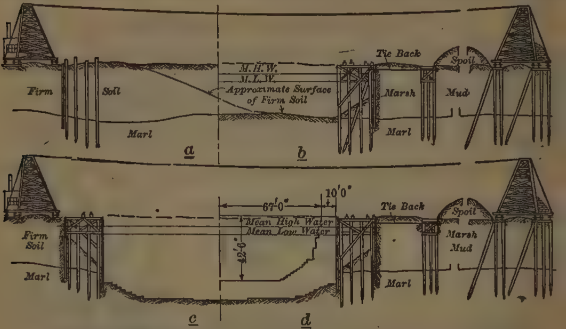

Fig. 54. Graving Dock, Charleston, S. C.

marl foundation. The entire site was surrounded with heavy sheet-piling, held in place by timber trestle work, brace piles, and shoring, as illustrated in Fig. 54. The final excavation into the marl is shown in (c), and completed structure in (d). The method employed in making the excavation for the structure was,—the first 10 ft were taken out by hydraulic dredging, the remainder of the excavation in the marl being taken out by clam shell buckets operated by cable-ways and by pick and shovel and blasting. Cofferdam around the entrance to the work is illustrated in (e).

The method of constructing the Naval Dry Dock at Mare Island, Calif., is as illustrated in Fig. 55. The excavation was made in water. Foundation piling was then driven in the bottom and the t mber crib of the general dimensions of the structure, built

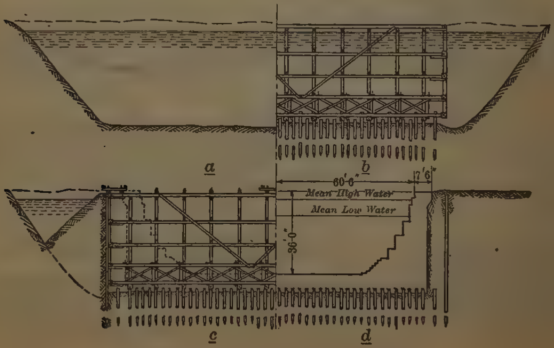

Fig. 55. Graving Dock, Mare Island, Calif.

up on the surface of the water, loaded, and lowered until it rested on certain of the foundation piling, as shown in (b). Timber sheet-piling was then driven around the crib work and then backed up with earth, as shown in (c). The interior of the crib was then pumped dry and the structure completed as illustrated in (d).

The side-wall, or English plan, is illustrated in Fig. 56. This method has been used, with success, in the construction of some European graving docks, (a) illustrating the preliminary step of driving sheathing and excavating a trench for the side-walls; b) completion of this trench and driving of the side-wall foundation piles; (c) the completion of the side-wall and the excavation of the interior or "dumpling," and the driving of the interior foundation piles; (d) completion of the work. In this method of construction there is a tendency for the side-walls to be thrust or move inward when the interior of the "dumpling" is removed. The floor work should be constructed in sections, or heavy bracing placed between the wall work pending completion of the bottom. A modification of this method was employed in the preliminary attempts at construction of Dry Dock No. 4, Navy Yard, New York, but failed, the uncompleted side-walls being thrust in.

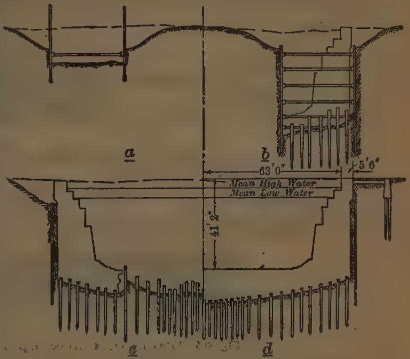

Fig. 56. Graving Dock Construction, English Trench Method

The dry dock at the New York Navy Yard was constructed by the method illustrated in Fig. 57. This dry dock was located in waterbearing quicksand soils. Open excavation

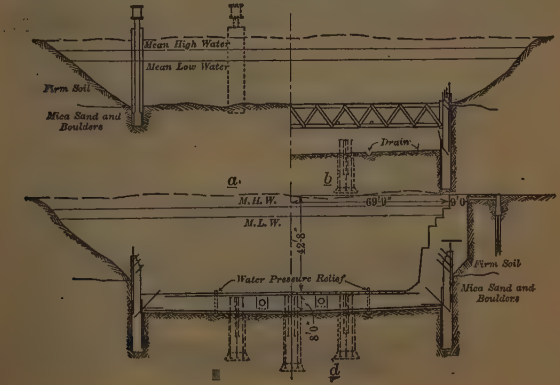

Fig. 57. Graving Dock, New York

was made by steam shovel to the quicksand. The entire site was then surrounded by a reinforced concrete cut-off wall, placed by pneumatic process. The excavation of the interior was then made, bracing being placed between cut-off walls, as illustrated in (b). Interior rectangular piers or anchors were placed by pneumatic process. The

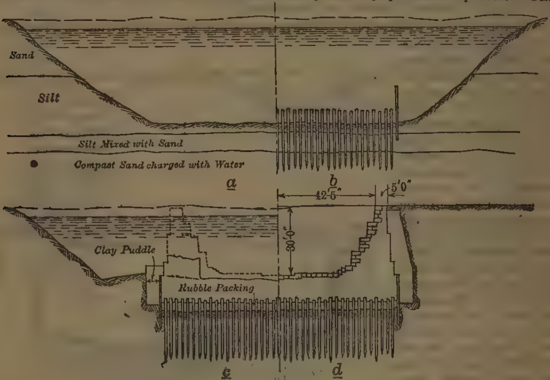

Fig. 58. Graving Dock, Kobe, Japan

floor was then built in 20-ft sections, entirely across the structure, as shown in (c). Side-walls were then built up and the structure backfilled.

At Kobe, Japan, the character of the site was such that after an unsuccessful attempt to construct in cofferdam in the dry, it was decided to employ a method not requiring the unwatering of the site. The plan followed is illustrated in Fig. 58. Excavation was made in water, as shown in (a), and piling then driven as shown in (b). Concrete was then deposited by skips and buckets under water, as illustrated in (c). Upon completion of placing of the underwater concrete up and above elevation of high water, the structure was pumped out and interior lining placed, as shown in (d).

A somewhat different method of construction proposed in connection with another dry dock is illustrated in Fig. 59. Excavation made under water, foundation piling

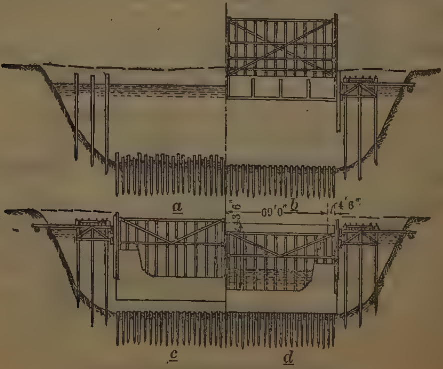

Fig. 59. Construction Employing Floating Caissons

driven as shown in (a), the foundation piling then cut off under water to grade, and the graving dock structure built in sections by means of caissons lowered to place, as illustrated in (c) and (d), in a somewhat similar manner to the method employed for Breakwater and Quay Wall Construction. See Arts. 3 and 15.

The above method was proposed for the construction of the Pearl Harbor, Hawaii, Navy Dry Dock. In the construction of this dock the general principle was used but the 16 sections were constructed on a floating dock, and then by lowering the floating dock a steel tank coffer dam was floated over a section and bolted to it. The floating dock was then lowered and the whole section floated to place, the tank coffer dam flooded and the section lowered, the side-walls and bottom of the section built complete in the coffer dam, the tank-coffer dam then floated by removing water from the tank, and then floated away and placed on the next section and so on. Space between sections was closed by concrete deposited in Tremie.

29. Gates and Pumping Plant

Caissons or Gates. Graving dock gates are, in many respects, similar to lock gates, description of which will be found in Sect. 11, Art. 19. In American practise caissons are more often employed for closing entrance to graving docks, and are usually box- or ship-shaped structures which are flooded and sunk in place at the seat, the removal of water from the interior of the dock drawing them up against the seat. When to be removed after the graving dock has been flooded, they are pumped out and hauled or towed to one side. The sliding type of caisson for which, in connection with the dry dock structure, a recess is provided at the entrance, is moved across the entrance by a hauling device, and returned to its recess in a similar manner, an illustration of which is shown in Fig. 60. This is the favorite type in English graving dock practise and it is employed for the entrance of the Quebec graving dock. The removable type of caisson is rectangular or ship-shaped, as shown in Fig. 61, or hydrometer-shaped, as shown in Fig. 62, the second type having a contracted section for a depth of 6 to 12 ft at the water line, to admit of more rapid raising and lowering when being pumped out or flooded. Or the caisson may be of the rectangular or fin keel type. Where the caisson bears on the sill, water is excluded by either depending on the close fit of a timber meeting piece, or on rubber or hemp gaskets. To resist water pressure the caissons are built and designed with a series of interior horizontal girders. When one of the types of ship-shaped caissons is in place and the graving dock pumped out, the lifting effect of the exterior water is only active on the surface of the caisson in contact with water, so that the buoyancy at such time is somewhat over half of that of the caisson when floating. However, in nearly all cases the dead weight without the water ballast is not sufficient to hold the caisson in place under these conditions. There are usually installed on the caisson, besides the pumping plant for raising the same, hand or power driven capstans at both ends and a series of large valves, power or hand actuated, so that the graving dock may be flooded thru the caisson by opening these valves Caissons of this type being floating structures, care must be taken in the design to assure proper stability under all conditions, and for that purpose it is necessary to make the calculations and curves transverse and longitudinal showing displacement, center of gravity, center of buoyancy, contained water, and metacentric heights under various conditions, especial attention being given to the effect of the contained free water during flooding and lowering. On completion of the caisson these calculations should be checked by inclining experiments.

Pumping Plant. A graving dock is freed of water by a power pumping plant, electricity or steam being generally used, the selection depending upon the special conditions obtaining in the locality. The plant should be divided into

two or more units, so that in case of a breakdown it would be still possible to operate the graving dock. The units employed are usually vertical or horizontal centrifugal pumps and should be of such combined capacity and design that the dock will be unwatered by the entire pumping plant in from 1½ to 2½ hours The water head at the beginning of the pumping will be o, the power being used up in friction and in velocity head, so that the pumping plant must be designed

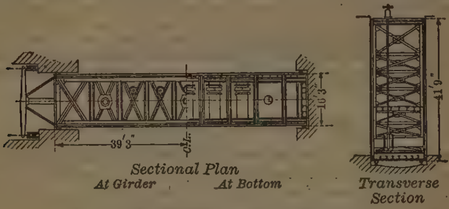

Fig. 60. Entrance Caisson, Sliding Type

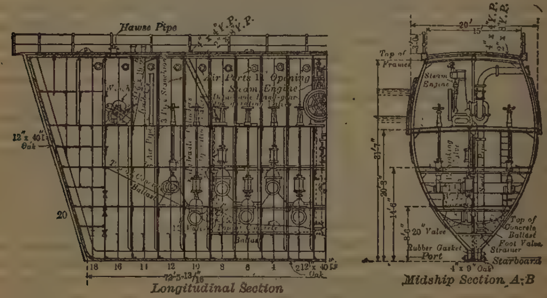

Fig. 61. Ship-Shape Caisson Gate

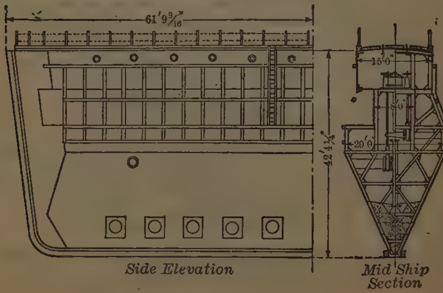

Fig. 62. Hydrometer-Shape Caisson Gate

for the especial conditions in order to obtain overall efficiencies, or over 50 percent. It is usually impossible to remove the last 2 ft of water over the floor

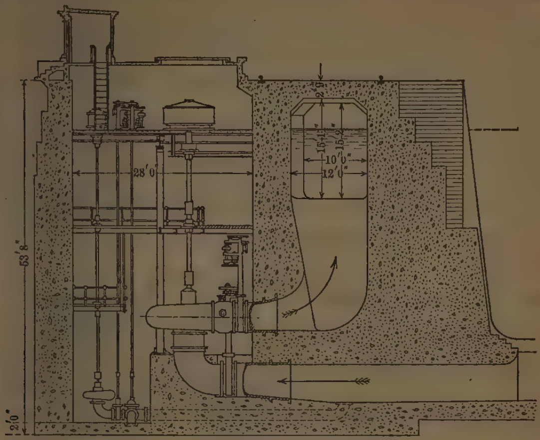

Fig. 63. Pumping Plant

by these main pumps, the blocking and block bearers holding back the water so as to result in a surging effect in the drainage forebay. Where possible, main pumps should be placed low enough and with intakes so arranged as to postpone as long as possible this surging effect. For finally freeing the graving dock of water and for regular drainage purposes, smaller drainage pumps are provided. Fig. 63 shows a sectional elevation of the graving dock pumping plant for Dry Dock No. 4, at the New York Navy Yard; there are 3 main pumps and 2 drainage pumps.

Fig. 63a shows a sectional view of the graving dock pumping plant for the new dry dock at the Navy Yard, Philadelphia, Pa. There are three electric-motor-driven pumps of 54 in size. The same general type of pumping plant is employed at the new Navy Dry Dock in the Navy Yard, Norfolk, at the State Dry Dock at Boston, Mass., and the Balboa Dry Dock at Panama.

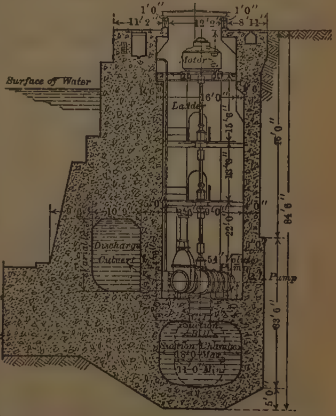

Fig. 63a Cross-section of Pumping Plant, Phila., Pa., and Norfolk, Va.

In the design of the main pumping

machinery, the work to be done by the entire plant is obtained by the total volume and weight of water contained in the graving dock at high tide; the product of this weight by the distance between its center of gravity, and the elevation of water surface at high tide, will give the work done. The required capacity of the pumping plant may then be obtained by dividing the product by the number of minutes length of time allowed for pumping out the dock, and in the same way the required motor horse-power obtained by assuming a 50% efficiency. It is customary to employ constant speed induction motors.

Flooding of the structure is usually accomplished by flooding valves installed in the entrance caisson or by sluice-ways and gates making connection with the sea or by both. These should be designed so that the structure can be flooded within 1 hour. On account of the location of the flooding gates in the lower part of gate caissons, frequently under certain conditions considerable sediment is carried into the dock by this method of flooding, so that sluice-ways and gates, connecting to tide water at a higher elevation, are often more desirable. When of large area, they also make more rapid the final leveling of water in the interior and exterior of the graving dock, and make possible a more expeditious removal of the entrance caissons.

30. Cost of Graving Docks

The Cost of Graving Docks varies between wide limits, depending, as it does, upon the character of foundation, dimensions of the graving dock, particularly the usable depth and the kind of material employed in its construction. In masonry dry docks the lining of the structure with stone work, particularly granite, will add considerably to the cost. Excluding land value, timber graving docks cost between $700 and $1200 per running foot of dock, masonry graving docks between $1500 and $3500 per running foot of dock, and may, in instances, exceed this figure.

Masonry Graving Docks

No.	Location	Built		Lgth.	Cost		
		Begun	Finished	Feet	Total	Per running foot	Per ton, max. ship docked
1	Boston, Mass., N. Y. #2	1899	1905	748	$1 100 000	$1470	$28.80
2	Charleston, S. C., N. Y. #1	1902	1908	575	1 250 000	2170	36.80
3	Mare Island, Cal., N.Y., #2	1899	1910	752	1 680 000	2210	44.20
4	New York, N. Y., N. Y. #4	1905	1912	703	2 450 000	3470	49.70
5	Norfolk, Va., N. Y. #3	1903 1910	1908 1911	732	1 730 000	2360	38.50
6	Phila., Pa., N. Y. #2	1899	1908	754	1 470 000	1950	38.50
7	Portsmouth, N. H. #2	1899	1906	751	1 125 000	1500	29.70
8	Puget Sound, #2	1908	1913	838	2 100 000	2500	32.70
9	Boston, Mass., State	1914	1919	1188	3 231 000	2500	28.09
10	Quebec, P. Q., Canada	1914	....	1190	3 000 000	2500	30.30
11	Norfolk, Va., N. Y. #4	1917	1919	1022	4 356 000	4250	46.85
12	Norfolk, Va., N. Y. #6	1918	1919	471	765 000	1625	63.75
13	Norfolk, Va., N. Y. #7	1918	1919	471	714 000	1515	70.00
14	Balboa, Panama	1911	1915	1100	2 795 000	2540	34.10
	Timber Graving Docks						
15	New York, N. Y. #3	1873	1897	668	555 000	835	23.30
16	Norfolk, Va., N. Y. #2	1887	1889	500	505 000	1010	38.30
17	Phila., Pa., N. Y. #1	1889	1891	500	549 000	1100	45.00
18	Puget Sound, W. N. Y. #1	1892	1896	650	633 000	970	27.20

The cost per ton of maximum size ship that can be docked was obtained by taking the product in feet of the usable length, allowing 5 feet clearance; the width of entrance at 1 foot above blocks, less 2 ft clearance; and the depth to top of blocks or 6 inches over sill at high water, dividing this by 35 to obtain long tons and taking 0.7 of this as a probable block coefficient. The following numbers refer to the table on page 1776.

(1) Founded on blue clay and gravel and is built of concrete lined with granite.

(2) Founded on stiff marl, is of concrete lined with granite.

(3) Founded on piles driven in soft clay. Built of concrete with granite sills and entrance.

(4) Founded on reinforced concrete surrounding walls and interior pedestals placed by pneumatic caissons in fine running mica sand and built of reinforced concrete lined with vitrified brick, granite sills and entrance.

(5) Founded on piles in clay and marl. Built of concrete, granite lined. This dock was, after completion, extended in length.

(6) Founded on piles driven in sand and gravel. Built of concrete, granite sills and entrance.

(7) Founded on ledge rock, concrete lined with granite.

(8) Founded on sand, gravel, clay; concrete and granite.

(9) Work nearing completion, founded on ledge rock, concrete, granite, entrance sills, coping and steps, intermediate seat dividing dock into two sections when desirable, side-walls lined with granite. Actual cost will be in excess of that given by perhaps $500 000, on account of war conditions.

(10) Completed in 1918. Founded on rock, concrete with granite altars and entrance, sills, sliding caissons at entrance.

(11, 12, 13) These docks founded on so-called marl containing much shell detritus at entrance and blue clay. Concrete laid directly on marl and clay except at entrance to No. 6 and No. 7, founded on timber piling.

The cost of graving dock appurtenances, while independent of foundation conditions, bears some relation to the character and size of the structure. Electric power capstans, including foundations, depending upon size, will vary from $7000 to $9000 each, and the pumping plant from $40 to $70 per motor or engine horse power. Caisson gate costs will be a function of the width and depth of the entrance and, in general, will vary as the product of the square of the width and the square of the depth.

The upkeep and maintenance cost of the body of masonry graving docks is small and should not exceed ¼ of 1 percent per annum. The upkeep cost of graving dock appurtenances varies with the character of the same, the cost of repair and replacing of blocking being high and, to some extent, dependent upon the frequency of use, and may be taken at from 10 to 15 percent of first cost, per annum. The upkeep cost of caisson gates is, in general, similar to that of the hulls of steel vessels and may be taken at from 3 to 5 percent per annum.

31. Floating Dry Docks

Definition. A floating dry dock is a structure of wood, wood and steel, steel, or reinforced concrete, capable of being submerged by the admission of water to its interior compartments, at which stage, if desired, a ship is floated into position; the structure is then raised by the removal of water from its interior compartments by pumping, or other means.

Relative Advantages. Lower first cost, less time to complete, less operating expense in pumping, and the fact that it is a movable property, are claimed as advantages for floating docks, as compared to graving docks.

The comparative first cost is entirely dependent upon the type of the floating dock and the location of the site available for the graving dock. Under the most favorable conditions for graving dock construction, the time consumed in the construction of a floating dock is somewhat less than would be the case with a graving dock. A graving dock has the advantage of permanence, more rigidity, less danger of accident, less expensive maintenance and repair, and less annual charges on account of its greater length of life. The selection of the type of structure is entirely dependent upon local conditions and requirements.

Types of Floating Docks are shown in Fig. 64: (1) The simplest type of floating dock is the solid trough type of timber or steel. It has the advantage of simplicity, of longitudinal rigidity, with the disadvantage that it must be built in its entirety intact, and can not be self-docked for repairing, cleaning, and painting.

(2) Sectional docks consist of a number of solid trough sections or slices of Type (1), and are constructed of such length that any one section can be docked, as shown, by one or two other sections. The sections are connected together by locking logs which hold them in alinement, but are not intended to furnish longitudinal rigidity for the entire structure. The operation of the dock usually requires skill and care in order that each section may take the load directly above it, the buoyancy of sections being adjusted by the amount of water pumped from them. This adjustment of weights, however, is not always necessary. With ocean-going steel vessels, the vessel itself is designed with sufficient longitudinal girder strength to distribute inequalities of load, unless the hull structure has been seriously injured, in which case the vessel should not be docked on a sectional type of floating dock. This type of structure is a favorite type in timber, especially for commercial use; on account of its low first cost and its flexibility, additional sections can be added, increasing the length of the dock.

(3) The Rennie type consists of continuous side-walls forming girders for longitudinal rigidity. These side-walls rest on, and are fastened to, a series of pontoons of such dimensions that one or more pontoons may be removed from under the side-walls and lifted for repair by the remaining structure. Docks of this character are built with steel walls and timber pontoons, or entirely of steel.

(4) In the Clark and Stanfield type the side-walls are continuous and extend to practically the full

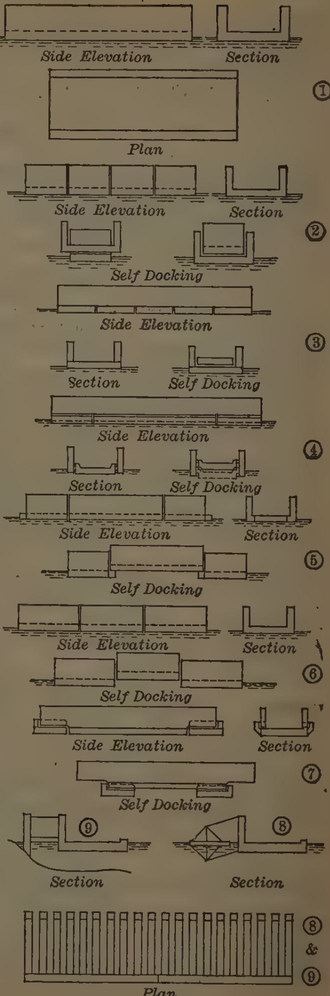

Fig. 64. Types of Floating Docks

depth of the structure, the pontoons being fastened between the side-walls, the fastening consisting of fish-plates and bolts. Pontoons can be self-docked; repair, cleaning and painting of side-walls being performed by careening of the entire structure. The side-walls being deeper than in the Rennie type, more rigidity is secured. Disconnection of pontoons for self-docking and repair is complicated. This type of dry dock is usually constructed of steel. The Havana dock now in commercial use in New York harbor, and the Naval dock at Algiers, La., are constructed on this principle.

(5) The Pola type is a sectional dock consisting of three sections, each a solid trough. The central section is of about the same size as the two end sections together. The sections are connected together for longitudinal rigidity, which connection, however, is complicated. The central section is locked by the two end sections by means of a projection on each. The end sections are docked by the center section.

(6) The Cunningham Sectional type of dock is, in many respects, similar to Type (1), Sectional dock, but consists of larger sections, provision being made for joining the sections together by fish-plates and bolts. Self-docking is accomplished by raising one section with two other sections.

(7) The Maryland Steel Company type consists of a main pontoon of solid trough section with side-walls extending beyond its length and carried on two shorter end pontoons having low independent side-walls for stability in self-docking operations. In self-docking the two end pontoons raise the central section and the two end pontoons are in turn raised by the center section. This type is constructed in steel. The Naval dock "Dewey" at Olongapo, P. I., is of this type.

(8) The Single Side Wall type consists of one rectangular side-wall and pontoon or a series of sectional pontoons. On the other side of the wall is provided a shallow pontoon with vertical members and series of two parallel members pin-connected to the vertical members and to the side-wall of the dock. The purpose of this pontoon is to afford stability and hold the structure upright when raising or lowering.

(9) The Off-Shore type is similar to the Single Side Wall dock, but the vertical member is fixed directly on shore, the pontoon being done away with.

(10) Types (8) and (9) can both be constructed with openings between pontoons so that the vessel after being lifted can be deposited on a separate floating structure or fixed platform, so that while the ship is undergoing repair the dock is ready to lift another vessel and is then known as a Depositing Dock. Neither of these types is in extensive use.

In the Burgess sectional dock the side-walls are replaced by an open framework in which slide ballast pontoons, which always remain on the surface and give stability to the structure. A structure of this character was built of timber in New York Harbor, but is not now in use.

Location. Floating docks require considerable depth of water for their operation, this depth being fixt by the draft of the maximum ship to be docked, height of blocks, clearance of blocks to keel of ship, depth of floating dock pontoons, and the allowance under the dock for clearance and for filling up. The requisite depth must often be secured by dredging and the expense of dredging operations at such great depth is considerable. In many harbors, the excavation for deep floating docks will rapidly fill up. Provision must also be made for mooring the structure, which is usually done by placing it alongside a pier built for that purpose. When this is not done, approach piers to the floating dock must be constructed. A pier or quay is also necessary outside of the entrance to the floating dock to moor vessels while awaiting docking, or to assist in guiding the vessel into the floating dock. Such a structure is also necessary in connection with the use of graving docks. Sheltered locations are desirable for floating docks; this being more necessary on account of the difficulty of handling the dock in a high wind.

Data on Design. A floating dock must have sufficient transverse strength so that the excess buoyancy of the side-walls and the pontoons at the sides will be enabled to carry the concentrated weight of that portion of the ship carried on the central keel and side bilge-blocking, and also when floated light carry

the excess weight at the sides of the side-walls and the pumping machinery. The floating dry dock, when fully sunk, ready to receive a ship, is usually flooded with water to within a small distance from the position of the outside water. This is especially so on timber floating docks. To guard against accidental over-flooding in the sinking of the dock, safety decks are often provided in the side-walls, above which the dock can not be flooded. When a ship has been placed in the dock and the operation of raising is commenced, the contained water is, as a rule, first removed from the side-walls. As the displacement of these side-walls per foot of lift is from necessity considerably less than the weight per foot lift of the maximum sized ship to be docked, the water is entirely removed from the side-walls when the ship has only been lifted a few feet, and the maximum water pressure due to difference between external and internal water head, occurs at the period when the side-walls have been emptied of contained water. The exterior sheathing or plating of the structure, beams, frames, and trussing must be analyzed for this condition of external pressure, which is illustrated in Fig. 65. In most floating dry docks this will not exceed

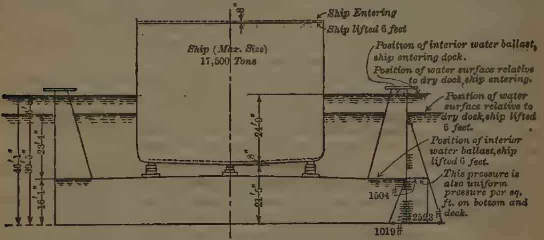

Fig. 65. Maximum Water Pressure on Dock

20 ft of water head. This condition may be avoided by pumping from compartments of the pontoon directly under the ship, before removing all the water contained in the wing walls. It is to be borne in mind, however, that with a floating dry dock it is possible to partially raise out of the water a ship of greater displacement than could be lifted clear of the water, and for this reason it is often advisable to design the structure to withstand water pressure equivalent to the maximum submersion of the pontoon deck. In timber structures, as the timber is more or less constantly immersed, a reduction should be made in the allowable strength in tension, compression, and bearing. In steel floating docks, the practise of structural steel and steel ship design should be followed, the plating being considered as a continuous beam and not a catenary.

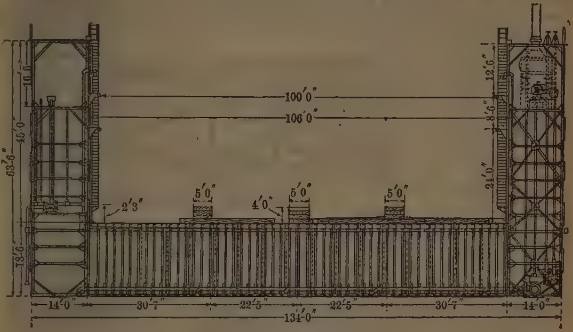
Fig. 66 is a typical cross-section of a self-docking steel floating dock, Maryland Steel Company type, having a gross lifting capacity of 18 000 long tons.

Fig. 66a is a plan longitudinal section and cross-section, side and end elevation of a 45 000-ton steel floating dock of the bolted, three-section trough type (Cunningham) designed but not built.

Fig. 67 is a half cross-section thru a section of a sectional timber dry dock, a type favored in commercial use on account of its flexibility, that is, the possibility of increasing its length and sizes by adding additional sections. The floating dock in question consists of 6 sections, each 80 ft long, having a combined maximum lifting capacity of 18 000 long tons.

Fig. 67a is a plan longitudinal and cross-section and half end elevation of a 12 000-ton timber sectional dry dock.

Loading. The loading conditions to which a floating dry dock is subjected are dependent upon the method employed in removing the contained water from the structure. It is desirable, to some extent, to pump water from the various compartments so that the buoyancy or lifting effect will bear some relation to the load or weight of that part of the vessel directly above this section of the floating dry dock. In order to obtain the maximum lifting effect of a floating dry dock, it is necessary to remove all of the contained water from the structure,



Transverse Section

Fig. 66. Steel Floating Dock

with the result that the bending strain must be taken by the dock structure or the ship being docked. Consequently the manner of regulating the pumping

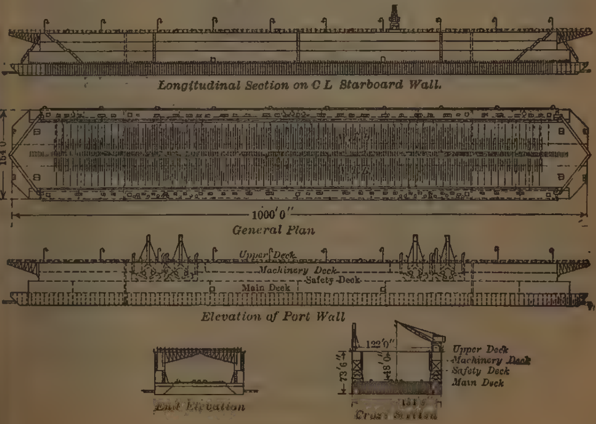


Fig. 66a. Cunningham 45 000-ton Dock.

and lifting dock and ship is of greatest importance, as it might readily be so operated as to seriously strain both ship and dock.

The Bending Moment produced in the ship and dock is shown graphically by Fig. 68: (a) showing the effect when lifting a long ship; (b) when lifting a short heavy ship, and (c) the method employed to decrease the bending moment by only removing a portion of the water from the end compartments. Fig. 69 illustrates the transverse loads to which a section of a floating timber dry dock is subjected.

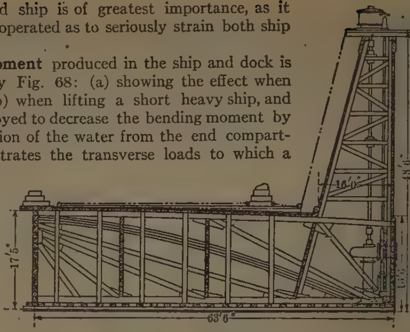

Fig. 67. Timber Floating Dock

Effective Capacity. The effective lifting capacity of a properly designed floating dry dock, whether of timber or steel, or a combination of both, will vary between 60 and 70 percent of the displacement of the pontoons In general, it may be taken that one-third of this displacement will represen the dead-weight of the structure and the contained water that can not b removed, and two-thirds will represent the effective maximum lifting capacity In timber floating dry docks the buoyancy effect of the timber must b counteracted by ballast of rock or iron, in which case proper allowance mus

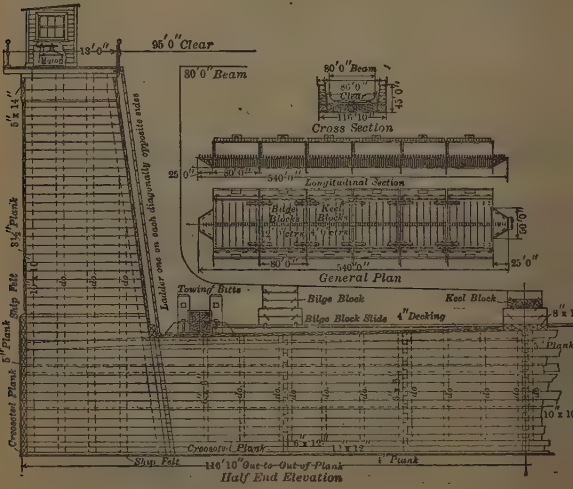

Fig. 67a. 12 000-ton Timber Dock

be made for the reduction in weight of this ballast by reason of its submersion. Ballast is not needed in steel floating dry docks and usually is not necessary in floating dry docks of steel and timber.

Costs of Floating Dry Docks of different types can be given only approximately, as these are influenced by the varying costs of materials, size of structure, and location in which it is to be built. Such approximate relative costs may be taken as follows:

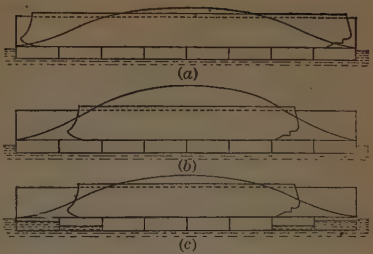

Fig. 68. Longitudinal Bending Moment

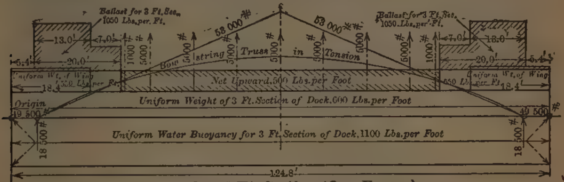
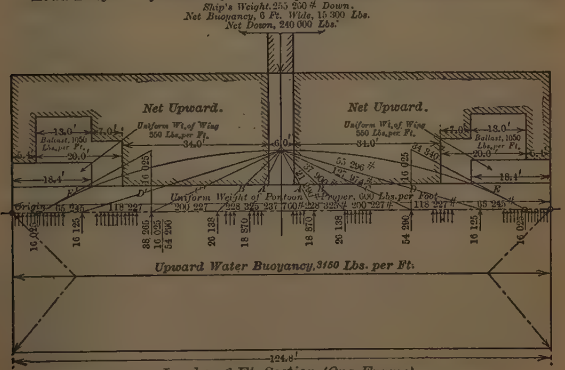


Load on 3 Ft. Section. (One Frame)

Load Diagram of Floating Dock, Light Condition, No Water in Dock.



Load on 3 Ft. Section. (One Frame)

Load Diagram of Floating Dock, Full Load, Ship on Dock.

Fig. 69. Transverse Loads

Timber solid trough type	\$28 to \$35 per lift long ton
Timber sectional type	\$25 to \$32 " " " "
Timber pontoons, steel wing walls	\$42 to \$48 " " " "
Steel, sectional or solid trough	\$52 to \$65 " " " "

These costs are for the floating dry dock complete, but take no account of the cost of the necessary work required in connection with the operation of the structure, such as piers, approaches, dredging, and other work. The variation given allows for differences in size and details and for location at which the floating dry dock is built, the higher figures for the steel structures being based on costs on the Pacific Coast of the United States.

The above given costs were those obtaining 1914-1915, the estimated cost in 1918-1919 taken from the bids and estimates on structures then designed are timber solid trough and sectional type, \$85 per lift ton; timber pontoon and steel wing walls \$95 per lift ton; steel solid trough or sectional, \$120 per lift ton.

The upkeep and maintenance costs of floating dry docks depend on the location and the materials employed. All timber floating dry docks have been in continuous use for 60 years, with only slight repair to them. In waters in which marine borers are prevalent, the exterior of timber pontoons must be protected by yellow metal, copper, tar felt covered with creosoted sheathing plank, or all planking creosoted. The interior of compartments will not require protection. The annual charge for upkeep of nine steel docks, as given by L. E. Clark, was 1.12 percent of first cost. Experience with such docks in warm climates indicates that annual upkeep cost will, in instances, exceed 3 percent of first cost. Steel structures in sea water require periodic painting to prevent undue corrosion. The most effective interior covering is by coating with bitumastic compound, costing from \$4 to \$7 per ton weight of structural steel in the hull.

32. Stability of Floating Docks

Stability. In order to secure the requisite stability against overturning when light or when lifting a ship, provision must be made for longitudinal and transverse watertight compartments. In a rectangular floating structure the general stability varies directly as the square of the number of watertight divisions. In timber floating dry docks, in most cases, the structure is divided into two transverse watertight compartments, additional longitudinal timber bulkheads being provided on either side of the central watertight bulkhead, these bulkheads merely acting as strengthening and swash bulkheads, and do not materially affect the transverse stability. In steel floating dry docks four to six transverse watertight divisions are usually provided. The metacentric height is represented by $GM = (I - GB \times V - \Sigma i)/V$

in which I is the moment of inertia of the water-plane of flotation, GB the distance between center of buoyancy and center of gravity, V the volume of displacement in cubic feet, and Σi is the summation of moment of inertias of interior contained water surfaces. Or the stability moment is

$$M_1 = \sin\theta/35\ (I - GB \times V - \Sigma i)$$

This calculation should be made for both transverse and longitudinal conditions, it being remembered that with a ship on the dry dock the stability of the ship must be taken into consideration; I, GB, V and Σi of the formulas being the combined expressions for ship and floating dock.

In order to apply the necessary formula, diagrams or curves should be available showing the characteristics of the floating dry dock under various conditions.

Fig. 70 gives an example which shows the curves of displacement, center of buoyancy, center of gravity, weight of contained water, and moment of inertia of exterior and interior water planes. Employing this and information as to similar characteristics of the maximum sized ship to be dry docked, curves can

be drawn showing the metacentric heights at various drafts of ship and dock as is shown in Fig. 71, which is a typical case for a 12 000 long ton capacity Timber Sectional Floating Dock.

Imprisoned Air. When sinking a floating dry dock it is necessary to afford means for the escape of the imprisoned air. This is done by providing piping

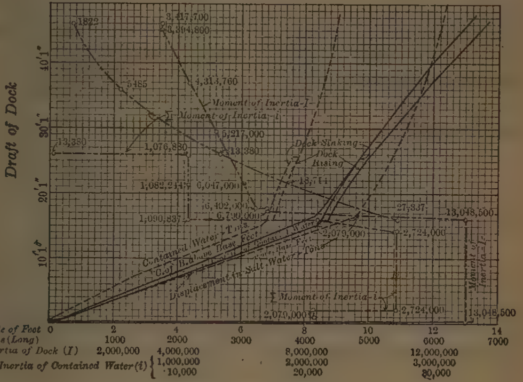


Fig. 70. Displacement and other Curves

for air escape with connections at the upper parts of compartments, or in timber dry docks, by providing air escapes directly thru the deck.

Wind Effect. Sufficient stability should be provided so that with a maxi-

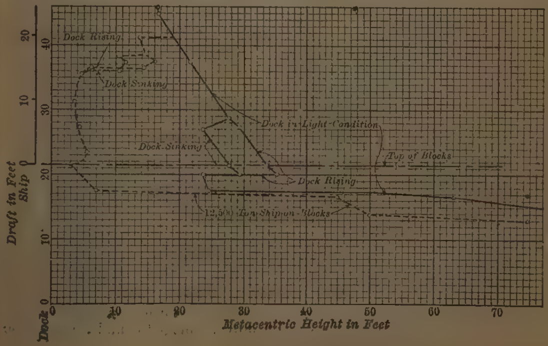

Fig. 71. Transverse Stability Curves

mum sized ship on the dry dock there will be no undue heeling of the structure due to wind action. The angle or heel of inclination θ is obtained from

$$\operatorname{Cot} \theta = D \times GM / A \times CL$$

in which A is total pressure of wind in pounds, D is the displacement in pounds, GM is the metacentric height, and CL is the distance between center of pressure and center of lateral resistance.

Pumping and Flooding Plant is so arranged that each watertight compartment can be controlled in pumping or flooding, independently of other compartments. In a solid trough dock, one or two main pumping plants are usually provided, on one or both sides of the dock connected to a pumping main, having a lateral connection to each compartment. Fig. 72 shows the general arrangement of such a pumping plant. Each section connection is controlled by direct-acting wedge-shaped valves, the valve rod being brought to one station by a system of bell crank levers, the dockmaster located at this station controlling the entire pumping of the dock. In sectional floating dry docks, it is necessary to provide a separate pump plant in each section. These may be driven individually or by means of continuous sectional shafting connected between section by universal couplings, the operating power being either steam or electric. The most satisfactory system at present in use is electrically operated vertical shaft centrifugal pumps. In sectional docks, with two pumps in each section, one on each side of the structure, a cross-connection is often provided so that in case one pump should break down, the section could still be operated by the other pump. This involves a longer time for pumping out and also serves to decrease the stability of the entire structure by decreasing the stability of one of its sections. The sinking by flooding is carried out by flooding valves or gates, leading to the various compartments, the dockmaster controlling this entire operation to insure even settlement without undue straining of dock or ship. Floating docks are often fitted with an indicator system to show in a central control station the depth of water in all compartments. An entirely satisfactory system has not as yet been successfully applied.

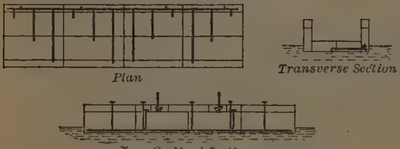

Fig. 72. Arrangement of Pumping Plant

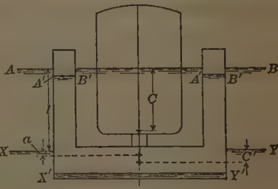

Fig. 73

It has been proposed to raise floating docks by compressed air, by removing the water from compartments by forcing air into them, and in a somewhat similar manner sinking by allowing this air to escape. While this has been tried experimentally on a small scale, it has not been successfully used in practise. The general idea has had some success applied to raising sunken vessels by pumping air into the hull or by forcing it into submerged cylindrical pontoons made fast to the hull by chains or wire cables.

Power Required in Operating a Floating Dry Dock. The work done in raising a floating dry dock with a ship is directly proportional to the weight of the dock light and weight or displacement of the ship.

$$E = D\,(l - c) + D'\,c' \pm (D - D')\,a$$

in which, as shown in Fig. 73, D is the displacement in pounds of ship and floating dock ready to lift, c is depth in feet below surface of water of center of buoyancy of D, D' is displacement in lbs of dock or ship and dock wholly or partially raised, c' is depth in feet below surface of water of center buoyancy of D', l is height in feet raised, and a is distance above or below surface of water of center of gravity of water removed from dock when dock is in its raised position.

The necessary data for application of the formulæ can be obtained from curves showing displacement and position of center of buoyancy of the ship and displacement of dock, weight of contained water and positions of center of gravity and center buoyancy. The characteristics of the pumping plant can then be obtained by fixing on the time in which it is desired to raise the floating dry dock with a ship of maximum weight, usually taken at from 1 to 1½ hours. The overall efficiency of an electrically driven centrifugal pump of the type herein described should be between 50 and 60 per cent.

Fig. 74. Blocking

Blocking. The arrangement of blocking on a floating dock is in many respects similar to that employed in graving docks, and is shown in Fig. 74.

FERRIES AND SPECIAL WORKS

33. Ferry Racks

Ferry Racks. The landings or terminals for ferries consist or a slip with piles and fenders on each side called racks, transfer bridge, platform, and ferry shed. The racks are usually built diverging outshore, the inshore ends closely fitting the guard rails of ferry-boats. The racks consist of one or more rows or banks of piles with upper, lower, and one or more intermediate string pieces or wales on which are fastened vertical fender planking of oak, yellow pine, or some other hard wood. Where the ferry-boats are small or light, and the traffic infrequent, a single row of piles is used, the piles being spaced about 3 ft centers. The rack is stiffened at the inshore end by additional piles or clusters of piles, as this portion of the rack receives the principal wear and shock. The height of the rack is dependent upon the range of tide, it being evident that the fender system must be of sufficient height, or depth, so that the guard rail of the ferry-boat, when loaded or unloaded, will never be below or above the rack. The wales are made up of several thicknesses of heavy planking or dimensioned timber, so as to be readily fitted to the required curve and are bolted to the round piles. The vertical fender planking is fastened to the wales by drift bolts or dock spike at the upper and lower extremity. Ribbon pieces are fastened to the wales and thru the vertical fenders by countersunk head screw bolts. The upper ends of fender planking are sawn off at a bevel to shed water, and the tops of piles rounded for the same purpose and often covered with canvas or zinc for protection against the entry of water and consequent rot. Frequently the fenders at the inner end of ferry racks are coated with heavy oil, or grease.

In heavy ferry rack construction, two, three, or four rows of piles are employed, the piles in the rear rows being staggered, and the tops of rear rows are cut off at a lower elevation. In two bank racks two or more wales are fastened to the back of the front high row and one or two heavy wales to the front of second pile row, so as to transmit the shock of the incoming ferry-boat to the second row of piles, and if three rows of piles are used, the third row is also provided with wales of this type. The outshore end or entrances of racks are usually constructed with a cluster of piles, driven a slight distance apart, and drawn together at the top, and lashed with wire cable fastened with staples, these dolphins or clusters fre-

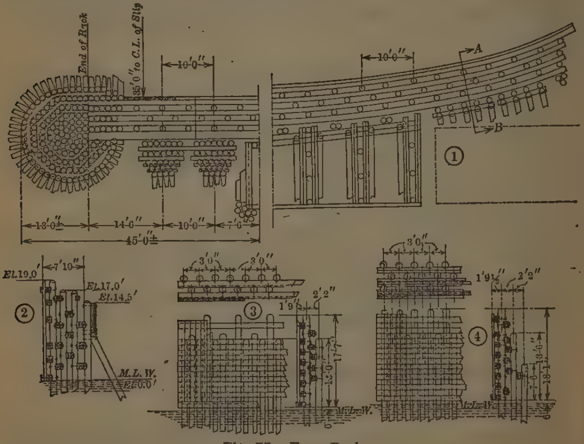

Fig. 75. Ferry Racks

quently receiving the first impact of the entering ferry-boat, guiding the ferry-boat into the slip. Fig. 75 shows general arrangement of various types.

(1) Plan of three and four bank rack for Municipal Ferry, New York City, 39th Street, Brooklyn.

(2) Typical section of (1). Front wales, two 6 x 12 in. Rear wales, three 4 x 12 in. Fenders, 5 x 12 in white oak.

(3) Typical elevation, section, and plan of two bank rack, D. L. & W. R.R. Passenger service.

(4) Elevation, section, and plan of three bank rack, D. L. & W. R.R.

The work can be laid out by securing plans of the guard rails of various ferry-boats that are to use the slip, and from these make a plan showing maximum dimensions. Lay out the slip with racks fitting this plan and measure ordinates from and perpendicular to the center line to pile locations. Construct a light temporary platform along the slip and on this locate points on which batten ranges can be fastened, giving the transverse range of piles, the piles being located and driven by measuring out the proper distance on this range. All piles need not be so located, but piles every 10 or 12 ft having been accurately located, intermediate piles can be driven in general conformity with the desired curve The work can be laid out from a temporary platform or existing adjoining pier or structure alongside of the site of the ferry slip. A ferry-boat can be moored in place and governing dimensions obtained by driving piles at intervals against the guard rail of the template used.

34. Transfer Bridges

Ferry Transfer Bridges should be of such length that at extreme tides, with maximum and minimum loading of ferry-boat, the gradient will be possible for traffic, the range being from low tide with heavily loaded boat having little freeboard to high tide with light load and greater freeboard. The outshore end of the bridge, when light, is usually carried by a pontoon, so that it will, at all times, float to about the elevation of the ferry-boat deck. For this adjustment of height the buoyancy of the pontoon is employed sometimes with the assistance of counterweights fastened to the bridge by wire or chain cables, and carried up over sheaves mounted on an overhead frame. The final adjustment of height is made by hand or power operated windlass fastened to the end of the bridge. The outshore end of the bridge is usually curved to fit the bow or stern of the ferry boat, and is provided with heavy hardwood or iron toggles which can be moved out to rest on the deck of the ferry-boat, so that when the weight of traffic leaves the ferry-boat and moves on to the bridge, this weight, in excess of the buoyancy effect of the pontoon, is carried by the ferry-boat and not by the overhead gear. The inshore end of the bridge is supported on rollers, in roller chocks, supported on the platform, or is carried on heavy hinges on a rolling or sliding bearing fitted with car springs or rubber buffers to assist in

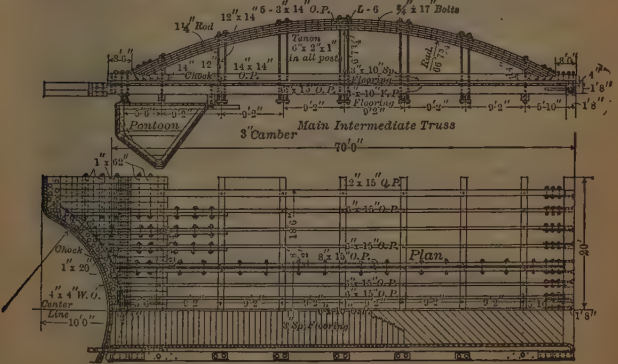

Fig. 76. General Traffic Transfer Bridge

taking up the shock of the incoming boat. The ferry-boat is secured to the bridge by means of two lines made fast to eyes or chocks on the dock of the ferry-boat, the slack in the lines being taken up by windlasses. The bridge itself usually consists of a platform suspended from two or four structural steel or timber trusses, a timber bow-string truss being frequently used. The overhead gear with counterweight should be of sufficient strength to support the outshore end of the bridge when unloaded, so that the pontoon may be removed when necessary for calking and repair. Fig. 76 shows a ferry bridge and pontoon and is typical of this character of structure in general use. Where double-deck ferry-boats are employed, elevated adjustable gangways or bridges are provided for the upper-deck traffic.

Ferry Houses or terminal sheds are, as regards materials employed and details, similar to pier sheds, structural steel framing with metal siding and sheathing being largely employed. The shed is carried out over the transfer bridge and often projects out a distance over the slip to afford protection against the weather.

Railroad Car Transfer slips are more rectangular than ferry slips for general traffic, and the racks are consequently built straighter or no rack used. Fig. 77 is a section of a typical three-bank rack; the fender planking is horizontal, and this appears to be standard practise for car transfer racks. The transfer bridges must be of sufficient length to insure a reasonably flat slope for variations in tide and freeboard of the car float. Where possible grades should not exceed 5 percent. It is not desirable to run locomotives on the float, and the transfer of cars is effected by using two or more pushers or empties to couple up with. When operating on a steep grade the locomotive remains on the level platform. The outer end of the bridge is supported on a pontoon or by means of a counter-weight.

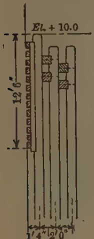

Fig. 77.

Fig. 78 shows a transfer bridge with pontoon and overhead gear. The adjustment of the height of track is made by removing water from the compartments of the pontoon by means of a small power pump or by filling it, the final adjustment being made by the overhead gear with hand-operated winches.

Fig. 79 is a two-track transfer bridge, employed by the N. Y. Central R.R. in Weehawken, N. J. In this the supporting pontoon is replaced by two counterweights each, weighing 46 short tons, the adjustment of height being made by a power-operated vertical

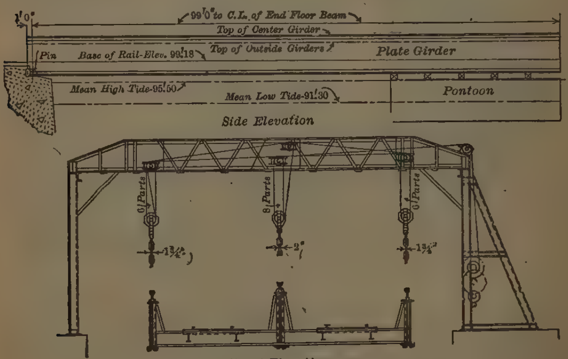

Fig. 78. Railroad Car Transfer Bridge

screw shaft. In this type the weight of cars is almost entirely carried by the overhead gear. The estimated weight of structural steel for one transfer is 740 000 lb.

The general type of railroad and car transfer in use often consists of a bridge made up of two or more timber Howe trusses hinged, or supported, on a rolling log inshore,

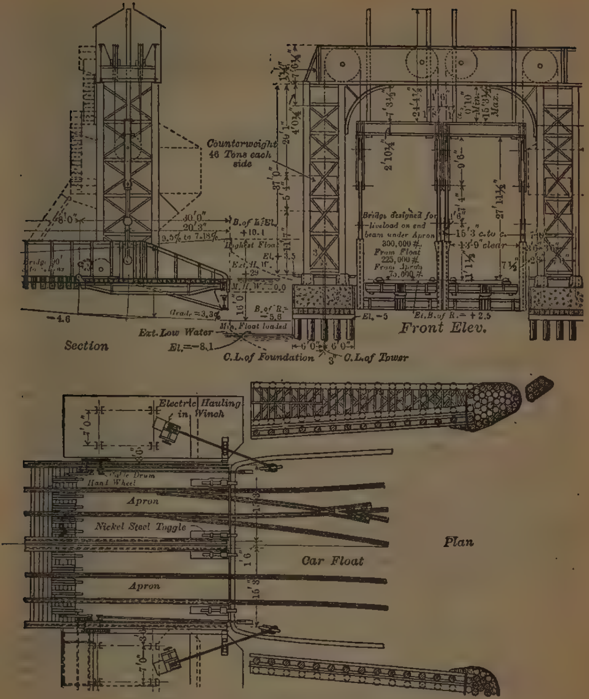

Fig. 79. Transfer Bridge, N. Y. C. & H. R. R.R.

with the outshore extremity resting on a float or pontoon. Directly over the outer end, and supported on pile foundations, on either side, an overhead or gallows frame is provided; the bridge is connected to this by chain or wire cable tackle, and the final adjustment of height made by this means.

River Car Transfers are employed in connection with ferrying railroad cars across rivers. When the range of tide is not very great, such transfers are similar to those used in harbors. However, when the elevation of tide fluctuates to a considerable extent, as in the great interior rivers of the United States, it is customary to use a method of transfer similar to that shown in Fig. 80.

This system has been in successful use for many years for transferring railroad cars from or to tracks from car floats. The arrangement is known as a "cradle." Standard gage railroad track is laid on an incline, usually diagonally, along the bank or river levee slope. The cradle running on this track is hauled up and down the incline accord-

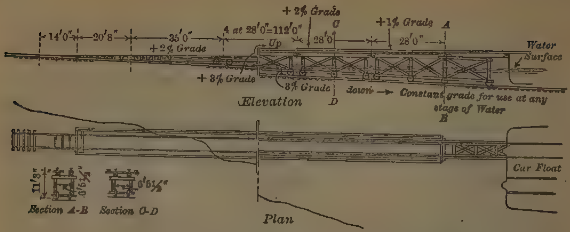

Fig. 80. Cradle, Ill. Cent. R.R., Mississippi River

ing to the stage of tide. Fig. 80 shows a cradle in use at Harahan and Baton Rouge, by the Ill. Cent. R.R. for transferring cars across the Mississippi River.

35. Coal, Ore, and Grain Plants

Coal Handling Plants are usually of two general types: (a) The wharf storage type, in which the coal is received by rail or otherwise from shore, by ship or barge from the water, and stored on the wharf itself for distribution and use. (b) The type where the coal is received by ship or barge cargo, and transferred to, and stored on shore, for shore consumption, or to be again distributed for ships' use; or delivered to the pier from the shore by rail or otherwise, and distributed directly to ships or barges. The last-mentioned type is often provided with some pier storage as an auxiliary feature.

Type (a) is, manifestly, somewhat limited in capacity, depending on the dimensions of the pier and the consequent storage-bin area, as it is inadvisable to store coal in bins to a greater depth than 20 ft, on account of the possibility of spontaneous combustion, and the consequent necessity for re-handling coal. The bins are usually given a bottom slope to permit of ready self-discharging, with a minimum of man-handling, the discharging being effected by portable chutes, collapsible or fixt, for discharge into ships or barges' holds, or for discharge on shore under the bins into carts or railroad cars, the loading of hoppers being effected by fixed hoists with collapsible cantilever arms, on which the bucket or unloading device travels transversely on trolleys or carriages, the distribution in the length of the bin being performed by bucket or belt distribution, or the entire loading device may travel longitudinally of bins for the purpose of distribution. Fig. 81 shows such a plant built in 1901, at the Navy Yard, New York.

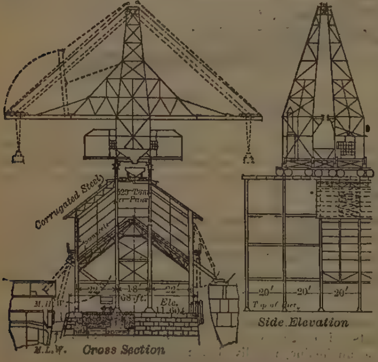

Fig. 81. Coaling Plant, New York

The arrangement of coal handling plants, of Type (b), is multitudinous in character, and no at-

tempt will be made to cover this feature in this section, other than to state that for small plants the stationary or movable coal tipple is employed with great economy. In larger plants, a very satisfactory method appears to be a loading apparatus, cable operated railroad dump cars. discharging to shore storage bins or piles. When coal is required for ship or barge cargo, cars are run out on the pier and discharged into smaller bins or hopper chutes convenient to ship or barge hatchways, cars being discharged directly over the bins by bottom or side dumping car, or, in some cases, by tipping the car.

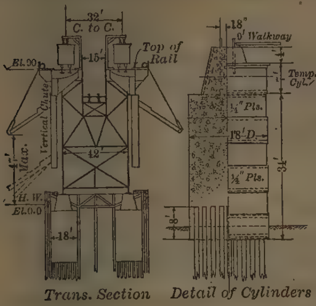

Fig. 82 shows the latest coal pier and plant of Norfolk & Western R.R., Lambert's Point, Va., the method of operation being: Coal from mine arrives at yard and travels by gravity over automatic weighers, and is hauled up incline to pier by power hauling cable to tipping platform, where the car is inverted and contents of car dumped, the capacity being 30 cars per hour. Empty car, on being righted, returns to yard by gravity. Special electric trolley pier cars are raised to the top of the pier by elevators, discharging coal thru hoppers and chutes. Empty pier cars are returned for new load. Capacity of this coal pier ranges between 3000 and 5400 tons per hour.

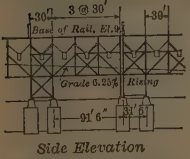

Fig. 82. Coaling Plant, Lambert's Point, Va.

Fig. 83 shows the layout of a somewhat similar plant in use by the D. L. & W. R.R., Jersey City, N. J.

Where a considerable amount of coal is to be stored, it may be placed in piles on shore in close proximity to the coaling pier by being dumped by cars from overhead tracks or trestles, or directly from grabs or buckets operating on travelers. When required, coal is re-loaded by means of grabs or buckets operated by travelers or locomotive cranes and placed in cars. Vessels are loaded with coal from coal barges placed alongside by manhandling in bags, and hoisting by ship's gear and winches. This method of loading is often found most economical, as the ship's crew is employed in the operation, and has other advantages

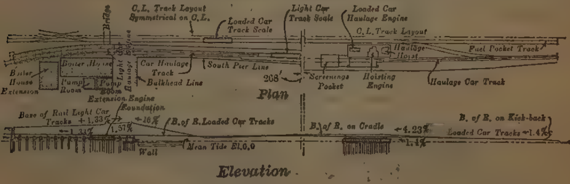

Fig. 83. Coaling Plant, Jersey City, N. J.

where coal bunkers are small, widely distributed, and access to them is difficult, such conditions especially applying to Naval vessels. Floating mechanical coal conveyors are also employed for loading coal on steam vessels.

Coal is sometimes stored under water in compartments or enclosures for that purpose, as there is no deterioration due to atmospheric action, no losses due to dust blowing away,

and the possibility of spontaneous combustion and consequent expensive re-handling is avoided. Coal stored under water 14 years shows a deterioration of only 1 ½ percent.

Ore Handling Devices for loading and unloading are generally similar in layout to Type (b), Coal Handling Plants, except that the material is seldom moved back and forth, but is usually moved in one direction either from the source to be loaded or from the ship to be unloaded. An important feature in the design is the considerably greater weight per cu ft of the ore.

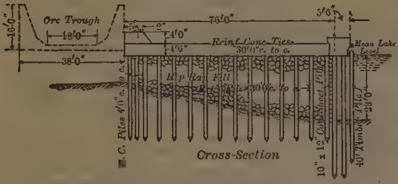

Fig. 84. Ore Pier, Cleveland, O.

Fig. 84 is a section showing an ore trough and pier at Cleveland, O. Ore can be delivered from the vessels directly to freight cars, to stock piles, or placed in the ore trough to be picked up for distribution by conveyors. The ore pier is provided with loading and unloading traveler operating longitudinally of the pier. Fig. 85 shows an ore pier at Two Harbors, Minn. The cost of this plant ranged between $3800 and $4500 per pocket, excluding dredging.

Grain Handling Plants. When cargoes of grain are to be handled in bulk, it is usually loaded and unloaded by means of grain elevators, the material

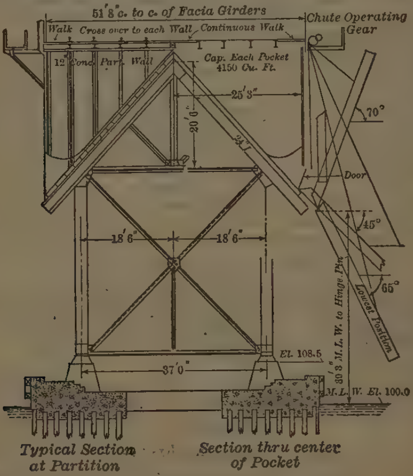

Fig. 85. Ore Pier, Two Harbors, Minn.

being stored in bins. Grain elevators may be portable, mounted on barges, or constructed on piers or quays. The material is handled by endless belts, a succession of buckets on a continuous chain, by pneumatic power, or in lesser

bulk by buckets or grabs. The pneumatic system of unloading has the advantage of extreme flexibility and can be applied in any position, saving the cost of hand trimming. Grain unloading plants for handling large cargoes are found on the Great Lakes, but not in other American ports where the plants are solely for loading into vessels. For unloading, floating equipment is most often employed, unloading the cargo of the vessel and loading barges for distribution and trans-shipment in the same operation.

Fig. 86 shows the latest type of grain elevator constructed at Girard Point, Philadelphia, Pa., Penn. R.R., having a total capacity of over 1 000 000 bushels. Grain comes in on cars on a descending grade, and is hauled to and from the unloading shed by cable.

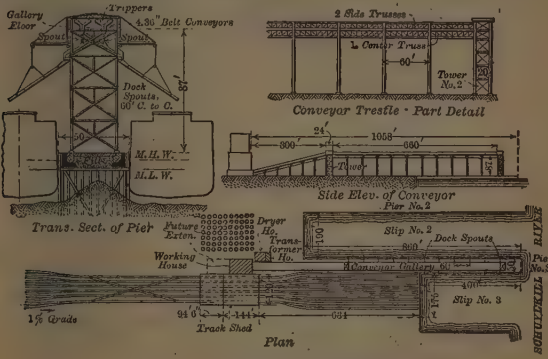

Fig. 86. Grain Handling Pier, Philadelphia

Unloading is performed by power shovels into receiving hoppers, discharging therefrom on receiving belts, and is raised to receiving garners and weighed, and thence by means of spouts distributed to the storage bins or to the pier shipping conveyor consisting of four 36 inch belts, from whence it is distributed by trippers thru side pier spouts.

36. Dumps and Landing Stages

Dumps are constructed and set aside for the handling of refuse material. On account of the importance of securing and retaining ample depth for the purpose of navigation, in most ports it is against the law to dump material within the navigable water area, whether the material is of such character as to sink to the bottom or float on the surface of the water and interfere with navigation or be unsanitary or obnoxious. In some

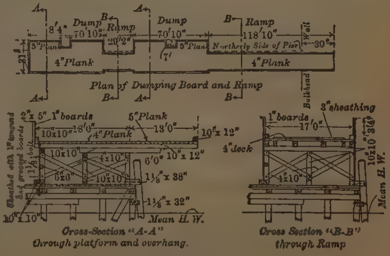

Fig. 87. City Dump

of the larger cities public dumps are provided where excavated material or refuse may be dumped into barges for trans-shipment for local filling, or disposal at sea. Fig. 87 shows a dumping board at Pier 33, New York City. Fig. 88 is a typical example of a dumping board for distribution of excavated material.

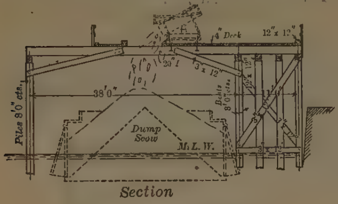

Fig. 88. Railroad Car Dump

Floating Landing Stages are provided where there is considerable range of tide and it is not desirable to incur the expense for the construction of a wet dock, or where, for a similar reason, it is inadvisable to construct a fixt pier or quay with two or more platforms to be used at various stages of tide. Floating landing stages on a small scale are employed for small boat landings and consist of a float or pontoon with a gangway from the pontoon to the pier or quay platform. When constructed, the deck is supported by its own buoyancy or on hollow pontoons, the buoyancy of which must be sufficient to carry the weight of passengers or cargo. The pontoon must be divided into two or more longitudinal and two or more transverse watertight compartments in order to insure stability against overturning when the compartments are partially full of water. The formula to be applied is given in Art. 32 under Stability of Floating Dry Docks.

Fig. 89. Landing, Memphis, Tenn.

The floating landing stage at Liverpool, Eng., consists of a deck supported on pontoons, and is 2500 ft long by 80 ft wide, and has eight gangways or bridges connecting it with the shore. The maximum range of tide at this port is 30 ft.

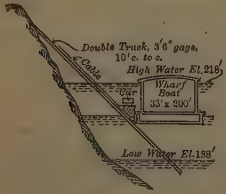

Fig. 90. Car Handling

On many of the interior rivers of the United States, there is considerable freight and passenger traffic, loading and unloading taking place at various places along the bank where no regular landings are provided, the light draft, stern wheel steamboats employed running close to the bank and transferring traffic by platforms or gangways. At many of the more important ports where the elevation of the river varies greatly, and ordinary wharves are not available or advantageous, floats are employed. Fig. 89 shows the usual arrangement, illustrating particularly the levee landing at Memphis, Tenn. The landing stages or floats are moved up and down the bank or levee incline as the river falls or rises.

Where the river bank is steep, and bulky cargo is to be handled, landing stages or floats are employed in connection with inclines, as shown in Fig. 90. This type of incline is usually double-tracked with a platform on each track, the two platforms being connected

together by a cable running over a drum of a hoisting engine which operates the mechanism. This particular type is in use on the Tennessee, Mississippi, and Ohio Rivers used in connection with the handling of iron and steel products, coal, and cotton. Telpherage transfer system is also extensively employed for river landings; typical example of which is shown in Fig. 91, employed by the Ill. Cent. R. R., South Memphis, Tenn.

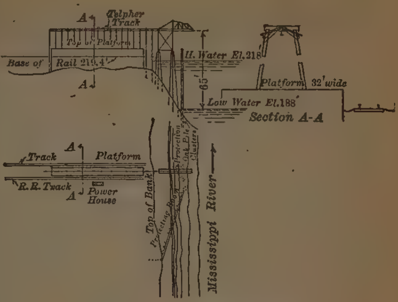

Fig. 91. Telpherage Landing

37. Shipbuilding Ways

While the construction and launching of ships come within the province of the naval architect, the design and construction of the platform or ways on which the vessel is built is a question of foundation design and one that will be dealt with briefly herewith.

Shipbuilding Ways are in many respects similar to marine railways, and are primarily inclined slips on which a vessel is built, and which project far enough out into and under the water so that when the vessel is ready to be launched it may pass down from the land to the water. As with marine railways, building ways may be of the lengthwise or broadside type. The broadside type is resorted to where the basin or stream into which the vessel is launched is narrow and does not afford the requisite width for lengthwise launching. Broadside ways are common on the Clyde River. Building ways consist of the fixt ways which is the incline or platform fastened to the foundation and the cradle or sliding ways. The vessel itself is built on the fixt ways or on blocking and the fixt ways are frequently not placed until shortly before the v ssel is ready for launching. Then the weight of the vessel is transferred to the cradle or sliding ways and in turn to the fixt ways by means of wedges. A lubricant is placed between the sliding and the fixt ways, usually a mixture of tallow and soap, and at the proper time the vessels released by sawing or a trigger device. The gradient or inclination of the ways is fixt dependent on the type and launching weight of the vessel so that with the release, by whatever method secured, the sliding ways and vessel will move down to the water and be launched into it. It is customary as a matter of precaution to place horizontal jacks to give the sliding ways and vessel a push or "kick."

The fixt ways consist of two longitudinal streaks, one on each side of the center line of keel, and of sufficient width to carry the maximum moving load of the vessel and sliding ways, the safe bearing capacity of the timber used across the grain being considered.

Inclination of Ways. Inclination or the gradient of the ways is dependent upon the length, type and probable launching weight of the ship to be built and is seldom greater than ⅞ in to the foot run. Ways for moderate sized-steel vessels with a launching weight of from 2000 to 4000 tons have a gradient of ⅝ to ¾ in; on larger heavier vessels ⅝ to ½ in is used while on very large vessels of great length such as the largest transatlantic liners and battle cruisers ½ or $^7/_{16}$ in is employed. For the last two classes of ships the ways are often built with a varying gradient; that is, with a very flat circular profile, so that the

ship when launched and moving down the ways moves on the arc of a great circle. This arrangement has the advantage of bringing less strain on the trigger or launching device, and the vessel once released and moving down the ways receives an increasing acceleration. With the vessel of considerable length this has the further advantage of decreasing the required length of the out-board or under-water portion of the ways; that is, the requisite depth of water at the end can be obtained in a shorter run.

Foundations. The foundations of the blocking, or fixt ways, must, of course, be designed to carry the maximum weight of that section of the vessel built directly above it, and the lower, or out-board portion, must be designed with a view to the fact that as the vessel is launched the maximum weight section will move down, superimposing its load over the entire lower ways as it passes over it.

As the vessel reaches the water and becomes submerged therein she is immediately in part water borne, and the foundation directly under the stern becomes relieved in increments of the superimposed weight, while the load under the bow or upper end of the vessel is increased by the upward force of the outboard vertical buoyancy effect. This change in condition continues until the stern or outboard end of the vessel is entirely water borne, and about to be lifted from the ways when a pivoting action about the upper end of the bow occurs, and that portion of the weight of the vessel representing the upper end reaction is concentrated at the bow or upper end. This pivoting pressure is the maximum pressure brought to bear upon the ways foundation and has a decreasing effect continuing down the ways from the initial point of pivot until the vessel leaves the ways entirely. With larger vessels a pivot cradle is constructed under the bows detached from the sliding ways or cradle, the hull of the vessel at the bow end resting in a trunnion saddle (a) which sets in the pivoting cradle (b), all shown in Fig. 91*a*. In designing ways it is imperative that all of the load and maximum weight pressure conditions be obtained. Fig. 91*b* shows the buoyancy pivoting hogging curves and maximum way pressure curves for a 3500-ton dead weight cargo coal barge. The ways must be extended outboard sufficiently so that the depth of water at the end will be approximately the draft of the vessel at the bow, where the sliding ways leave the fixed ways when the vessel is launched; otherwise the vessel would drop through a vertical distance represented by the excess in draft at this point. In practice, it is quite usual to launch expecting and providing for some drop, the opening between the fixt ways at the outboard end being cleared sufficiently so that the hull of the vessel at the bow will not strike any obstruction and cause damage to the hull or the ways.

Fig. 91*a*

The type of foundation required is dependent entirely upon the location and can be treated similarly to other foundation conditions. However, due to the necessary restrictions of being located on some foreshore, timber or concrete piling is the general rule. When timber piling is employed it is, of course, subject to rot and decay above the wet line. Sometimes to avoid the necessity of constantly repairing this portion of the ways, the piling is cut off at mean tide or wet line and concrete or masonry cross walls or concrete piles built on the timber piles, or the necessity of such construction is avoided by the use of reinforced concrete piles of the pre-cast or cast in place type, the relative advantage of the two types of construction being, as in other foundations, a question of the particular conditions and restrictions involved. It is impossible to lay down a rule as to the relative desirability or permanency in ways foundations as it so frequently

happens that for reasons of development and change in ship dimensions and design or for other reasons it becomes necessary to materially change the carrying capacity of a ways if it is utilized during the life of that particular shipbuilding

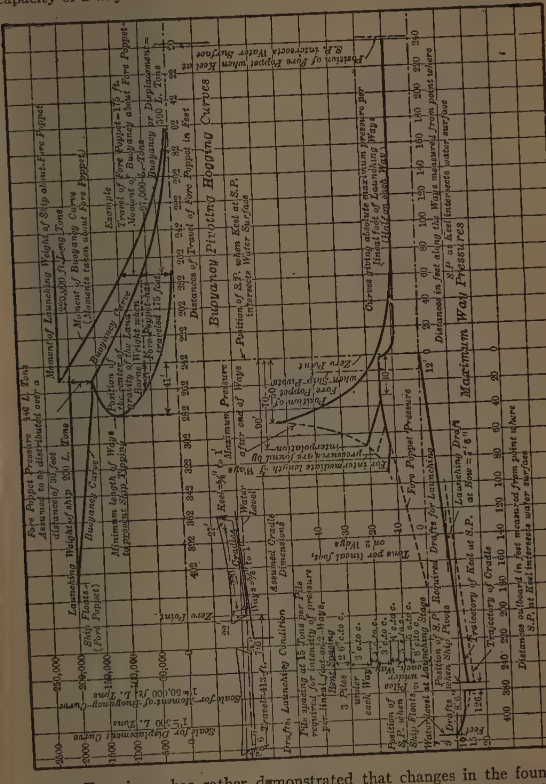

Fig. 91b. Hogging Curves and Way Pressusre

plant. Experience has rather demonstrated that changes in the foundation, usually with a view to increasing its carrying capacity, are called for whenever a new ship is to be laid down.

The outboard end of the ways, as with the marine railway, must be constructed below water level, and must be heavily braced longitudinally and transversely. A portion of the ways can be built by sawing off the foundation piles by an underwater saw arbor, or by employing divers, or the entire site can be enclosed by a coffer-dam and the water then removed and the ways constructed in the dry. The last method is frequently resorted to in new ways,

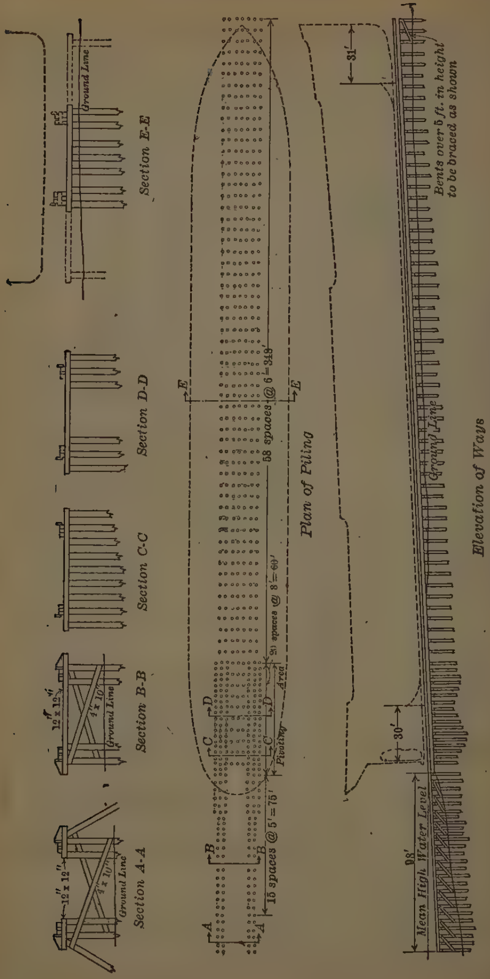

Fig. 91c. Cross-section Showing Transverse Bracing

as the under water part of the ways is so subject to damage in the course launching or damage by passing vessels, or floating objects, it is customary ore launching to carefully inspect this portion of the ways by divers and to uild it also when needed by this method. Fig. 91*c* shows the plan and eleva- 1 of a typical building and nching ways for a 9000-ton d weight cargo ship, the nching weight of which is umed at 2850 tons. Atten- 1 is invited to the piling n necessary at the out- rd end where the founda- 1 at *CC* and *DD* is greatly nforced. This is to take e of the pivotal pressure einbefore referred to.

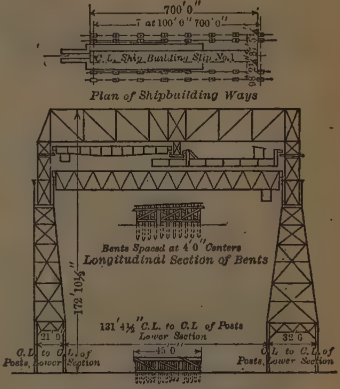

Fig. 91*d*. Timber Building Ways

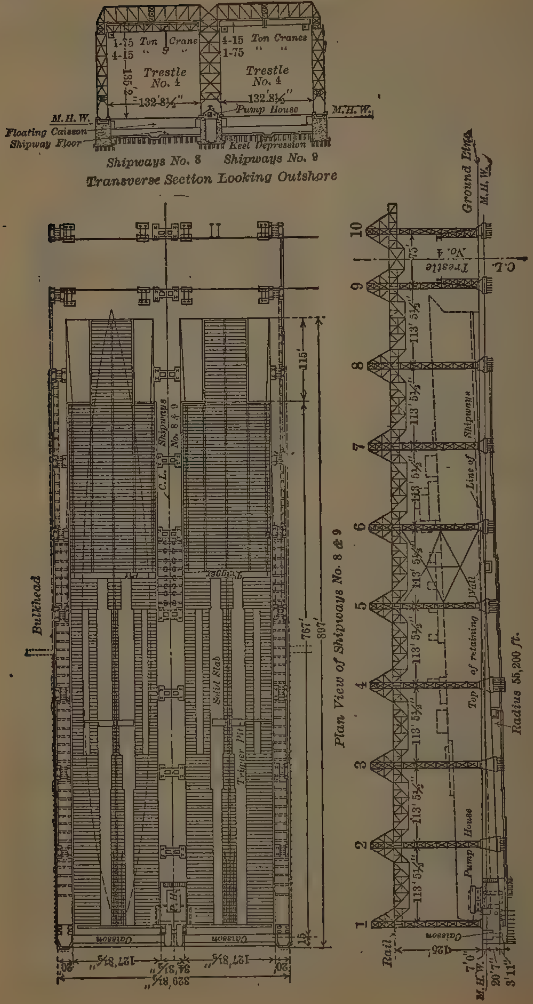
n construction of merchant sels frequently the launch- weight is always the weight displacement of the bare light ship, the boilers, ma- nery and most of the acces- ies having been placed ile the vessel is on the ways ler construction. It is en desirable either for the pose of rapidly clearing ways and getting it ready another ship, or by reason of the fact that the particular plant does not struct and install the machinery and other ship's gear, to launch the hull l place the machinery, etc., afterwards, in which case the launching weight o that extent so much less. In the construction of naval vessels, especially tleships and cruisers having heavy armor and armament, the exterior armor, ret armor and often turrets, together with much of the machinery and all of guns, are placed after the vessel is launched, so that the launching weight is ally from 30% to 40% of the full load displacement.

Types of Building Ways. The ways shown in Fig. 91*c* is of the simplest e, and that most generally used, and has the advantage of economy of t cost. As previously stated a more permanent foundation is obtained by use of concrete cross walls or pillars. Ways of this character have the dis- antage that the outboard end is under water, not subject to visual inspection, l when preparing to launch there is, of course, some difficulty in providing proper lubricants under water. They must always be extended some tance out to insure a depth for clearance.

A twin set of ways have been constructed by the Newport News Shipbuilding ., a plan, section and side elevation of which are shown in Fig. 91*e*. In these ys the water is excluded from the lower end by means of floating caisson es. The ways have the advantage of permanency, shorter length and less ght required for overhead crane run way structure. They undoubtedly olve the element of a much higher first cost and entail drainage of the lower tion of the site during the process of building.

The type of ways above described naturally leads to the consideration of the of a shallow graving dock for shipbuilding purposes. Ships have in the past



Longitudinal Section Looking North Showing Battle Cruiser on W...

Fig. 91e. Timber Ways

en built in a basin or graving dock which results, of course, in tying up this portant part of the :epair plant and preventing its use for ship docking and air work; such use would not be resorted to in ordinary circumstances unless ere was assurance that the dock could not be profitably used for ordinary cking purposes. A shallow dock has been built at the Puget Sound Navy rd especially for shipbuilding purposes. A shipbuilding ways of this type particularly adaptable to this location on account of the extreme range of tide, arly 20 feet, which would have made the length and cost of an ordinary build- ; ways and the maintenance of the under water portion very expensive as mpared to other locations.

Shipbuilding Cranes. As this matter begins to come within the scope of e shipbuilding plant layout, and design, it will be very briefly dealt with as a

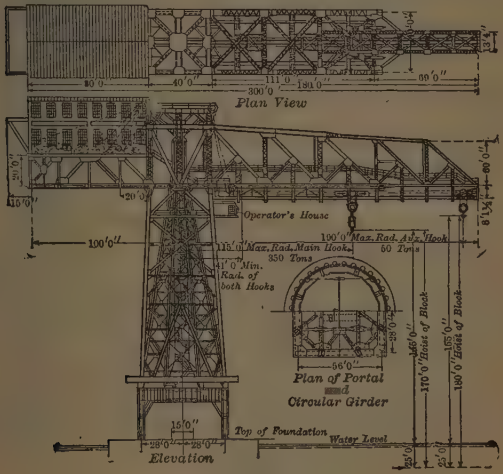


Fig. 91f. 350-Ton Fitting-out Crane

tter of general information. A simple and very effective method of handling frames, shapes, plates, built-up bulkheads, etc., for a ship is the employ- nt of two or more aerial cable ways, usually arranged longitudinally, picking material at the head of the slip and moving it longitudinally and trans- sely to the desired location. It has been effectually employed in merchant pbuilding, and is especially adaptable to certain types of work.

An effective type of crane is the light, fixt hammer-head tower crane. This ally has a lifting capacity of from 5 to 15 tons, and must be so arranged as cover the entire area of the vessel and be able to handle material from storage l assembly spaces alongside of the ways. They are usually grouped on either e of the ways, three, five or seven being employed. The arms must be put varying elevations so as to avoid interference and give the requisite clearance the depth of hull, etc.

A similar type crane is sometimes employed on one or both sides of the ways, but instead of being fixt travels on a standard gage or special gage track parallel with the ways and to one side, or cranes of this character may be of the jib or luffing type.

When a large complicated passenger vessel such as the transatlantic liners or a battleship or battle cruiser is to be built it has often been considered desirable to resort to more complete and extensive weight handling devices than can be afforded by the fixed or movable tower crane service. The building ways of several of the important shipbuilding plants are served by longitudinally traveling cranes; it will be noted in Fig. 91*e* that the twin ways of the Newport News Shipbuilding Co. are each served with one 75-ton and four 15-ton longitudinal cranes, which pick up material from the assembly and storage space at the head of the ways. Fig. 91*d* is a plan and cross-section of typical building ways and overhead crane structure employed by the Navy for the shipbuilding ways at the New York, Philadelphia and Norfolk yards The upper cranes each span one-half of the width of the ways, are of 15 tons capacity and the lower, larger crane is of 40 tons capacity. They handle material from the head of the ways and also are so arranged as to pick up material from cars running parallel with the ways. Section 91*f* is a side elevation and plan of a 350-ton hammer head fixt crane which is to be employed for placing of heavy weights on vessels after they are launched. It is designed to be placed on a special fitting out pier and vessels are brought to the pier and traversed longitudinally along its side so as to come within the reach of this appliance.

38. Cargo Handling Cranes

Cargo Handling devices and appliances for miscellaneous merchandise do not appear to any extent in successful use in American port practise, altho in more favor in European harbors. In American practise the cargo is unloaded and loaded largely by using ship gear, the hoists being made by ship boom or from gallows frames and uprights along the side of the pier shed; mixed cargo when handled on the pier is sorted by hand and distributed by man-handling on push trucks. In two-story pier sheds freight elevators, chutes, and continuous belt inclines are sometimes used.

In European practise, which is in favor in some larger South American ports, shore cranes are often employed for loading and unloading, the cranes being generally of the portable type. Numbers in the following examples refer to Fig. 92.

(1) and (2) Antwerp, Belgium, on the Scheldt. Quay wall runs entire length of the city. Principal wharfage capacity is derived from interior wet docks. Range of tide is 16 ft. Open sheds constructed some distance from quay wall. Portable crane spans outside railroad track; cranes handle cargo from the ship to cars, or to the face of the shed, in which it is handled by hand trucks for storage or transfer to cars in the rear for reshipment. Shed is for transfer or temporary storage. Warehouses for permanent storage are usually found with railroad connections close by.

(3) Hamburg, Germany, on the River Elbe. A greater amount of wharfage room is secured by interior basins. The plant of the Hamburg American Line is the one illustrated. The sheds are about 2500 ft long and 175 ft wide, and are from 30 to 35 ft from the face of the quay wall. In this space are operated electric cranes which span an outside railroad track which handles the cargo from steamer to railroad track or to side of ship. In interior of shed cargo is handled by hand trucks thru the shed for local storage or to carts or railroad tracks in the rear for direct delivery, or delivery to warehouses.

(4) Bremerhaven, mouth of the Weser on the North Sea. Tide has range of 8 ft, but on account of insufficient depth of water, wet docks are employed. Shows typical section of the North German Lloyd terminal. Sheds are about 200 ft wide, of corru-

gated iron siding wooden roof trusses, tar and gravel roofs. Electric cranes are provided for loading and unloading; cranes operate by picking up cargo from the holds of steamers by circular movement, swinging on to railroad cars on three lines of track, or to the sides of the shed. Loading and unloading are accomplished by this system on the shore side, and by barges and ship's boom and tackle on the water side.

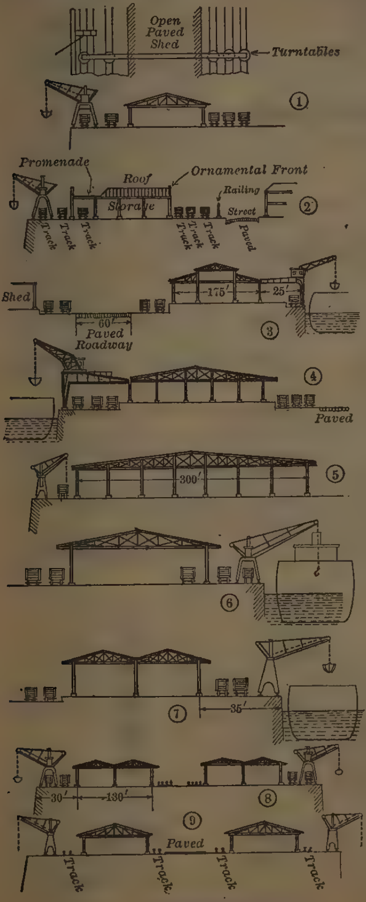

Fig. 92. Cargo Handling Methods

(5) Havre, France, at the mouth of the Seine. Range of tide 25 ft. Wet docks employed. Coffee and cotton landings. Sheds are 300 ft wide and 2600 ft long. The sides are continuous rolling doors, roof of tar and gravel, with glass skylights. Cargo is handled by crane from ship to side of shed or to railroad track.

(6) Southampton, Eng., American Line terminal.

(7) London, Eng., shows system of handling at Albert dock. Sheds are of light corrugated iron construction and run entire length of quays.

(8) London, Eng., Tilbury docks. (9) Glasgow, Scotland. Typical arrangement of cargo handling.

Movable Shore Cranes for miscellaneous cargo handling, while not generally employed in American practise, are usually employed in connection with handling of homogeneous cargo in bulk, various types of standard gage locomotive cranes being used for that purpose. Special cranes or traveling transporters are extensively used, the following types being shown in Fig. 93.

(1) One of four loading and unloading bridges at Rotterdam, Holland, 8 long tons capacity. (2) One of two transporters, 10 long tons capacity. (3) Coal loading and unloading bridge. (4) Loading appliances.

Fig. 94 shows type of heavy locomotive crane employed in connection with

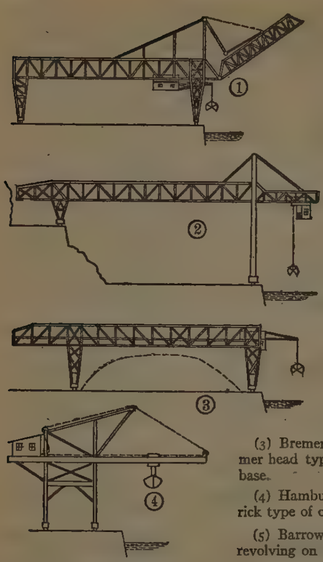

Fig. 93. Cargo Handling Travelers

ship repair and dry dock work. The crane is of 50 long tons capacity at 68 ft radius, of lesser capacities at greater reach and of 15 long tons capacity at 123 ft reach, and travels 120 ft per minute, with a maximum load. Cost, about $50,000. Cranes of this type are in extensive use in various U. S. Navy Yards.

Stationary Cranes. Fig. 95 shows types of fixed shore cranes for heavy lifting and for building or repair purposes.

(1) 150 ton hammer head crane at Bremen, Germany. Interior spindle is supported on base step bearing, the crane revolving in the 4 leg tower.

(2) 150 ton revolving crane at Kiel, Germany. Crane of the hammer head revolving type. Interior spindle, stepped at the base, operating within the 3 leg support.

(3) Bremen, Germany, capacity 100 tons, hammer head type, revolving on circular track at the base.

(4) Hamburg, Germany, 100 tons, stiff leg derrick type of crane.

(5) Barrow-in-Furness, Eng., 120 ton jib crane, revolving on pedestal base.

Cranes of the hammer head type have been constructed of 250 long tons lifting capacity. Fig. 96 illustrates English practise, and shows a crane at Portsmouth Dock Yard.

Fig. 97 illustrating German practise, and is a 250 long ton capacity crane constructed for Blohm and Voss at Hamburg, Germany, in 1912. The crane is supported at a bear-

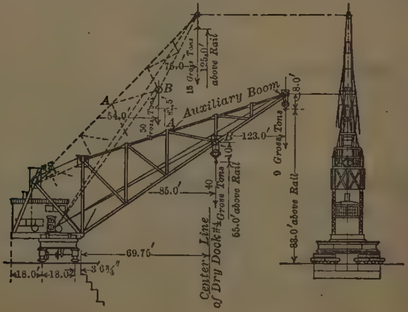

Fig. 94. Traveling Dry Dock Crane

ing on the top of the fixed spindle or tower, the enclosing structure revolves with the crane and bears against a track at the base.

Sheer legs are often used for heavy lifting. Fig. 98 showing a 100 long ton sheer leg with luffing jib device, the reach of the sheer leg being regulated by power operated horizontal screw, connected to the foot of the rear inclined member. This horizontal screw is sometimes replaced by a vertical quadrant with worm screw drive or pinion and racking. Sheer legs are also used for floating [redacted]

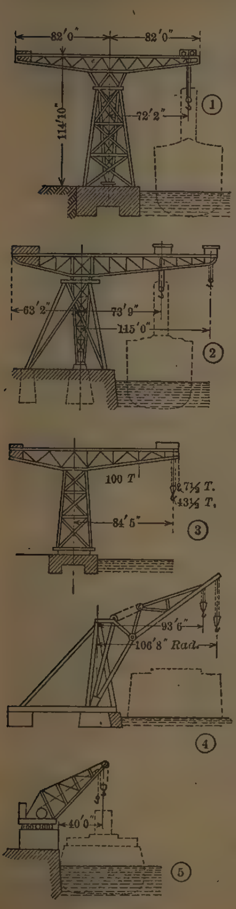

Fig. 95. Heavy Fixed Cranes

Floating Cranes are employed in connection with shipbuilding and repair, for loading and unloading heavy weights, handling lock gates, and for wrecking purposes. Fig. 99 shows the "A" frame boom type in extensive use in American practise. The "A" frame may be held in position by back stays of structural material or by wire cables, or in smaller derricks the "A" frame may be replaced by a mast. Cranes of this kind are in use from 10 tons to 250 tons capacity, the larger capacity being obtained in one crane by a lift directly over the bow, employing water ballast at the other end.

Fig. 100 shows a revolving tower floating crane of 75 long tons capacity. A crane of this type is employed in New York by the Dept. of Docks and Ferries, for placing quay wall concrete blocks. A similar crane is in use at Navy Yard, Boston, Mass. The load moment is taken care of by fixed ballast, water ballast, and the stability of the structure.

The Bridge type of floating crane is shown in Fig. 101, the bridge or trolley running thru the uprights so that the load may be transported from shore or vessel to the deck of the crane, or thru the crane to be handled on barge or shore at the other end. This crane was constructed in 1901, and rebuilt in 1910, and is at the Navy Yard, New York. Cost, $205 000. A similar crane is at the Navy Yard at Bremerton, Wash. Two bridge cranes of 150 tons capacity at the Navy Yards, Boston, Mass., and Pearl Harbor, H. T., cost slightly over $300 000 each. The load moment is counterbalanced by power, automatically operated counterweights or by water ballast.

An Incline Bridge Crane is illustrated in Fig. 102, and is in use by Schneider & Company, Chalons, France, built in 1911, of 25 tons capacity. The revolving jib type crane is shown in Fig. 103. One of 250 long tons capacity is self-propelling and is in use at Wilhelmshaven, Germany. Two similar cranes of same capacity, with less reach, are in use in the Isthmian Canal Zone, where they are to be employed for removing and placing lock gates, and for other purposes. These cranes cost about $450 000 each, and can lift 672 000 pounds. The pontoons are 150 ft long, 88 ft wide, and 15 ft 9 in deep.

39. Design of Cranes

The Design of cranes involves the field of mechanical, electrical, and civi engineering, and for floating cranes, also Naval architecture. For stationary o movable shore cranes, the structural features are analyzed and designed in accordance with prevailing structural steel practise, the operating machinery in accordance with electrical and mechanical machine design. Having decided on the required lifting capacity and the speed of lift, in order to obtain the horse power of the power unit, allowance must be made for the loss in friction in hoisting blocks, gearing, bearings, and operating mechanism. Three to five percent loss in friction should be allowed for each block sheave. The diameter of sheaves should preferably be 50 times the diameter of the wire cable and should not be less than 30 diameters. Steam power is generally used, altho on larger stationary or floating cranes electric motor operation has come into general use, generated by central plants or by isolated plants installed on the crane.

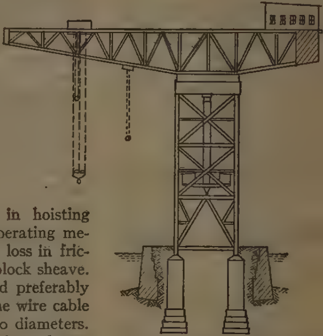

Fig. 96. 250 Ton Crane, Ports mouth, Eng.

With the application of the maximum load moment, structural steel work must be designed to carry this and also the wind load, taken at 10 lb per sq ft of exposed surface or without load, 40 lb per sq ft. For floating cranes the longitudinal and transverse stability is obtained, applying the formulas

$$GM = (I - B\,G.V - \Sigma i)/V = \text{Metacentric Height}$$

$$RM = \sin\theta/35\ \ (I - B\,G.V - \Sigma i) = \text{Righting Moment}$$

for which purpose the position of the center of gravity for the entire structure is secured. This calculation is made for the crane when light and when lifting the maximum load at maximum reach. The point of application of the lifted load will be at the center of the sheave pin on the jib or boom of the main structure. The overturning moment due to the lifting of this

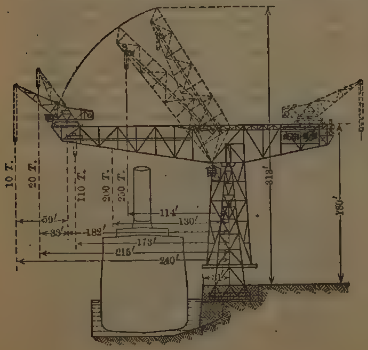

Fig. 97. 250 Ton Crane, Hamburg, Germany

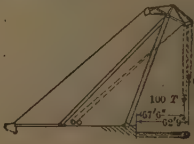

Fig. 98. Sheer Legs

load is the product of the load by the horizontal distance from the center of the load to the center of the float or pontoon, and the change of trim due to the application of

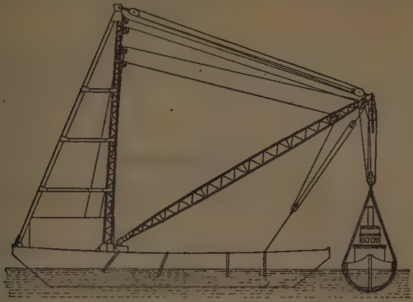

Fig. 99. "A" Frame Boom Crane

such load may be obtained in approximate terms by dividing this overturning moment by the moment due to inch change of trim.

Moment due to change of trim of 1 in $= D \times GM / Wl$

In these formulas GM = Metacentric height in feet; I = Moment of inertia in feet of water plane of flotation; BG = Vertical distance in feet from Center of Buoyancy to center of gravity; V = Volume of displacement in cu ft. D = Displacement in tons or lbs; Σi = Summation of moment of inertia in ft of interior water planes; Wl = length of waterline in inches. Half of the total change of trim will represent the reduction in

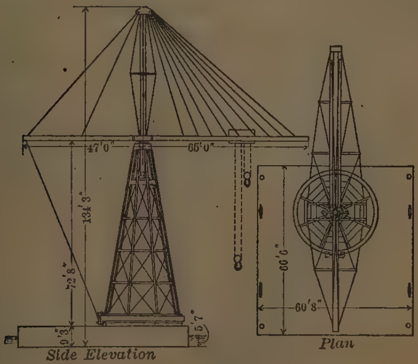

Fig. 100. Revolving Tower Crane

freeboard at one end of a rectangular pontoon and the increase in freeboard at the other end. The heel or inclination due to wind pressure is given by

Cot $\theta = (D \times GM) / (A \times C\ L)$

in which A = Total wind pressure in tons or lbs, and

$C\ L$ = distance in feet from center of pressure to center of lateral resistance.

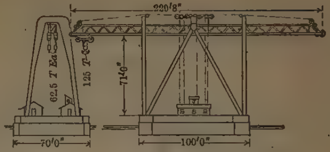

Fig. 101. Bridge Type Floating Crane

40. Port Development

The Growth and Development of a port involve many problems other than those of improving its strictly natural advantages by engineering works. The popular idea of the essential attributes of a port is its foreign water-borne commerce, with the necessary approaches, channels, quays, piers, docks, and structures to adequately receive, protect, and afford berths to vessels while loading or unloading. Imports and exports are generally considered as principally involved, little attention being given to domestic cargo, land-hauled freight, with the requirement of rail terminals and interchange facilities, which all go to complicate the intricate problem. Proper provision for water-front handling as it affects ocean-borne trade is undoubtedly necessary, as is also similar provision for domestic or coastwise shipping. However, incoming cargo is not consumed at the water-front of a port, or even within the port itself, nor does outgoing cargo originate on the water-front or even entirely come into being in the port. The water carriage in nearly all instances is only a part of the transportation involved. In view of this condition, port development at a large commercial center includes a proper provision for transfer between water carriers, land carriers, water and land carriers, and land and water carriers. Short land hauls from the

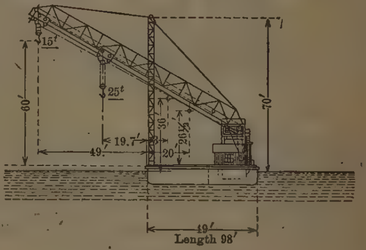

Fig. 102. Incline Bridge Crane

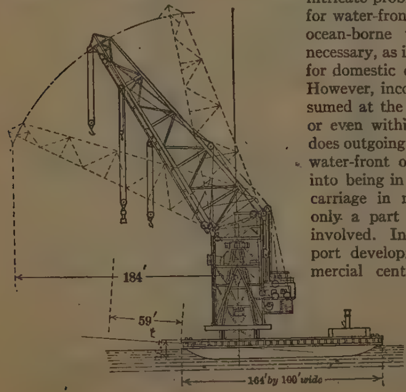

Fig. 103. Revolving Jib Type

water-front terminal may be made by cartage, but the bulk of land transportation would, of course, be by railway, so that any comprehensive port plan must take account of and provide for economical co-ordination of water and land carriers, with expeditions and complete interchange of freight at reasonable rates. In ports with a large and populous hinterland two or more railroad trunk lines with their terminal will be involved.

It is obvious that for outgoing and incoming cargoes these must be delivered or taken from all of the rail or other inland carriers and in turn delivered to, or taken from the vessel. A vessel, can of course be moved from pier to pier accumulating her cargo in that manner. Considering the usual high charter rate or per diem cost of large seagoing vessels, this involves loss of time and expense and must be avoided where possible so that it is customary to, in as far as possible, accumulate cargoes in advance.

Belt Lines, connecting main railroad feeders, are essential to proper port development, and should comprise in general an outer belt, which, while perhaps not a part of the port itself, serves to divert heavy traffic and afford an interchange between railroads without the freight tonnage having to go through the congested terminals of the port, and in that way relieves freight congestion in the port terminals; an intermediate belt, which affords means of transfer between port railroad terminals and upon which will often be located industrial works and factories of the port community itself, so that these may have ready access, by means of this belt, to interior shipping points or to water-borne carriers; a water-front belt, which serves as the direct interchange between water-borne and land carriers, and this belt may be an actual railroad belt or its equivalent in whole or part,—a lighterage belt, that is, the transfer is effected by lighter in the waters of the harbor and its tributaries, the lighterage taking place in loose bulk or packages or by lighterage of railroad cars or car floats. New York City is a conspicuous example of a large port with such a lighterage belt. The facility and economy with which such interchange and co-ordination are made by lighterage undoubtedly have contributed largely to the growth and prosperity of the port of New York.

Development of the port of New York thru lighterage has undoubtedly been an artificial one forced by certain economic competition between rail trunk lines who have absorbed in the freight rate all or a greater part of the lighterage cost.

Imports and Exports, while in the popular mind the most important business feature of a port, are in reality, in nearly all cases, the least important as regards tonnage, altho the providing of proper facilities for the export and import trade is essential to the continuation of the growth of the port. The very conditions involved have complicated the problems further, as it is found that in nearly all instances large commercial ports are thickly populated and the centers of populous districts, seldom or never entirely self-sustaining as regards food, clothing, implements, machinery, building materials, etc., so that a very large portion of the incoming freight, land- or water-borne, principally the former, is for local consumption or for redistribution from the port, inland or coastwise, as a manufacturing or sales center. This condition makes it necessary to give attention to features of port development other than those involved directly in export and import facilities.

Port Planning involves intricate economic studies based upon statistical research of present and probable future growth, character of local manufactured products, consumption of materials, rail and other transportation rates, which in all need the careful attention of experienced specialists. Haphazardly placed piers, wharves, warehouses, transit sheds, sometimes placed in too exposed locations and without due correlation to other economic requirements, have undoubtedly resulted in considerable loss of time and ill-advised expenditure of funds.

The Free Port has not been resorted to in American port policy. The nearest approach is in the bonded warehouse referred to in Art. 23. A free port is an area on the seacoast or on navigable water within the boundaries of which imports or foreign cargoes may be brought, unloaded and stored without being required to pay the legal tax impost of the country in which a port is located. The advantages of a free port are that importers and foreign merchants can store and retain dutiable goods within the area without the additional investment of the duty involved, and can retain such goods within the area of the free port until it is brought inland, when duty is collected at the boundaries of the port, or it may be trans-shipped without being subjected to the collection of duty or expense other than that of handling and storage. Raw materials may be worked into manufactured articles within the confines of a free port, and such articles trans-shipped without payment of custom fees or if taken over the boundary of a free port are subject to the impost on these manufactured articles. The various advantages of the free port have greatly stimulated the growth of such ports, as is witnessed in the case of Hamburg, and this method of port legislation and regulation might with profit be followed in American port economics.

41. Shipping Terms

Tonnage. When displacement of a vessel or docking capacity of a dry dock is referred to the tons are always long tons of 2240 pounds, and in all ship and dock computations 35 cu ft of sea water or 36 cu ft of fresh water are taken as weighing one ship ton.

The gross tonnage of a vessel is the measure of her cubic capacity in terms of 100 cu ft and is the volume in cubic feet of all enclosed spaces inside of frames divided by 100 cubic feet.

The net registered tonnage is in the same way the gross tonnage less the volume in 100 cu ft of certain machinery and other spaces not accessible to cargo. Such as crew space, steering-gear house, chain lockers, stores, etc.

The term "registered," as applied to net tonnage, refers to the measurements for that particular vessel as measured and registered by one of the national registry agencies, such as British Lloyds, Bureau of Veritas of France, or the American Bureau of Shipping. The displacement of a vessel is the weight of the vessel or water displaced by the vessel under any particular conditions and varies with the draft of the vessel at any particular time.

The dead weight tonnage of a vessel is the gross carrying capacity in tons and is the displacement of the vessel fully loaded, full draft to the Plimsoll mark, less the displacement of the vessel light and bare without coal, crew, and ship or crews' supplies. The cargo carrying capacity of a vessel in tons is something less than her dead weight tonnage; being this dead weight tonnage less the weight of bunker coal, crew, ship and crew supplies, etc.

The actual cargo carrying capacity of any vessel is dependent on the spaces or cubage available for cargo loading and dead-weight tonnage exclusive of fuel, etc., carrying capacity. The ideal arrangements for which stevedores contend is to take advantage of full weight carrying capacity and completely fill volume of cargo carrying holds. In general and for approximation purposes cargo carrying steamers in the ocean trade will carry about two-thirds of the tons of freight represented by dead-weight tonnage or about the number of tons weight represented by the numerals in the term "gross tonnage." Forty cubic feet are generally considered as representing a cargo ton.

In the design and construction of dry docks the weight to be lifted or the draft considered is that of the vessel light with no cargo and little coal. Dockage and other tolls are usually based upon the registered gross tonnage; an extra charge being made for cargo or excess fuel, etc. The Plimsoll mark is the mark made on the sides of the hull amidship to indicate the depth to which the vessel may be safely loaded.

SECTION 17

IRRIGATION AND DRAINAGE

BY

HORACE W. KING

PROFESSOR OF HYDRAULIC ENGINEERING IN UNIVERSITY OF MICHIGAN

IRRIGATION

1. Fundamental Considerations

Definition. The practice of supplying water to crops by artificial means is called irrigation. Irrigation is essential in arid districts and may be profitable in semi-humid regions where the rainfall is occasionally insufficient to mature crops and for certain purposes in humid regions as an assurance against droughts. Irrigation water may be obtained from gravity flow by the diversion of natural streams or by pumping from surface or sub-surface supplies.

Localities where irrigation is essential to successful agriculture may be found in western United States and Canada, the western countries of South America, southern Europe, Egypt, Persia, India, Australia and other parts of the globe. The census of 1910 showed that in the United States there were approximately 32 000 000 acres of land under irrigation projects either wholly completed or in process of construction. Of this nearly 15 000 000 acres were being actually irrigated. The total expenditure for irrigation works in the United States up to 1910 was $308 000 000 and the total estimated cost of all irrigation works, including the cost of completing those under construction, was $424 000 000. The estimated cost of preparing 32 000 000 acres of land for irrigation was $443 000 000.

The Development of the Irrigation Resources of a country usually begins with the bottom lands lying close to the stream which provides the water supply. In the early days of irrigation, ditches were built to serve a single farm or a small group of farms. Later, community ditches were built and irrigation companies were formed which irrigated larger areas under a single system. In the United States and other countries whose irrigation resources have been extensively developed, the more accessible lands are under irrigation and the flow of streams during the irrigation period has been largely appropriated. There thus remains for development only the more inaccessible lands and those which must be supplied by the storage of flood flows and water not available during the irrigation season. In general, irrigation may be divided into four operations: the storage of water, the diversion of water, the conveyance of water, and the application of water to the land.

The Soils of arid districts extend to a greater depth and are commonly more fertile than those of humid localities. In the irrigated sections of the United States the soils are generally deep and of uniform texture. Hardpans are found near the surface of the ground in some localities, but they are usually dissolved by irrigation. Care should be taken to determine the crops to which an irrigated area is best adapted. This may depend upon the length of growing season as well as the soil formation. A strong growth of sage brush, bunch grass or other vegetation indicates fertile soil. Salt grass and grease wood are indicative of alkali. In general, the soils of arid districts are well supplied with lime, potash, and nitrogen, but are low in humus content.

2. Disposal of Irrigation Water

Soil Moisture occurs in three forms, usually termed hygroscopic, capillary, and gravity water. Hygroscopic water is the moisture which perfectly dry soil will absorb from the water vapor in the air. It either may form an extremely thin coating of the soil particles or be held in loose chemical combination. It can not be removed without artificial heat and has no value in sustaining plant life. Capillary water exists as a thin coating of the soil particles. It moves from a wet soil to a drier soil in any direction. Capillary water is of chief value in supplying moisture for vegetation. Gravity water is the water contained by soil beyond its capacity to contain capillary water. It moves downward by

gravity and is not retained by the soil, as such, if there is satisfactory drainage. After rains or if water is applied by irrigation, gravity water near the surface of the ground in passing downward may become capillary water in the lower strata.

The amount of hygroscopic water in the soil depends upon the temperature, humidity of the air, texture of the soil, and other less important factors. It varies from a minimum of about 0.5 percent of the weight of the soil for coarse sand to maximums of 8 and 17 percent respectively for silt and clay. The limit of soil to hold capillary water is usually reached when it contains from 15 to 20 percent of its weight of moisture. Water will rise from 0.5 to 2 ft in one day and from 0.7 to 4 ft in one week by capillary action. The rate of capillary movement increases with the fineness of the soil particles. The distance which moisture may be drawn by capillarity varies from about 2 ft for sand to 5 ft for fine silt or clay. Cultivated soils contain from 30 to 50 percent of voids which marks the limit of their capacity to hold water.

General Methods of Disposal. Irrigation water applied to land may be disposed of by (1) plant transpiration, (2) evaporation from the ground, (3) percolation to strata beyond the reach of plant roots and (4) surface waste. Only the water used in plant transpiration serves a useful purpose, and in successful irrigation disposal by the other three methods should be reduced to a minimum.

Plant Transpiration is the process by which growing plants obtain nutriment from the soil. Carbon, which constitutes about one-half of the dry plant, is taken by leaf action from the carbon-dioxide in the air. Plants contain from 2 to 10 percent of mineral matter obtained from the soil moisture in which it is dissolved. The remainder of the plant is composed of the elements of water combined with the mineral matter and carbon. There is a continual upward current of water through the plant. The soil moisture, containing mineral matter in solution, enters the hair roots of the plant, the water being dispelled by the leaves into the air in the form of water vapor. The rate of movement of the water usually varies from 1 to 6 ft per hour, but may be much greater than this. The rate of transpiration from the ground is greater for moist soils. It may be equivalent to a depth of ½ in over the ground surface per day when the ground is wet, but reduces as the capillary water in the soil becomes depleted.

Evaporation from Soil. The rate of evaporation from the surface of saturated soil may be nearly three times as great as the rate from free water surface in the same locality. Under ordinary field conditions, however, the evaporation is usually less than from free water surface. In general, the amount of evaporation decreases with the soil moisture. The evaporation is greatest from uncultivated ground where capillary movement of the moisture is continually bringing water to the surface of the ground. Cultivation of ground forms a mulch which greatly retards capillary activity and consequently reduces evaporation. A mulch of 6 in will save 80 percent of the water which would be evaporated from uncultivated ground.

Percolation. When irrigation water is applied to land the surface becomes saturated and the water gradually percolates to the lower strata. In the passage capillary water is retained. If the amount of water applied to the land is small enough, the percolation will not extend beyond the depth where it may be reached by the roots, but if a larger amount is applied, some of the water will pass beyond the reach of the roots and be wasted.

Sandy loam soils will retain about 2 in of water within a depth of 6 ft, but when more than this is applied, the greater part of it will pass to a greater depth. Coarse soils will retain less moisture than fine soils and therefore require more frequent irrigation.

Surface Waste. There is always a certain portion of irrigation water which is lost before it soaks into the ground This may occur in two ways, by evapora-

tion and by running off the surface of the ground. The first of these is ever present and can not be controlled to any extent. The latter loss, however, may be prevented or materially reduced by care in irrigating. Where proper care in using water is not exercised, this loss is frequently more than 20 percent of the water applied.

3. Water Requirements

Units. The unit of volume commonly used in irrigated districts to express storage or the quantity of water required to irrigate a given area of land is the acre-ft. It is the amount of water required to cover an acre of land 1 ft in depth or 43,560 cu ft. An acre inch is 1/12 of an acre ft. The unit used to express flowing water is cu ft per sec. One cu ft per sec flowing for 24 hrs is equal to 1.9835 acre-ft. A unit of measure for flowing water that is becoming obsolete in the miners inch (see Sect. 13, Art. 28).

The Factors Affecting the Quantity of Water required to mature crops are: the character of soil, the climate, the time of irrigating, the number of irrigations, and the method of irrigating. The first two of these conditions are fixed, but careful study should be given to each locality to determine the system of irrigating which will provide the most economical use of water. This matter has been carefully investigated by the United States Department of Agriculture and by many of the western states. It has been found that while the use of water up to a certain amount is beneficial, beyond this amount little if any apparent increase in the productivity of the land results. It has also been found that where the supply of water is insufficient to irrigate all of the available land lying under it, there is an economical limit to the amount of water which should be applied. In other words, a greater profit from a given quantity of water may, in some cases, be obtained by spreading it over a larger area. This point is illustrated in the following example by Widtsoe (Principles of Irrigation Practice, page 337), assuming that sugar beets are worth $5 per ton and the cost of producing them, including interest on investment, is $60 per acre:

30 acre-inches spread over	Inches of water on each acre	Yield of beets per acre (tons)	Total yield of beets (tons)	Price paid for ton of beets	Gross income from beets	Cost per acre	Total cost.	Net income from beets
1 acre........	30.0	21.0	21	$5	$105	$60	$60	$45
2 acres......	15.0	19.5	39	5	195	60	120	75
3 acres......	10.0	18.6	56	5	280	60	180	100
4 acres......	7.5	16.3	65	5	325	60	240	85

The above table shows that the greatest yield per acre is obtained by applying the 30 acre-inches of water to 1 acre of land, but the greatest net income for this quantity of water is obtained by spreading it over 3 acres.

The Character of Soil greatly affects the amount of water used for irrigation. From two to four times as much water is used on coarse sandy soils as on silt and clay soils. On the Umatilla project in Oregon, where a coarse sandy soil predominates, an average of nearly 16 acre-feet per acre was used in 1912. By proper methods of irrigating the amount of water required may be greatly reduced. On coarse soils much water is usually lost by percolating to the lower strata beyond the reach of roots. This can, in a large measure, be avoided by irrigating only a small area at one time and using a large head of water so that the area can be irrigated quickly. Since coarse soils have less capacity for holding capillary water than fine soils, they require more frequent irrigations, but a

smaller quantity of water at each application. In general, the more fertile the soil the less water is required. Cultivating the soil forms a mulch over the surface and thus reduces the evaporation and the water requirements.

The Kind of Crop has an important bearing on the amount of water required. Excepting fruits the water required will vary with the length of the growing period. Alfalfa, which grows thruout the entire season, requires more water than plants of quicker growth.

The Quantity of Water Used for different crops in the United States as determined from extensive experimental data is given approximately in the following table. Frequently much larger quantities than the maximum given are used, but in most cases these could be reduced by better methods of irrigating. Results of investigations in southern Europe, Egypt, India and Australia indicate requirements practically the same as the United States.

Water Requirements for Different Crops

Crop	Soil	Water requirements in acre-feet per acre		
		Average maximum used	Average minimum used	Average for most economic use of water
Alfalfa (three cuttings)	Clay and sandy loam	4.0	1.5	2.5
	Porous sandy soil	10.0	4.0	6.0
Grain	Clay and sandy loam	3.0	1.0	1.5
	Porous sandy soil	5.0	1.5	2.5
Potatoes	Clay and sandy loam	3.0	1.0	1.5
	Porous sandy soil	5.0	2.0	2.5
Sugar beets	Clay and sandy loam	3.0	0.5	1.2
	Porous sandy soil	5.0	1.2	2.0
Deciduous fruits	Clay and sandy loam	2.0	0.7	1.0
	Porous sandy soil	4.0	1.5	2.0
Citrus fruits	Clay and sandy loam	3.0	1.2	1.7
	Porous sandy soil	5.0	2.0	3.0

The Times to Irrigate to secure the best results from a given water supply will be such that come nearest to fulfilling the ideal condition that the soil shall have an adequate and uniform moisture content thruout the growing period. Since transpiration from large plants is greater than from smaller ones, and also because maximum growth is obtained late in the summer when evaporation is greatest, more water should be applied during the latter part of the growing season. After vegetation has attained its full growth and becomes well matured, but little water is required. When water is obtained directly from streams this ideal condition is not usually attainable, since the water supply which is plentiful during the early part of the growing season usually decreases rapidly as the summer advances. If the source of supply is from storage reservoirs water is available when needed. An important consideration is that the ground should be thoroly moist at seeding time or when plant growth begins. To accomplish this, fall, winter or early spring irrigation has been practiced with excellent results. If the fall and winter rains are heavy enough to supply adequate spring moisture such irrigation is unnecessary. In localities where water is not available during the growing period, short-season crops such as grains and early fruits have been grown successfully with fall and winter irrigation only.

If the soil is well filled with moisture at the time plant growth begins in the spring, the first irrigation of the crop should be deferred until the need for more water is apparent. This permits the roots to obtain a more vigorous growth. After the first irrigation successive irrigations should follow as required. As a rule frequent irrigations using comparatively small quantities of water are advisable. The usual practice, for fine soils, is to apply from 3 to 5 in of water at each irrigation. A smaller quantity of water should be used for coarse soils, if practicable, but the irrigations should be more frequent.

The Number of Irrigations varies with the crop and the character of the soil. For fine soils, alfalfa should be given one or two irrigations for each cutting; potatoes, sugar beets, corn and similar crops are usually irrigated from 3 to 5 times, the bulk of the water being applied from July 1st to August 15th in the northwestern states; grains are given from 1 to 3 waterings near the time of seed formation; deciduous fruits require a fairly uniform distribution of moisture, with rather more at the time fruit is forming; citrus fruits require irrigation thruout the year, with the maximum requirement in the fall. Coarse soils require more frequent irrigations than the finer soils.

Duty of Water is a coined term which has been used variously to express the water used and the water required for irrigation. The meaning of the term is ambiguous and its use could well be dispensed with. As more commonly applied the duty of water for a given crop means the quantity of water used for irrigating the crop, as for example, 2 acre-feet per acre or a continuous flow of 1 cu ft per sec to 80 acres. The net duty of water for an irrigation project may mean the average rate of use per acre for the project, water being measured at the farmers' intakes. The gross duty of water will then be the average rate of use per acre measured at the diversion, and thus includes all conveyance losses.

4. Conveyance Losses

Seepage and Evaporation. All canals and other conduits used for conveying water are subject to losses from seepage and evaporation. Earth canals form fully 90 percent of the water-carrying systems of irrigation projects and from these, seepage losses usually amount to a large percentage of the water diverted. Evaporation losses in earth canals are always much less than seepage losses and the two sources of loss are usually considered together. When water is first turned into a canal, the banks and sides of the canal absorb water rapidly until the ground has been filled to its capacity with capillary water, after which there is a steady and fairly uniform loss from gravity water. The coarser the soil, the greater the seepage. If canal waters contain silt this will tend to deposit in the pores of the soil and reduce seepage.

Less important factors that are believed to influence the amount of seepage are the depth of water in the canal, velocity of water, and temperature of soil and water. When canals are located below other irrigation systems there may be an inflow of water which, in a measure, will counteract the effects of seepage and evaporation. Conveyance losses in canals may be expressed conveniently as a function of the wetted area. Extensive experiments in this and other countries have been made to determine the losses for different soils. The following table represents approximately the mean of these investigations for canals that have been in service five or more years, but it should be considered as subject to a possible error of at least 25 percent. The main difficulty will be found in proper classification of the soil.

Canal Linings have been used extensively to reduce seepage losses. The most satisfactory linings that have been developed are concrete or cement mortar, crude oil, and clay puddle. Which of these should be used depends upon the materials that are most readily available and other local conditions. Concrete linings are also effective in reducing friction losses and in the case of

canals excavated in rock this consideration may be more important than the prevention of seepage. Canal linings are always expensive and for this reason they have not been used extensively except where water is very valuable. In southern California many entire canal systems are lined thruout, while in other localities only those portions of canals are lined where seepage losses are greatest.

Seepage and Evaporation Losses in Canals in Second Feet per Mile for Average Conditions

Wetted perimeter of canal section in feet	Kind of material							
	Clay	Clay loam	Sandy clay loam	Sandy loam	Fine sand	Coarse sandy soil	Sandy soil with some gravel	Very gravelly soil
5	.08	.12	.27	.38	.49	.61	.92	1.53
10	.15	.24	.55	.76	.98	1.22	1.83	3.06
15	.23	.37	.82	1.15	1.47	1.83	2.75	4.58
20	.31	.49	1.10	1.53	1.96	2.44	3.67	6.11
25	.38	.61	1.37	1.91	2.44	3.06	4.58	7.64
30	.46	.73	1.65	2.29	2.93	3.67	5.50	9.17

90	1.37	2.20	4.95	6.87	8.80	11.00	16.50	27.50
95	1.45	2.32	5.22	7.26	9.29	11.61	17.42	29.03
100	1.53	2.44	5.50	7.64	9.78	12.22	18.33	30.56

Concrete Linings are made of various thicknesses ranging from ½ to 5 in. For the thinner linings only very fine aggregate should be used, and for linings 1 in or less in thickness a cement mortar is preferable. The proportions of cement to aggregate should be about 1 to 8 for the thicker linings and 1 to 4 for linings less than 1 in thick. When properly made, concrete linings will reduce the amount of seepage from 75 to 95 percent, the thicker linings being more effective. There is also a tendency for silt to deposit in the pores of the concrete which renders it more impervious with age. For a lined canal of a given area, the cross-section should be such as will give the maximum hydraulic radius practicable, but the slopes of the banks should not be less than the angle of repose of the material thru which the canal is constructed. Canal linings of cement mortar from ½ to 1 in thick which have been constructed in western United States have given excellent service. By using a comparatively dry mixture, concrete may be placed without forms on canal banks having a slope of 1 to 1. For steeper slopes forms will be necessary. The very thin linings should be used only for small canals. The following is the approximate range of costs of canal linings in western United States. In a few cases the costs have been much greater than are here given:

Thickness of lining in inches	Cost in cents per sq ft	Thickness of lining in inches	Cost in cents per sq ft	Thickness of lining in inches	Cost in cents per sq ft
½	2.5 to 3.5	1½	4.2 to 6.0	3	6.6 to 9.7
¾	3.0 to 4.1	2	5.0 to 7.2	4	8.4 to 12.3
1	3.4 to 4.8	2½	5.8 to 8.6	5	10.1 to 14.8

Oil Linings are made by sprinkling from 1 to 3 gal per sq yd of crude oil on the sides and bottom of the canal. Several light applications are used, and in some cases the surface is worked with a rake or harrow after each application. Good results have been obtained, however, by leaving the surface undisturbed after applying the oil. The oiled surface is generally rolled or otherwise compacted. Experiments indicate that oil linings when new will reduce seepage losses in canals from 50 to 75 percent. They deteriorate, however, and their effectiveness diminishes with age. The average cost of preparing oil linings in the United States, not including the cost of the oil, has been about 1.5 cents per gal of oil used.

Clay Puddle Linings have been used in localities where suitable material is available within a reasonable distance. The clay is deposited in a layer from 3 to 6 in thick along the bottom and sides of the canal, after which water is turned into the canal and the material is puddled by harrows or the tramping of animals. A good clay puddle lining will reduce the seepage loss by from 60 to 80 percent. It does not deteriorate, but becomes more effective with age. Fine surface soil thrown into a canal containing water and thoroly stirred up by teams dragging heavy chains or otherwise agitated has in some cases been quite effective in reducing seepage.

5. Water Supply

Total Water Supply. One of the first considerations in the investigation of an irrigation project is the determination of the amount of water available for the project. The discharge of the stream or streams forming the source of supply should be carefully investigated. A knowledge of the distribution of the flow as well as the total annual discharge for a period of years is essential. The best data on which to base an estimate of future discharge are continuous discharge records covering a period of years. Such records, for many streams in the United States, are published in the Water Supply and Irrigation Papers of the U. S. Geological Survey. They may also in some instances be obtained from State Engineers' offices or from private sources. On many streams, however, available discharge records cover only a comparatively short period or they may be entirely lacking. It also may be found that discharge measurements on a stream have been made at a place quite remote from the proposed point of diversion. Precipitation records are valuable for supplementing incomplete stream discharge data. Such records, published by the U. S. Weather Bureau, are available at one or more points for practically every drainage basin in the United States.

The safest data for estimating future discharges are actual discharge measurements, near the place of diversion, covering a period of not less than ten years. A record for this period will probably include ordinary high and low water stages of the stream, and show the general distribution of flow thruout the year. If a project is under investigation and discharge records near the place of diversion are not available, a gaging station should be established at the first opportunity. If there is any doubt as to the adequacy of the water supply for a proposed project, construction work should be delayed until supplementary data sufficient to provide a satisfactory estimate of discharge have been obtained. In general, at least 2 years of continuous discharge records should be available near the place of diversion and these should be supplemented with such additional data that a reasonably reliable record for a period of at least 10 years may be estimated

Prior Rights to Water. In estimating the water available for irrigation from a given stream, all prior rights should be investigated. In western United States the streams are controlled by the states and the laws regulating their use are not uniform and are continually being changed by new statutes and court decisions. The state laws governing the stream should therefore be understood. The waters of some streams have been adjudicated by the states and in such cases records of prior rights are obtainable at State Engineers' offices. In many instances it will be found that the records of water rights are in such a condition that an examination of each canal diverting from the stream must be made to determine the amount of water actually used and the area of land under it that is entitled to water.

Water Supply Available. The difference between the total water supply and the quantity of water represented by prior appropriations gives the water supply available. The estimate of available water supply is usually prepared by months by deducting from the discharges for each month of the period covered by measured or estimated discharges the water represented by prior rights for corresponding months. These differences give the estimated amount of water that would have been available for each month during the period considered and if the period is long enough (preferably at least 10 years) they may be taken to represent the available future supply.

The Water Supply Required for a given area will be that necessary to provide for the irrigation of crops and in addition all seepage and evaporation losses in canals and reservoirs. (Arts. 3 and 4.) An estimate of the water supply required should be prepared for each month by adding the estimated seepage and evaporation losses. By comparing the water available with the water required, the deficiency for any month of the period covered by records may be determined. If storage is to be provided, such deficiencies will give the amount of storage required. About 20 percent of an irrigable area will be occupied by roads and buildings or for other reasons will not be irrigated. This area should be deducted for purposes of estimating water requirements for an irrigation project.

6. Canal Systems

The System of Conduits and structures necessary to convey water from the place of diversion to the farmers' laterals is commonly called the canal system. It may consist of any or all of the following: Canals, flumes, pressure pipes, tunnels, drops, wasteways, and various small structures. These should be so designed and constructed as to provide for the economic delivery and distribution of the water used by the project.

Canal Sections. (See Sec. 11, Art. 24.) The canal section of a given area which will provide the greatest carrying capacity, other things being equal, is the one having the greatest hydraulic radius. With the side slopes ordinarily

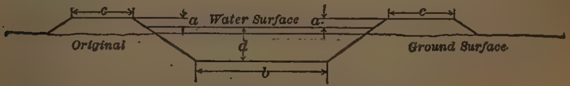

Fig. 1. Canal Section for Level Ground

necessary in earth canals the section of maximum hydraulic radius has a bottom width less than the depth. There are practical objections to the use of such sections for earth canals. Figs. 1 and 2 represent respectively cross-sections

of earth canals for level and sloping ground. As commonly constructed $b = 3d$ to $4d$, $a = 0.4d$ to $0.6d$, $c = 1d$ to $2d$. The side slopes of canals in level ground and of the embankment side in sloping ground are usually 1 on 2 or 1 on 1½. On steep hillsides the uphill side of the canal may have a slope of 1 on 1, all slopes being kept as steep as possible in order to reduce excavation. In designing canals the cross-sectional area of the excavation is usually made about 10 percent greater than that of the embankments to allow for waste and shrinkage.

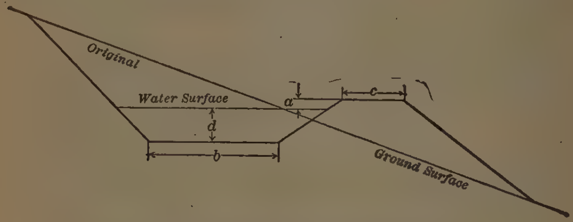

Fig. 2. Canal Section for Sloping Ground.

The Most Economical Velocity of water for earth canals is usually the maximum velocity which may be maintained without erosion. (See Sect. 9, Art 17.) This permits the smallest cross-sectional area of the canal prism and results in a minimum construction cost. The lower velocities are also objectionable in that they may permit the deposition of silt and the growth of aquatic weeds and grasses. In exceptional cases velocities lower than would otherwise be advisable may be used to conserve head. The velocity at which erosion begins varies with the character of material, the following being approximately the maximum allowable mean velocities in ft per sec for different kinds of earth:

Very light find sand	1.0 to 1.5	Clay	3.0 to 4.0
Coarse sand	1.5 to 2.0	Fine gravel	3.5 to 4.0
Sandy soil	1.8 to 2.2	Coarse gravel	4.0 to 5.0
Light alluvial soil	2.0 to 2.5	Cemented gravel or hardpan	6.0 to 7.0
Clayey loam	2.5 to 3.5	Rock	8.0 to 15.0

In a canal designed to carry water at a given velocity care should be taken to maintain this velocity at all points. Where a drop is constructed in a canal the opening in the drop should be just sufficient to discharge the capacity of the canal while maintaining the normal depth of water. Similar precautions should be taken above any structure which modifies the conditions of flow. A disturbance usually exists for some distance above and below any structure which requires a change in velocity and riprap or some other form of protection for the bottom and sides of the canal is usually necessary. The velocity of the water will accelerate at the concave side of a bend in a canal and on sharp curves some protective lining may be necessary.

Canals in Rock are excavated with steep side slopes, commonly 1 on ¼, and with bottom widths not more than two times the depth. They are also sometimes built with a semi-circular cross-section. Canals excavated in rock are usually lined with concrete. For canals in hardpan or other indurated material the conditions are intermediate between those for earth and rock.

Flumes (see Sect. 11, Art. 15) are used to convey water across streams, ravines or other depressions of the ground, and also around hillsides to avoid difficult

excavation. They are built of wood, steel and concrete, or of combinations of these materials. The substructure may consist of piers or posts of concrete or of wooden or steel posts or trestles. Trestles should be braced longitudinally and posts should be well tied together with both transverse and longitudinal bracing. Concrete bases or mud sills may be used for supports. Flume channels usually have rectangular cross-sections when constructed of wood

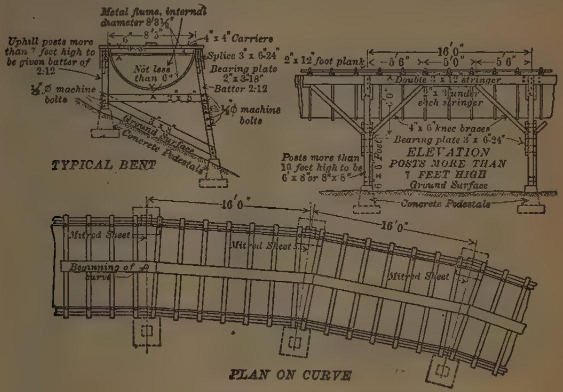

Fig. 3. Steel Flume with Wooden Substructure.

or concrete and semi-circular cross-sections when constructed of steel. Fig. 3 shows a steel flume with wooden substructure and concrete pedestals. Short flumes have been built over 100 ft high, but as a rule flumes are better adapted to conditions where the height is not much over 20 ft. For greater heights especially for long depressions pressure pipes will usually be more economical.

Pressure Pipes (see Sect. 10, Art. 21 and Sect. 11, Arts. 13 and 14) for irrigation purposes are usually built of wood, steel, or reinforced concrete. For small quantities of water, if the pressure head does not exceed 20 ft, vitrified sewer pipe and plain concrete pipe have proved satisfactory. Pressure pipes are used to carry water across depressions or around steep hillsides; small pressure pipes may be used as laterals for distribution systems.

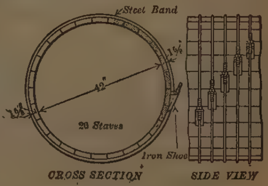

Fig. 4. Wooden Stave Pipe

Reinforced concrete pipes are best adapted to pressure heads of less than 100 ft. Wooden stave pipes have been used for heads of 300 ft or more, tho 250 ft is probably very near to the economical limit of such construction. For the higher heads, steel is used exclusively. The average life of steel pipe is greater than that of wooden pipe, but the life of each is dependent upon the care with which it is maintained. (Art. 32.) Under ordinary conditions of use, concrete pipe should last indefinitely. Wooden pipe being smoother than concrete or steel has a greater capacity for a given diameter. De-

posits will form on the inner surface of a steel pipe, which may reduce its capacity from 25 to 30 percent after a few years of service. In determining the most economical pipe for a given locality, where continuous service is required, the first cost, life, and carrying capacity of each kind of pipe should be considered. Fig. 4 is an example of a wooden stave pipe, as manufactured by the Washington Pipe and Foundry Company.

Tunnels (see Sect. 11, Arts. 32 to 41 incl.) may be constructed across points to shorten canal lines, or thru divides to divert water to a different drainage basin. They are also built in the sides of rocky canyons where canals, flumes, or pressure pipes would be expensive to maintain. In difficult side hill location, the water may be carried successively in canals, flumes, tunnels, or pipes, following each other in any order.

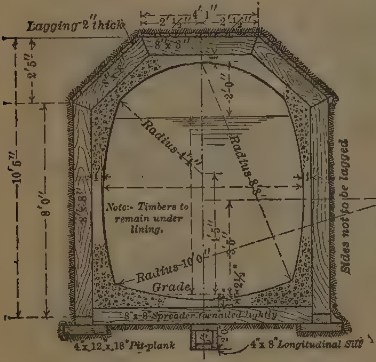

Fig. 5. Strawberry Tunnel, Shale Section.

Tunnels for irrigation purposes are usually lined with concrete, tho short tunnels in firm rock are sometimes left unlined. Concrete linings serve the double purpose of preventing caving of tunnels and of reducing resistance to the movement of water, thus increasing their capacities. The minimum dimension of the cross-section of a tunnel, except for very short tunnels, should not be less than 6 ft and preferably 7 ft in order to allow free movement of the workmen. Beyond this limit they should be kept as small as practicable in order to reduce the cost. Velocities of 10 to 12 ft per second in concrete lined tunnels are permissible. Fig. 5 shows a cross-section of the Strawberry Tunnel, Utah. The following table gives data relative to some of the more important tunnels of the U. S. Reclamation Service. All tunnels are concrete lined.

Data for Tunnels of U. S. Reclamation Service

Name of tunnel or project	Shape	Maximum height, ft	Maximum width, ft	Length, ft	Capacity cu ft per sec	Area, sq ft	Cost per lin ft
Gunnison......	Arched...	11.4	10.5	30 580	1300	100	95

* Total length of four tunnels. † Total length of three tunnels.

The Grade and elevation of water surface at the controlling points of a canal system should be thoroly investigated. Special consideration is required wherever a change in the velocity of the water occurs. When water from a canal

enters a pipe or culvert, changing to a higher velocity, allowance should be made for velocity head and head lost at entrance. A similar allowance should be made where a canal is changed to a smaller section. In this case the difference in elevation of water surfaces above and below the change in section represents head allowance for entrance conditions and change of velocity. If change from a higher to a lower velocity is made gradually some of the velocity head may be converted into static head.

In designing a canal or other structure for the passage of water the engineer should make liberal estimates of capacities. Uncertainties as to the proper values of coefficients necessarily exist and in general it will be safer to design a structure with a capacity slightly greater rather than less than that required.

7. Drops and Chutes

The Grade in Earth Canals should be ordinarily that which will give the greatest velocity that may be carried without eroding the sides or bottom of the channel. When, therefore, it is desired to drop an earth canal to a lower elevation, the excess grade must be taken up by a structure designed for the purpose. The function of such a structure is to maintain the normal velocity of the water in the upper canal and deliver it at the normal velocity to the canal at the lower elevation. Two types of structures, commonly called Drops and Chutes, have been used for this purpose.

Drops are structures which concentrate the fall at one or more points. They usually are built of concrete or wood, the latter being satisfactory for temporary construction. The essential parts of a drop are the brest-wall, which extends across the channel and connects the upper and lower canals, the water cushion or platform on which the water falls, the various wing walls which connect the

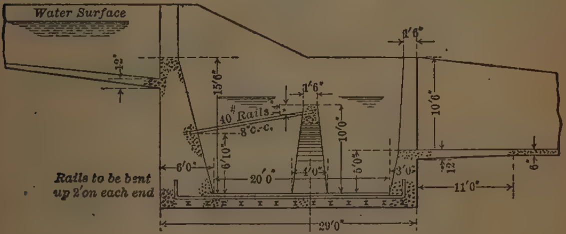

Fig. 6. Drop with Grating and Water Cushion

structure to the sides of the canal, and the canal linings, which prevent erosion immediately above and below the structure. The brest-wall extends from the elevation of the highest water surface in the upper canal to the bottom of the lowest part of the structure. Sufficient opening should be left in the portion of the brest-wall which extends above the bottom of the upper canal to discharge just the required volume of water while maintaining the normal depth of water in the canal. The opening in the brest-wall may be either a weir or one or more notches. Trapezoidal notches, having the narrower of the two parallel sides flush with the bottom of the canal, are frequently used. Such notches may have semi-circular lips projecting from the base which causes the water to spread out and reduces the impact of the fall.

The notched form of fall crest with water cushion below has been used with excellent results. It appears to reduce the difficulties from erosion above and below the fall

Steel rails placed under the fall have not proved very satisfactory. Cut-off walls should be built into the backfilling, which should be moistened and thoroly tamped to prevent the water from breaking thru. Reinforced concrete has largely replaced other materials for the construction of drops. Fig. 6 shows a section of a 10-ft drop with grating and water cushion at Uncompahgre, Colorado. Ordinarily, drops are not built more than about 15 ft high. For greater heights two or more drops in a series may be used. The amount of excavation for the canal leading from the drop increases as the slope of the ground decreases. In gently sloping ground a series of low drops may, therefore, be more economical than one higher structure.

Chutes are either lined canals or flumes, constructed on steep grades which connect two canals of different elevations. In addition to the conduit a chute must have a structure at the entrance to connect it to the upper canal and a structure at the exit to retard the velocity of the water before discharging it into the lower canal. The opening at the entrance to the chute should be just large enough to discharge the required volume of water while maintaining the normal depth of water in the canal. The conduit usually discharges into a water cushion in which baffles may be built to help break up the high velocity of the water. Canals should be paved for a short distance above and below the chute. The conduit may be of any length, and chutes several hundred feet long are not uncommon. Chutes with short conduits built on steep inclines are used in place of drops, Fig. 7 shows a reinforced concrete chute with a short conduit, of the Okanogan project, Washington.

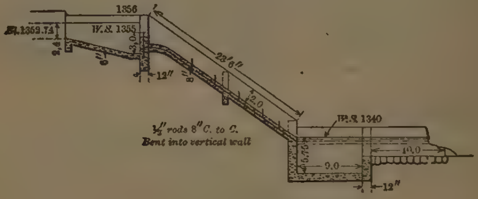

Fig. 7. Reinforced Concrete Chute

The velocity of water in a chute will accelerate until it is just great enough to overcome the frictional resistance. To determine the required dimensions of the conduit it should be divided into short reaches and the hydraulic computations made for each reach. The rate of reduction in area of the cross-section of the conduit will be more rapid at the upper end.

8. Minor Structures

Canal Crossings for Natural Waterways. At every place where a canal crosses a natural drainage channel, whether such channel carries water continuously or at infrequent intervals, provision must be made for conveying the natural drainage to the lower side of the canal. This may be done in either of the following ways: (1) by carrying the water under the canal; (2) by carrying the water over the canal; (3) in the case of small flows which may be expected only at rare intervals, by allowing the water to flow into the canal with provisions for it to escape over the opposite embankments; (4) by intercepting ditches above the canal which collect the drainage from small channels and convey it to some other channel for which a crossing is provided. Before designing a structure for this purpose a careful estimate of the maximum flow that the

channel may be expected to carry should be made, and a liberal waterway should be provided in all cases.

If the bottom of the canal is high enough natural drainage waters in small quantities may be carried under the canal in culverts or pipes. For crossing streams where large flows may be expected, it will generally be safer to convey the canal water over the stream in a flume, preferably supported by a truss, or under it in a pressure pipe. Short flumes or overchutes are sometimes used to carry small quantities of water over canals. Where drainage water is allowed to enter a canal a depression should be left in the upper embankment which, together with a short section of the canal, is usually lined with concrete. The objection to this method is that sediment is washed into the canal.

Wasteways are structures which may, in an emergency, divert the entire flow of a canal into a natural drainage channel. They are intended primarily as a safeguard to the canal and should preferably be located above the weaker portions where breaks are most likely to occur. In case of a break or other trouble, if there is a wasteway above, the water may be turned out of the canal more promptly than if the headgate alone must be relied upon for this purpose and the resulting damage will be less.

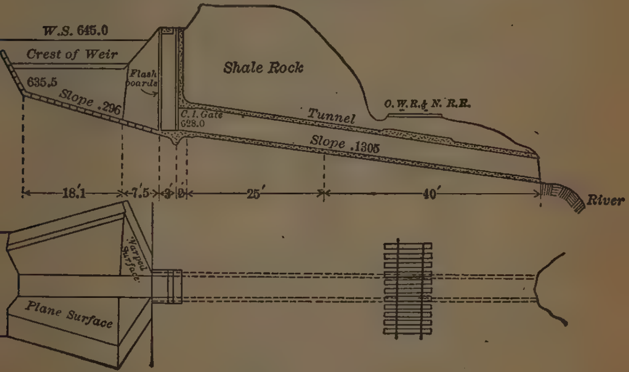

Fig. 8. Wasteway from Canal

The essential features of a wasteway are a system of gates in the lower embankment of the canal and provision for diverting the water thru them. Many different types of wasteways have been built. Usually the gate sills are placed at an elevation lower than the bottom of the canal in order to increase the head on the gates. A low submerged weir is sometimes placed across the canal below the gates to help divert the water thru them. A similar weir upstream from the gates will retard the velocity of the water in the canal when the gates are open and reduce the erosion above the structure. If built in earth the canal for a short distance above the wasteway and the channel leading from it should be concrete lined or paved. Fig. 8 shows a wasteway discharging thru a tunnel of the Umatilla project, Oregon.

Spillways are constructed by depressing the lower embankment of a canal to the elevation of the highest water surface which the canal is designed to carry. A spillway in an earth canal should have its crest and both slopes of the embankment lined with concrete. Spillways protect a canal against overflow, when drainage water enters it, when the water is backed up by an obstruction in the canal, or when a sudden rise in the stream from which the diversion is made allows too great a volume of water to enter the headgates.

Bridges must be provided where a canal is crossed by road or railway. Highway bridges may be built of wood or steel, or concrete arches may be used. Wooden bridges resting on concrete piers and abutments are in very common use. For earth canals, where the velocity of the water is low, piers or posts in the channel are not objectionable except that they create a slight tendency to erosion in their vicinity.

At Railway Crossings it may be found that the road bed is too low to allow clearance for the water under a bridge. In such cases short inverted siphons or pressure conduits are used. The intake and outlet of short pressure conduits should be carefully designed to provide for the entrance and exit of water with the least possible disturbance, in order

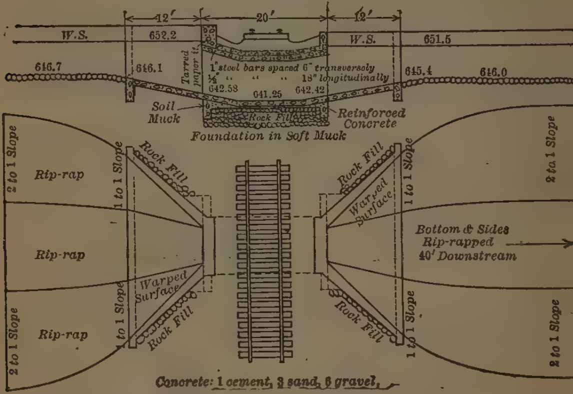

FIG. 9. Canal Crossing under Railroad

to make the crossing with a minimum loss of head. Fig. 9 shows a crossing of the Feed canal of the Umatilla project under the O. W. R. and N. railway.

Sand Gates and Sand Traps. Streams used for irrigation frequently carry large quantities of silt, especially during flood stages. Diversion works on such streams may be designed to exclude a portion of the silt, but some of it will usually enter the canal. The finest sediment will be carried in suspension by the minimum velocities that usually obtain in a canal system while the coarser material will be rolled along until it is finally deposited in the bottom of the canal. The fine material that is carried thru a canal system to the irrigated land is a valuable fertilizer but the coarser material which is deposited in canals reduces their capacity and is objectionable. The water in canals acting as feeders to reservoirs should be made as free from silt as practicable in order to reduce to a minimum the deposition of silt in the reservoir.

Different types of structures have been designed to remove the coarser material carried by canals. In general such structures consist of an enlarged canal section which terminates in a low weir placed across the channel or a basin having its bottom depressed below the subgrade of the canal, with sluice gates at the lower end. Owing to the retarded velocity of the water at this place the coarser sediment will move closer to the bottom or be deposited and a portion of it may be scoured out or allowed to pass out thru the sluice

gates. Frequently sand traps are built a short distance below headgates to remove the sediment as soon as possible after it enters the canal. In such cases, when there is more water in the river than is required for the canal, the sluice gates may be left open allowing a continuous discharge thru them. If there is no surplus water, the gates are opened only occasionally for sluicing out the sediment which has been deposited. Sand traps built on this plan may also serve as wasteways, or regulating works for the purpose of regulating the flow in the canal.

Telephone Systems are essential for the proper operation of large irrigation projects. Telephone booths should be placed at intervals along main canals and at other critical points and connected to the operator's house at the headgate. This enables the water to be shut off promptly in case of a break in the canal or other trouble and also assists in the economical distribution and delivery of water.

9. Diversion Works

Purpose. Wherever water is diverted from a natural stream into an artificial conduit some form of diversion works is necessary. This usually consists of a diversion dam or weir, which controls the elevation of the water surface in the stream, and a headgate, just above the diversion dam, which regulates the amount of water allowed to enter the canal. Sluice gates thru the dam and adjacent to the headgate or other devices to prevent the entrance of silt into the canal may be provided. Structures, called *regulating works*, are sometimes constructed a short distance below headgates for the purpose of diverting surplus water back into the stream. With such a structure the amount of water entering the canal may be more effectively regulated than when the headgate alone is relied upon for the purpose. A sand gate is frequently combined with the regulating works. The laws of most states require that fish ladders be constructed in dams across natural streams. In some cases logways must also be provided.

Low Diversion Dams. In general, when the diversion is made at a place where the stream lies in a flat sedimentary bottom, the natural regimen of the stream should be changed as little as possible. Under such conditions a very low dam or weir is preferable. If the stream has a flood plain subject to inundation, the diversion dam should extend across the natural channel of the stream and earth embankments several feet higher than the highest flood stage should connect the structure to the higher land on either side of the stream.

Low diversion dams are commonly built of concrete or wood or a combination of the two. Concrete dams are usually constructed on rock formations. For earth or gravel foundations, a substructure consisting of a rock and timber grillage or bearing piles tied together with walings and caps covered with a deck of heavy planking, will be satisfactory provided it is built low enough to be continually submerged. On this substructure either a wooden or concrete weir may be built. Fig. 10 shows a plan of the diversion works and a cross-section of diversion weir of the Umatilla project, Oregon.

High Diversion Dams may be built where a suitable site is available. Any type of dam may be used for this purpose, the problem being similar to that encountered in constructing a dam for other purposes. High diversion dams may be built in rock canyons to avoid expensive canal construction, the proper height being that which will result in the lowest combined cost of canal and dam.

Between the highest and lowest types of diversion weirs any intermediate height may be used. Each diversion presents special features and the height and type of dam must be chosen to conform to them. Collapsable weirs may be used when it is required to

reduce the flood elevation of the water above the dam. Temporary brush and rock dams are sometimes used for diverting water into small canals.

Headgates control the entrance of water into the canal. They are preferably built on the line of the bank of the stream at right angles to the diversion dam. They should be joined to the diversion weir so as to form part of the same structure with it. Headgates usually consist of a series of gates separated from each other by piers. The piers rest upon a floor, of the same elevation as the bottom

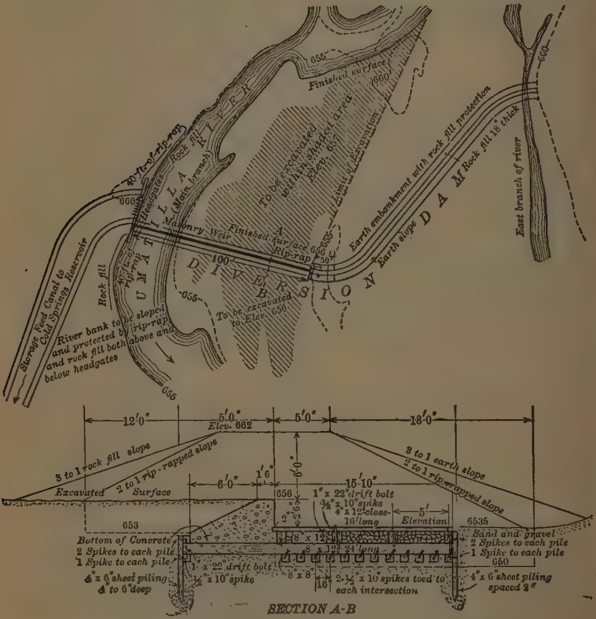

Fig. 10. Low Diversion Weir with Earth and Gravel Foundation

of the canal, which should be of sufficient thickness to give the required strength and stability. Cut-off walls should be provided to prevent erosion and excessive seepage beneath and around the structure. The width of gate opening will be the distance between piers and the height of opening is regulated by curtain walls between the piers. A walk is usually built across the top of the structure and hoisting devices to operate the gates rest upon the walk. Gates should preferably be of such a size that they can be operated by one man. The total gate opening should be sufficient to discharge the maximum capacity of the canal in the contingency that one gate cannot be operated.

Headgates are commonly built of concrete, but wood may be used for temporary construction. Gates may be made of cast iron, steel, or wood. They are usually set in steel or iron guides imbedded in the concrete. The bottom and sides of an earth canal should be protected by riprap or concrete lining for some distance below the headgate to prevent erosion. Headgates diverting from streams which carry drift during flood stages should have the noses of piers protected by fenders to prevent clogging of the gate openings. Fig. 11 is a cross-section of the headgate shown in Fig. 10.

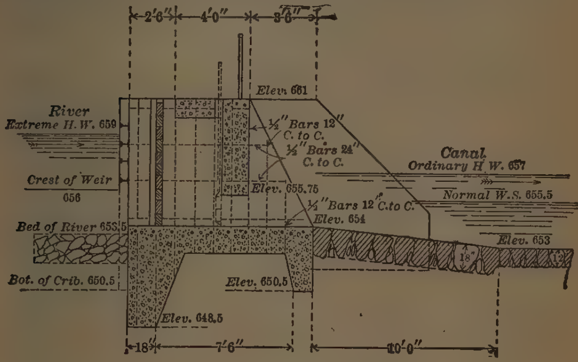

Fig. 11. Headgate for Low Diversion Weir

Sluiceways are openings in a diversion weir, usually adjacent to the headgate. They may consist of open panels in the weir or gates near the base of the weir. The latter are especially adapted to the higher dams. Sluiceways are necessary only on streams that carry considerable sediment. They serve to keep an open channel immediately in front of the headgates and to prevent the heavier sediment from entering the canal. They may also be used to regulate the elevation of the water surface above the dam. Sluiceways must be kept closed when it is desired to divert all of the water in the stream, but with a surplus of water they may be left partially or entirely open.

10. Storage

Necessity for Storage. Storage is essential to the complete utilization of a stream for irrigation purposes. Only those waters are directly available which flow during the irrigation period and are not in excess of the immediate requirements of the area which they serve. Without storage all water in excess of that which is directly available must be wasted. On many streams, further development for irrigation purposes is restricted to the use of stored waters.

Storage Reservoirs. The possibility of economical storage is dependent upon the availability of suitable reservoir sites. Natural lakes or basins may be used for storage when a suitable dam site exists at the outlet. A reservoir may be located on a stream from which water is diverted, or on a tributary of this stream. The water supply from a tributary may not be sufficient to fill a reservoir located upon it, in which case the flow may be supplemented by a feeder canal

diverting from some other stream. If conditions are favorable water may be taken thru a canal or tunnel from an adjoining watershed.

An investigation of the feasibility of storage for a stream should include a complete reconnoissance of the drainage basin. Each possible site should be first roughly investigated to determine approximate data relative to capacity, character of dam site, geological formation of the area to be flooded, availability of construction materials, value of rights of way and other information relative to the cost and value of storage. From these data the sites appearing to possess the greatest merit may be selected and for them a more thoro examination may be made. Topographic maps of reservoir sites are indispensable in computing capacities.

Seepage and Evaporation from Reservoirs. One of the first considerations in investigating the feasibility of a proposed reservoir should be to make a careful study of the geological formation of the area to be flooded with a view to estimating possible seepage losses. Many instances can be cited where reservoirs have proved worthless after construction because of their inability to hold water. Such a condition results in great financial loss and humiliation to the responsible parties. The problem requires the mature judgment of the most experienced engineer. No rules can be laid down which will be safe guides in each case. In general, it may be stated that seepage losses from basins lying in rock (not volcanic rock) or clay will not be excessive. Reservoirs built in formations of fine loam or volcanic soil have generally given satisfaction, tho seepage losses from such reservoirs have been greater than from those lying in rock or clay. If any portion of the banks or bottom of the reservoir is formed of sand or gravel, even tho it may be overlain with a blanket of fine soil, and such sand or gravel might form an underground channel leading around or under the impounding dam or to some other drainage basin, there is grave danger of excessive seepage loss. On account of the large areas involved, efforts to reduce seepage in reservoirs by clay puddle or other methods have usually been unsatisfactory. If the water flowing into the reservoir carries much sediment, there will be a tendency for the reservoir to silt up and reduce seepage losses. Seepage losses from reservoirs in rock or clay formations should not be more than 5 percent of the inflow, and in fine loam or other soil probably not more than 10 or 20 percent. In coarse sand or gravel they may be anything up to the entire inflow. In determining the net supply of storage water evaporation losses should be deducted. These may be obtained from tables of evaporation losses from free water surfaces. (See Sect. 13, Art. 19.) The apparent capacity of a reservoir may be considerably increased by BANK STORAGE. (See Sect 9, Art. 43.)

The following rules of caution are given by A. P. Davis (Engineering News-Record, April 4, 1918; p. 665): 1. Avoid reservoirs adjacent to gypsum deposits and to limestone deposits which show evidence of caves. 2. Examine critically reservoirs in volcanic rock, as a few have failed in such locations. Coarse-grained sandstone seems to be an object of suspicion and should be critically examined. 3. Natural depressions are treacherous and should be examined with care, and if they are near deep canyons or underlain with coarse material where water might readily escape, no superficial tightness will avail to make them effective.

Storage Problems commonly encountered in irrigation work are the determination of reservoir capacity to supply a given quantity of water at specified rates of use, and determination of the amount of water available for irrigation from a reservoir of a given capacity. Where a reservoir receives all or a part of its water thru a feeder canal it will also be necessary to determine the capacity of canal required to supply the storage. The solution of such problems may be readily accomplished by applying the principles of the mass diagram. (See Sect. 9, Art. 43.) In all cases irrigation water will be drawn from the reservoir at a variable rate and the use line will be curved.

11. Distribution Systems

The Function of a distribution system is to convey water from the main canal to each parcel of land to be irrigated. Water is usually diverted first into main distributing canals, then into main laterals and sub-laterals, and finally into the farmers' ditches, from which it is applied directly to the land. It is desirable to have as few openings as possible in the banks of main canals in order to reduce the danger from washouts and hence farm ditches should divert from laterals and sub-laterals rather than from main canals. The distribution is usually made thru a system of earth canals, but where water has a high intrinsic value, or where seepage losses would otherwise be excessive, water may be delivered in flumes, pipes, or lined canals.

Location. Water should be drawn at proper intervals from main canals into moderate sized branches so located as to command the greatest area and serve the land in the most direct manner practicable. The distribution is most economically affected when the main distributing canals are located along the tops of ridges so that they can supply water to laterals on either side. The laterals likewise should conform to the dividing lines between watercourses. It may not be found practicable, however, to conform rigidly to this plan. On flat areas distributing canals may be run along or parallel to property lines. Fig. 12 illustrates distributing canals and laterals diverting from a main canal.

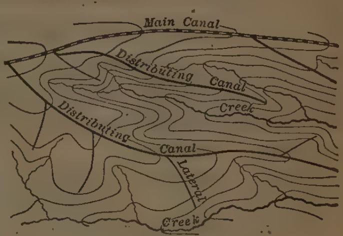

Fig. 12. Distributing System

A Topographical Map of the area to be irrigated, with a contour interval of not more than 5 ft, should be prepared before attempting the design of a distribution system. In addition to topographical features, this map should show non-irrigable lands and other areas to be excluded from the project. Special features, such as vegetation, property lines, improvements and soil formation, are in some instances required.

Design of Distribution System. In general, the entire distribution system should be planned, and the scheme for irrigating each part of the project should be worked out before any construction work is begun. This should be done even tho the construction for a portion of the system is to be deferred for some time. As the plan is developed the position of all canals, flumes, pipes, and other structures should be projected on the topographic map, and the area to be irrigated under each should be determined.

Capacities of Canals should be based upon the water requirements for the period when the greatest amount of irrigating will be done. It is customary to determine the number of acres that will be served by 1 cu ft per sec, during the period of maximum requirements. The required capacity of main canals and distributaries may vary from 1 cu ft per sec for each 120 to 160 acres irrigated, for fruit lands where the water supply is fairly uniform and maximum economy in the use of water is practiced, to 1 cu ft per sec for each 50 acres irrigated, where the supply of water is available for comparatively short periods and conditions are otherwise unfavorable. For diversified crops where the water supply is regular a capacity of 1 cu ft per sec for each 70 to 90 acres irrigated is commonly used. The capacity of farm laterals should not be less than

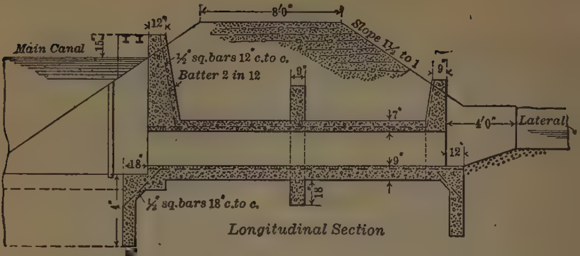

Fig. 13. Reinforced Concrete Turnout to Lateral

the maximum head to be used in irrigating. This will vary from 1 to 2 cu ft per sec where furrow irrigation is practiced to 5 to 10 cu ft per sec for flooding methods. If rotation irrigation is to be practiced the capacity per unit area served should be greater for laterals than for main canals in order to provide flexibility in operation. In general, an allowance for seepage and evaporation should be added to the above figures.

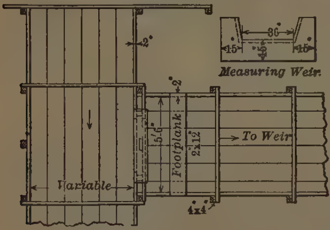

Fig. 14. Wooden Head to Lateral

Structures for Distribution Systems are similar to those for main canals. Turnouts must be provided, where water is diverted from main canals to distributaries and at the heads of all laterals. Flumes or pressure pipes are constructed for carrying water across depressions. Drops are required in earth canals where the slope of the ground is greater than the allowable grade. These structures may be built of wood or concrete. Wood is more commonly used for the small turnouts and lateral heads. Measuring devices, generally weirs, are placed at the heads of farm laterals. Figs. 13, 14, and 15 are examples of structures for distribution systems.

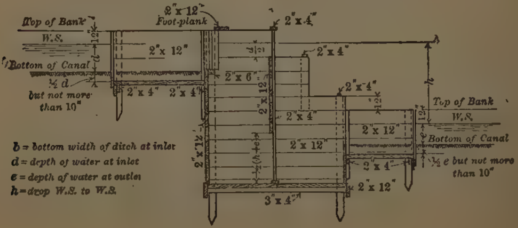

Fig. 15. Wooden Drop for Lateral

12. Irrigation by Pumping

The Source of Water Supply may be either a natural stream, canal, or well. The pumping plant may be of any capacity from a single pump capable of serving a small farm to a number of large units supplying several thousands of acres. Large pumping projects are usually supplied with water from some surface source, while small areas may be irrigated from wells or surface water. Limited areas of bench land lying above the main canals of gravity projects may in some instances be economically irrigated from these canals by utilizing water power generated at drops. Any kind of power that is cheap enough may be used for pumping. Steam and crude oil engines have been used successfully for large plants in the United States, while gasoline engines and electric energy transmitted from central stations have proved satisfactory for irrigating small areas.

The Feasibility of irrigation by pumping depends upon the cost of water and its value to the land. The first cost of a pumping project may be low as compared to the cost of many gravity projects, but the operating expense and resulting cost of water will generally be higher. Pumping against heads of over 100 ft is not profitable except where the crop is valuable or the water requirements small. Irrigation of fruit lands by pumping from deep wells has been practiced for many years.

Cost of Pumping for irrigation depends upon the unit cost of power, and the head or vertical lift. The power required will be the theoretical power necessary to raise the water at the required rate divided by the efficiency of the pumping plant. In general the efficiency of pumps increases with their size, and will vary from 30 to 80 percent, depending upon the size, make, and care with which installations are made.

The Unit Cost of Power is generally less for large than for small plants. This is because greater efficiency and smaller cost of attendance is possible for the larger installations. The cheapest power is that obtained directly from water power. Power may be produced from coal or oil in large plants at from 1 to 2 cents per horse-power hour, while in small plants of low efficiency the cost may be as much as 5 cents per horse-power hour.

Cost of Raising Water per Acre-foot with Power at 1 Cent per Horse-power Hour

Pump efficiency	Head in ft									
	10	20	30	40	50	60	70	80	90	100
100	$0.14	$0.27	$0.41	$0.55	$0.69	$0.82	$0.96	$1.10	$1.24	$1.37
80	.17	.34	.51	.69	.86	1.03	1.20	1.37	1.54	1.72
70	.20	.39	.59	.78	.98	1.18	1.37	1.57	1.77	1.96
60	.23	.46	.69	.92	1.14	1.37	1.60	1.83	2.06	2.29
50	.27	.54	.82	1.10	1.37	1.65	1.92	2.20	2.47	2.75
40	.34	.69	1.03	1.37	1.72	2.06	2.40	2.75	3.09	3.43
30	.46	.91	1.37	1.83	2.29	2.75	3.20	3.66	4.12	4.58
20	.69	1.37	2.06	2.75	3.43	4.12	4.80	5.49	6.18	6.86

13. Preparation of Land

Clearing. Arid lands are usually covered to some extent with native vegetation. This may consist of grasses and small brush which can be plowed under, or heavy brush or scrub trees. All surface vegetation and roots that will interfere with the cultivation of the land should be removed and burned.

Sage brush is the most widely distributed of all of the desert plants. It commonly attains a height of from 2 to 5 ft. A substantial growth of sage brush usually indicates a fertile soil. Sage brush may be removed by grubbing, or broken off by a team dragging a steel rail over it, or by other special devices. The cost of clearing land of sage brush usually varies from \$3 to \$6 per acre. The cost of removing large brush and trees may vary from \$25 to \$75 per acre, depending upon the size and thickness of growth.

Grading. Unimproved land must usually be graded before water can be distributed over it uniformly. Proper grading is very essential to the economic use of water. It reduces the expense of irrigating and insures maximum crop returns with a minimum consumption of water. Many areas are comparatively smooth and the cost of preparing the land for irrigation is inconsequential. The cost of grading rough or rolling land may be from \$15 to \$40 per acre. The method to be employed in irrigating (see Art. 14) may greatly affect the amount of grading required. Before beginning excavation, a detailed plan of the grading to be done should be worked out on an accurate topographic map.

In many irrigated districts the soil is of uniform texture for some distance below the surface. Other localities have a comparatively thin surface soil which is underlain by a less fertile sub-soil. Where the latter condition obtains, too extensive excavation may seriously affect the productivity of the soil, and it may be advisable to modify the plan of grading and system of irrigation from that which would otherwise be desirable. Where land is sufficiently valuable, it may be practicable to move to one side the surface soil from the areas to be excavated or filled, and after grading to recover them with the surface soil. Grading is usually done with scrapers. Buck-scrapers and Fresno scrapers may be used to advantage if the haul is short, while wheeled scrapers are preferable for long hauls. Road graders and various types of home-made levelers are used for smoothing the surface of the ground.

The First Cultivation of raw land is frequently difficult and expensive and the first crop returns will usually be less than later ones. Light sandy soils are especially difficult to subjugate, as they are apt to drift and allow the seeds to be removed by wind action. Such soils must usually be cleared and planted in small areas, and protection from wind provided as soon as possible. Straw or manure placed over the exposed surface may provide a satisfactory protection. Sometimes rows of sage brush, about 50 ft apart, at right angles to the direction of the wind, are left temporarily on the ground to act as wind breaks. A hardy grain, such as rye, is frequently used for the first crop.

14. Application of Water to Land

Classification of Methods. The different methods of applying water to land may be classified as surface and sub-surface methods. Sub-surface irrigation, or sub-irrigation, is usually more expensive than surface irrigation and is not commonly practiced except where particularly favorable conditions exist. Surface irrigation may be accomplished by lateral percolation or by flooding.

Farm Ditches. In any plan of irrigation farm ditches should be laid out with a view to providing the maximum efficiency and economy in the distribution and use of water. The water must be delivered to the highest point of the area to be irrigated, from which point it is conveyed by a field lateral to distributing ditches.* Fig. 16 shows a system of ditches that may be used for several methods

of applying water where the topography of the ground is suitable. Preferably farm ditches should run along fences and property lines or be parallel to them, but often they must be curved to better conform to topographic features. The best practice is to put farm ditches from 330 to 660 ft apart. Their capacity should be the maximum irrigating head that is to be used.

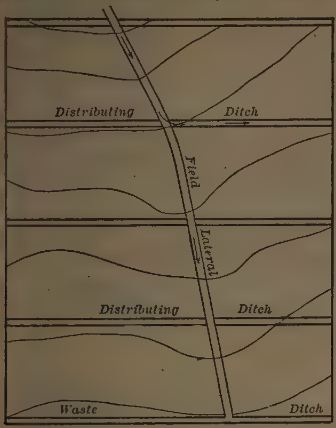

Fig. 16. System of Farm Ditches

Uncontrolled Flooding requires less grading than other methods of irrigating, but it is more wasteful and does not provide a uniform distribution of water. This method is illustrated in Fig. 17. A ditch is constructed along the upper end of the field and at intervals of preferably not more than 20 rods other ditches roughly parallel to the upper ditch are constructed. The area between any two ditches may be irrigated by opening the upper ditch at several points and allowing the water to flow over the land to the lower ditch. Usually many small dikes must be thrown up while irrigating to force the water over the higher areas.

Fig. 17. Flooding of Meadows.

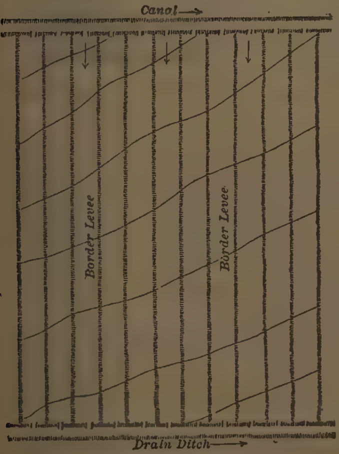

Fig. 18. Flooding by Border Method

A modification of the above method consists in making small temporary ditches or furrows which lead from the supply ditch along the ridges and higher places in the field. Water is turned into these temporary ditches which overflow their banks and cause water to be distributed over the field. This method is used for irrigating grain and alfalfa and is an improvement over the uncontrolled flooding method.

The Border Method of Flooding is shown in Fig. 18.

Parallel ditches should extend across the field at intervals of from 20 to 40 rods. Small levees called borders are built between ditches from 2 to 4 rods apart. The areas between each set of borders should be graded so that the profile of the ground on any cross-section will be approximately level. Water turned on the land between two borders is confined to the area between them and if the grading has been done properly the water is distributed uniformly. The objection to this method of irrigating is that the upper portion of the area receives more water than the lower portion.

This method is best adapted to fields having a gentle uniform slope. A slope of about 1 ft in 500 ft is preferable. Where the natural slope is greater than this the grade may sometimes be reduced by running the borders diagonally across the field. The cost of preparing land for irrigation by the border method, including ditches, will vary from $10 to $30 per acre.

The Contour Check Method of Flooding requires a supply canal at the upper end of the field with distributing ditches leading from it which pass directly down the slope (Fig. 19). Check levees are constructed along contours between

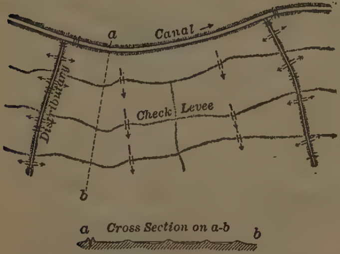

Fig. 19. System of Check Levees

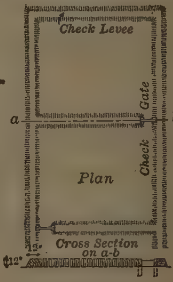

Fig. 20. Flooding by System of Squares

the distributing ditches, and cross levees divide the basins thus formed into two approximately equal parts, which are called checks. Each check may then be filled with water from the ditch adjacent to it. Levees should be about 9 in high and at least 6 ft wide at the base. Material for construction of levees is taken from the high places and the surface within each check should be graded to a fairly level surface. The cost of grading, where the slope of the ground does not exceed 50 ft per mile, is from $10 to $30 per acre. The size of checks which has proved most satisfactory is from 1 to 3 acres. A large head, preferably 5 to 10 cu ft per sec, should be available for irrigation by this method, the full head being used to fill one check at a time.

A modification of the above method of irrigating has been used on rough land and hillsides where the slope exceeds 1 in 20. The cost of grading is proportionally higher as the slope or degree of roughness of the land increases. The ground is graded to a series of level benches and terraces with a check levee at the top of each terrace. The levees follow roughly the direction of the contours, but the checks are usually irregular in shape and vary considerably in size.

The Square Check Method of Flooding is best adapted to gently sloping ground. This method is similar to the contour check method, except that the

field is laid out in square checks without regard to contours. The size of checks varies from less than 1 acre to 5 acres or more, but for best results checks of not more than 3 acres are preferable. Sandy soils require smaller checks than the more impervious ones. Water may be turned into checks from distributing ditches or if the checks are small it may be allowed to flow from one check to another (Fig. 20). The latter plan has the disadvantage of giving the upper checks more water than the lower ones. The cost of grading for irrigation by this method, including the cost of ditches, will usually range from $10 to $30 per acre.

The Basin Method is a modification of the check method employed for irrigating orchards. Levees are built around each tree and water is supplied from ditches placed between alternate rows of basins or allowed to flow diagonally across basins as indicated in Fig. 21. Mounds of earth are usually placed around the trees to prevent the areas immediately adjacent to them from becoming submerged. Jointed pipes extending from a supply canal to the lowest basin coming under it are sometimes used for filling the basins. After the lowest basin is filled, joints of pipe are removed and the next basin above is filled. This process is continued until all of the basins in the row have been irrigated, when the operation may be repeated for the other rows. This method is economical of water and is well adapted to the use of a small irrigating head.

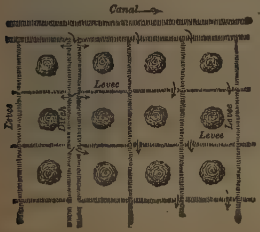

Fig. 21. Basin System of Irrigation

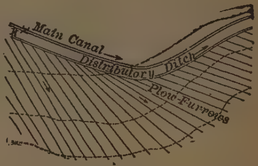

Fig. 22. Furrow Irrigation of Grain

The Furrow Method of Lateral Percolation may be used in place of flooding methods for irrigating grain or meadows (Fig. 22) and is used almost exclusively for irrigating crops planted in rows. The land is prepared by constructing supply ditches across the field at suitable distances apart and running furrows down the slopes between them. Furrows are made with plows or with special machines called markers. Very little grading is necessary for irrigating by this method and the cost of preparing the land for irrigation is less than for any of the flooding methods. Furrows are frequently made on slopes as great as 5 or 10 ft per 100 ft, but light soils may be eroded if placed on too steep slopes. The grade of furrows may be reduced by running them diagonally down a hill.

For irrigating grains and alfalfa the furrows are made from 3 to 6 in deep and spaced from 2 to 4 ft apart. Crops planted in rows may have a furrow in each space between rows, or in alternate spaces between rows. For young orchards a furrow is usually placed on either side of the trees and after the trees mature several furrows are used for each row. Deep furrows are believed to give more satisfactory results than shallow ones. The irrigation is accomplished by turning water into several furrows at one time and allowing it to flow to the end of each furrow, the moisture being distributed thru the soil

by lateral percolation. This method has the advantage of reducing evaporation and providing a uniform distribution of moisture. It is objectionable in some cases in that large heads cannot be handled to advantage, and in general it requires more labor to apply the water to the land than other methods of irrigation.

Sub-Surface Irrigation or sub-irrigation is the name applied to all those methods in which the water is applied below the surface of the ground. The water is conveyed in underground channels containing openings, beneath the area to be irrigated, and thru these openings the water percolates and is distributed thru the soil by capillary action. The underground channels may consist of ordinary tile drains or perforated pipes. The cost of installation of such systems is high and in general the advantage obtained by them has not warranted the additional expense. In most localities surface irrigation is to be preferred to sub-irrigation.

Some lands are naturally sub-irrigated. Generally these are bottom lands underlain by gravel where the surface of the ground is but a few feet above the normal water surface of the stream. Water is drawn from this sub-surface supply by capillary attraction to or nearly to the surface of the ground. Deep rooted crops such as alfalfa are especially adapted to naturally sub-irrigated lands. Porous soils underlain by an impervious stratum quite near the surface may sometimes be sub-irrigated by simply digging ditches at intervals of from ¼ to ½ mile. Water flows down the slope between the two strata, and if near enough to the surface, is available for plant growth.

Spray Irrigation has long been used in cities for watering lawns and small gardens. In certain humid districts it is used for supplementing the rainfall on larger areas devoted to the production of truck and small fruits. The essentials for this method of irrigating are a pumping plant and distributing pipe system. Hydrants may be located at suitable intervals over the field from which the water is applied to the land through hose, or parallel pipe lines from 50 to 60 ft apart, elevated a few feet above the ground and provided with nozzles at suitable intervals may be used to distribute the water over the field. An irrigation system of this kind is expensive, but the increased returns will often more than justify the expense.

15. Distribution and Use of Water

Distribution of Water among Users. At certain periods of the irrigation season the water requirements of crops are greatest and the demand for water may be excessive. The use of water cannot exceed the capacity of the irrigation system, and some adjustment in the use of water is usually necessary during certain portions of the irrigation season. On many large projects the farmer is required to give written notice from 1 to 6 days in advance, stating when he will want water and the head that he desires. When it is not possible to deliver water to all users on the date requested without exceeding the supply of water, or the capacity of the irrigation system, the distribution is adjusted so as to accord as closely as possible with the requests of the various consumers.

Rotation in Irrigation. The consumer's right to the use of water is frequently expressed as a certain continuous flow, usually in cubic feet per second, thruout the irrigation season. As it is not economical to irrigate with a small head, it is customary for farmers whose rights to water are thus expressed, to rotate in its use, each taking a suitable head for such a time that the total water used will not exceed the allotment for the season. In many irrigated districts the right to water is expressed in some unit of volume, such as acre-feet per acre, or inches depth for the area to be irrigated. Such units are preferable for districts with an assured water supply.

Measurement of Irrigation Water. In order that irrigation water may be equitably distributed some plan for measuring the water turned into each farm lateral is necessary. The ideal method of measuring such water is with a meter that records the flow in some unit of volume such as cubic feet or acre-feet. Tho numerous devices for this purpose have been suggested none of them has been developed to a practicable working state. The present practice is to measure the rate of flow, and to multiply this rate by the time to get the volume of discharge. Weirs have been generally used for measuring the flow of irrigation ditches where sufficient head is available. Headgates may be used as submerged orifices by rating them with a current meter and determining the coefficient of discharge for different gate openings and heads. Similarly a discharge curve may be obtained from current meter measurements for a flume or a permanent section of a canal. Cone's Venturi flume may be used for measuring discharges where sufficient head is not available for installing a weir.

Economy in Use of Water. In most arid districts the area of fertile land is much in excess of that which can ever be irrigated by the most effective use of all available waters. The limit of irrigation is therefore fixed by the water supply and not by the land area. Any water that is wasted or used in excess of that which may be applied to the land beneficially reduces the irrigable area. On the other hand, any improvement in methods of irrigation which reduces the water requirements, and all waste prevention, increase the area of land which may be reclaimed. Investigation of the use of water that will yield the greatest net return is therefore an important branch of irrigation engineering.

The Method of Payment for water has much to do with the economy of its use. Commonly the farmer's contract calls for a maximum quantity of water and there is no incentive for him to use a smaller amount. A better method of payment is for the farmer to pay for just what water he uses, or, if his contract calls for a fixed quantity of water, to allow a bonus for any smaller amount that he may use. Under such conditions, the farmers will readily become interested in practicing economy in the use of water and in developing more efficient methods of irrigation.

SWAMP AND OVERFLOWED LANDS

16. General Considerations

Classification. Those areas which are covered with water or whose soils contain an excess of water either continually or to such an extent as to render them unfit for cultivation are commonly spoken of as swamp or overflowed lands. There are three general divisions: inland marshes, river-bottom lands, and tide lands. Most of these areas are susceptible of reclamation, and in many instances their development is of great economic importance.

Location and Distribution. Swamp and overflowed lands are distributed quite generally thruout the world and many such areas have been successfully reclaimed. The largest enterprises of this kind have been in Europe, where land values are high. Notable examples are the English Fens, where 700 000 acres of tide lands have been reclaimed, and Haarlem Lake, Holland, where a shallow lake 43 000 acres in extent has been converted into a fertile farming district. Large drainage enterprises have also been successfully completed in France, Italy, and other European countries. Of the large areas of swamp and overflowed lands in the United States only a small fraction have been reclaimed.

The following is the reclaimable swamp area by states, according to the statistical abstract of the United States for 1910, issued by the Department of Commerce and Labor:

	Acres		Acres
Alabama	1 120 000	New Jersey	601 900
Arkansas	5 760 000	New York	576 000
California	1 850 000	North Carolina	2 400 000
Connecticut	37 700	North Dakota	226 000
Delaware	200 000	Ohio	200 000
Florida	18 500 000	Oklahoma	35 000
Georgia	2 400 000	Oregon	500 000
Illinois	2 688 000	Pennsylvania	96 000
Indiana	1 000 000	Rhode Island	17 900
Iowa	800 000	South Carolina	1 760 000
Kansas	160 000	South Dakota	226 000
Kentucky	224 000	Tennessee	800 000
Louisiana	9 600 000	Texas	1 620 000
Maine	240 000	Vermont	70 000
Maryland	356 000	Virginia	384 000
Massachusetts	138,700	Washington	75 000
Michigan	4 400 000	West Virginia	2 500
Minnesota	4 500 000	Wisconsin	2 500 000
Mississippi	6 173 000	Wyoming	25 000
Missouri	1 920 000		
Nebraska	256 000	Total	74 481 700
New Hampshire	43 000		

Soil. Marsh lands are commonly covered with decayed vegetable matter and are usually very fertile. In many cases, however, some element of plant food is deficient and certain crops will not grow satisfactorily without artificial fertilization. This is especially true of peat and muck lands, which are usually lacking in potash. The subsoil of inland marshes is ordinarily similar to that of the surrounding country. Overflowed lands along rivers are composed largely of sedimentary deposits, silt and fine sand usually predominating. Tidal marshes may be formed of clay, sand and silt in any proportions. The soil formation of swamp and overflowed lands should always be carefully investigated with a view to determining its fertility and its influence on construction methods and plan of drainage.

Natural Vegetation. Inland marshes frequently contain heavy growths of timber, or where the timber has been cleared they may be covered with dense underbrush, stumps, and fallen trees. Other marshes contain growths of coarse grasses, reeds, or moss. In all cases the expense of clearing must be included in the cost of reclamation.

Topographic Map. The general characteristics of a drainage project can best be studied from a topographic map, which should be prepared early in the investigation. Contours of the area to be reclaimed should ordinarily be shown for 1 ft intervals, and natural drainage channels should be carefully indicated. Information as to soil formation, property lines, and source and amount of water to be disposed of may be recorded on the map. Existing maps may sometimes be of value in determining tributary areas which naturally drain into the area to be reclaimed.

17. Run-off

Surface Drainage. The channels and outlets of a drainage system should be of adequate capacity to provide for the removal of water at such a rate that the ground will be ready for early cultivation in the spring, and that the growth and harvesting of crops will not be seriously retarded. It is therefore the maximum or flood flows which must be considered in designing a surface drainage system, and the same principles apply regardless of the scheme of reclamation. Excessive run-off may result either from heavy rains, or the sudden melting of snows, but the most severe floods are caused by the former.

The Maximum Run-off per unit area that may be expected from any drainage basin decreases as the area increases. In general, the law of maximum discharge from flat areas, similar to those encountered in large drainage projects, may be represented by the equation

$$Q = KM^{0.75}$$

in which Q is the maximum discharge in cubic feet per second, M the drainage area above the point at which Q is required, in square miles, and K an empirical coefficient. If A is the area in acres, the formula may be written

$$Q = 0.00786KA^{0.75}.$$

Values of K obtained from measurements of maximum run-off of a number of drainage projects in the Mississippi valley range from 20 to 60. They correspond to rainfalls of from 3 to 7 in in 24 hours. The measurements were made on areas varying from approximately 2 to 200 square miles. The value of K depends primarily upon the maximum rainfall, but is influenced to a large extent by several other factors. It increases with the slope of the ground and the degree of imperviousness of the soil. The condition of the ground also influences the value of K. A heavy rain falling on wet ground will cause a greater run-off than the same rain falling on dry ground. If the ground is frozen or covered with ice, conditions will be favorable for a large surface run-off. Precipitation records covering as long a period as possible should be consulted to determine the maximum rainfall to be provided for. This need not be necessarily the heaviest recorded rainfall, as it may be considered a better business proposition to allow the crops to suffer damage once in several years than to go to the expense of providing drainage adequate for the immediate removal of flood waters resulting from the severest storms.

The Total Annual Run-off from a given area is the difference between the annual precipitation and the water returned to the atmosphere thru evaporation and plant transpiration, subject to modifications from ground water conditions and possible deep seepage losses. The effect of the two latter considerations is commonly neglected in approximate calculations. Many factors affect the amounts of evaporation and transpiration, the more important being the mean annual temperature, and the amount and distribution of rainfall. The humidity of the air, velocity of the wind, character of vegetation, degree of cultivation, and soil formation are also important influences.

An accurate estimate of transpiration and evaporation losses for a given area involves a thoro investigation of the various factors involved. Rough estimates may be made by considering only the temperature and precipitation. Mean values of combined transpiration and evaporation losses, based upon observations in the United States, are given in the following table. The yearly run-off in inches is obtained by subtracting the proper tabulated value from the annual precipitation. Observed values may be expected to differ by as much as 5 in from those given in the table.

Average Annual Transpiration and Evaporation Losses in Inches

Annual precipitation, inches	Mean annual temperature (Fahr.)								
	35°	40°	45°	50°	55°	60°	65°	70°	75°
25	16	17	18	19	20	21	22	23	24
30	17	18	19	20	21	22	23	24	25
35	18	19	20	21	22	23	24	25	26
40	19	20	21	22	23	24	25	26	27
45	20	21	22	23	24	25	26	27	28
50	21	22	23	24	25	26	27	28	29
55	22	23	24	25	26	27	28	29	30
60	23	24	25	26	27	28	29	30	31
65	24	25	26	27	28	29	30	31	32
70	25	26	27	28	29	30	31	32	33

18. Pumping Plants

Capacity. The removal of water may be accomplished by gravity or pumping or by a combination of the two methods. A pumping plant should be of adequate capacity to remove water at a rate that will prevent injury to crops up to the point where additional capacity will cost more than the damage to crops that will result if the additional capacity is not provided. The time which land may be flooded without serious damage differs for different crops, truck being more susceptible of damage than corn, sugar cane, grains and similar crops, but in general the land should not be submerged for more than 24 hours. The capacity of pumping plant must be based upon a consideration of maximum run-off (Art. 17) and also upon the storage provided by canals, the maximum length of time that crops may be submerged without damage, and the slope of the reclaimed area. Areas with considerable slope require greater pump capacity than more level areas, because of the tendency of water to collect and flood crops at the lower elevations.

In southern Louisiana pumping capacities sufficient to remove from 1 to 1.5 in per 24 hours have proved sufficient for areas of from 5000 to 10 000 acres. One inch of run-off in 24 hours is equivalent to approximately 27 cu ft per sec per sq mile. In the upper Mississippi valley a pump capacity of from 0.25 to 0.50 in for similar areas has been found satisfactory. The records of the U. S. Weather Bureau at New Orleans for the 22 years preceding 1914 show that for this period there were 43 storms during which the precipitation in 24 hours exceeded 3 in. These storms are classified as to their intensity as follows:

43 rains exceeding 3 in in 24 hours.
19 rains exceeding 4 in in 24 hours.
7 rains exceeding 5 in in 24 hours
3 rains exceeding 6 in in 24 hours.
2 rains exceeding 7 in in 24 hours.
2 rains exceeding 8 in in 24 hours.
0 rains exceeding 9 in in 24 hours.

The Period of Operation. Ordinarily pumps will be operated early in the spring to get the ground ready for cultivation, and after heavy rains during the

growing period. In the lower Mississippi valley, where plant growth continues thruout the year, the pumping plant must be ready to operate at all times. In northern United States pumping usually is not required for more than 20 days, while in the extreme south it may be required from 40 to 50 days in the year.

Location. Pumping plants should be located near the natural drainage outlet if the area is approximately level, so that the water will travel the minimum length of canal. Unless electric power is supplied from a central station the facilities for transporting fuel must be considered in selecting a location for the plant. The ground should also be explored with a view to obtaining a favorable foundation for the plant.

Buildings. The footings under machinery and buildings should be of concrete, and if built on earth they should be supported by piling. The pump should be mounted on the same block of concrete as the engine that operates it so that subsequent settlement will not throw them out of line. Buildings should be durable, of fireproof construction, and of sufficient stability to withstand the heaviest winds.

Power. The kind of power to be used in a particular case must depend upon local conditions, but each possible source of power should be investigated. The power finally selected should be that which requires the smallest operating expense, based upon interest charges, attendance, fuel, maintenance and depreciation. Pumping by electricity has in many cases proved satisfactory and where several drainage projects are in the same vicinity the generation of electric energy at a common central station might be advantageous. Windmills have been used in Holland, but the uncertain character of this power renders it unsuitable for drainage purposes, except possibly as an auxiliary power. Steam, oil, gas-producer, and gasoline have been used for pumping in the United States. Gasoline engines have been used chiefly for small plants. Gas-producer plants have generally proved unsuccessful for intermittent service. Oil engines using crude oil have proved very satisfactory both as regards oil consumption and the cost of attendance. Steam is more generally used for large plants than other sources of power, but the large initial cost in foundations, settings, and appurtenances, and the high grade of mechanical ability required to operate steam plants, and the expense of keeping them continually ready for service are serious objections.

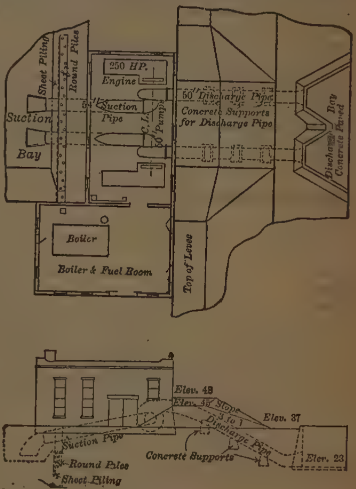

Fig. 23. Pumping Plant for Drainage System

Pumps should be selected and operated so as to secure the maximum efficiency practicable. The maximum lift will not usually exceed 10 ft and the bulk of the water will not be lifted more than 3 or 4 ft. It is at the lower lifts also that the greatest pumping capacity is required. It is desirable, therefore, that the pumps should operate at very nearly their maximum efficiency for the lower lifts and operate at a satisfactory efficiency thru the entire range of lift. Centrifugal pumps have been quite generally used for drainage reclamation work. Fig. 23 shows an outline of the plan and elevation of the pumping plant for Louisa-Des Moines Drainage District No. 4, Iowa.

The rated capacity of ordinary low head centrifugal pumps is based upon a velocity thru the discharge opening of from 10 to 12 ft per sec. The loss of head due to friction may therefore equal or exceed the static lift. For this reason the suction pipe and discharge pipe should be made as short as possible and sharp bends should be avoided. The outlet should be submerged so as to induce siphon action in the pipes, and the discharge pipe should be flared at the lower end so that the water will discharge at a velocity of not over 5 ft per second. The suction pipe must be air-tight and the water should be drawn from a concrete lined intake several feet deeper than the minimum elevation of water surface to be maintained. Centrifugal pumps if properly designed and installed should give efficiencies of 60 to 70 percent thruout the range of lift ordinarily encountered in drainage work, but improperly selected pumps may give very much lower efficiencies. These figures refer only to the pumps, and friction losses in pipes and velocity head at exit must be added to the static lift to obtain the actual head against which the pumps must operate.

Average Loss of Head in Feet per 100-ft Length of Suction or Discharge Pipe of Pumps

Velocity in pipe ft per sec	Diameter of pipe in inches													Add for each 90° bend
	6	9	12	15	18	21	24	30	36	42	48	54	60

Cost. The cost of drainage pumping plants varies widely according to the type of machinery, expense of transportation, character of foundation and difficulties of erection. The following tables give costs of power plants and single unit pumping plants and fuel costs for different types of installation in Texas and Louisiana from data obtained in Bulletin 71 of the U. S. Department of Agriculture. The costs of pumps include foundations and piping, and the costs of power plants include engines, boilers, and their foundations and auxiliaries. The costs of intakes, buildings, and discharge canals or flumes are not included.

Cost of Power Plants and Single Unit Pumping Plants

Indicated horsepower	Type of engine: Simple slide valve, non-condensing, From	To	Compound condensing slide valve, From	To	Compound condensing Corliss, From	To	Single unit centrifugal pumping plant, From	Total	Capacity of pump Gallons per min.
20	$1 100	$1 500	....	....	....	....	$2 000	$3 500	5 000

19. Levees and Ditches

General. Excepting the pumping plant, where pumping is necessary, the bulk of the labor of land reclamation by drainage consists of the construction of levees and ditches. Drainage ditches are required to remove surplus water, and levees must be built to prevent the entrance of outside water upon lands subjected to overflow. The study, therefore, is largely one of designing and locating these levees and ditches so as effectively to protect and drain the tract at a minimum cost, and in such a manner as to require the smallest future outlay for maintenance and repairs.

Levees Subject to Current and Wave Action should be designed on liberal lines and carefully constructed (Fig. 24). They should preferably be located on the higher ground and between ridges to reduce excavation and secure a firm foundation to build on. The alignment should be as regular as practicable, however, and sharp turns should be avoided.

The slope of the face of a levee on the exposed side should not be steeper than 1 on 3 and if built of light material a slope of at least 1 on 4 should be used. The inner slope should be at least 1 on 2 and preferably 1 on 3. The borrow pit, which is always on the outer side of the embankment, should be separated from it by a berm of 30 to 50 ft. The width of the top of the embankment, should be at least 6 ft and a freeboard of 3 ft or more should be allowed between the highest water planned for and the elevation of the top of the levee. A tile drain is usually placed along the inner slope of the levee to intercept seepage water and make the base of the levee more firm. All vegetable matter should be removed from the strip of land which the levee is to occupy and usually this area is corrugated with longitudinal plow furrows before the embankment is placed. A cut-off trench, filled with selected material, may be built near the center of the base of the levee. Levees subject to wave action should be protected by rock riprap or other construction to prevent erosion. (See Sect. 6, Art. 41.)

Levees in Still Water may have a somewhat smaller cross-section than those subjected to current or wave action. They are commonly located on property lines without regard to the topography. This results in regularly shaped districts and minimum length of levee, but frequently the cost of construction and maintenance may be reduced by following the higher and firmer land and deviating somewhat from the more direct line.

Common dimensions for this type of levee (Fig. 24) are 1 on 2 or 1 on 3 for embankment slopes, a top width of embankment of 6 ft, a berm of 10 ft and a freeboard above the maximum high water elevation of 3 ft. To reduce seepage, the borrow pit should

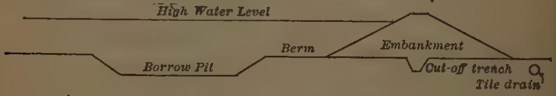

Fig. 24. Cross-section of Levee

be on the outer side of the levee, but it is sometimes placed within the tract and thus serves as a drainage canal. All vegetable matter and humus should be removed from the strip of land on which the levee is to be built and as far as practicable only the better grade of material should be placed in the embankment. Carelessness in these regards may result in excessive seepage thru the levee. Levees built of the mud commonly found in swamps will shrink from 20 to 50 percent of its original volume, and allowance for this shrinkage should be made when the material is placed. The shrinkage will be less for sandy soils than for those in which clay predominates.

Ditches of various sizes must be constructed and so located as thoroly to drain the area to be reclaimed. On pumping projects the larger ditches also

serve for storing water after heavy rains and thus give greater flexibility to the pumping plant. In many instances the latter function is fully as important as the former, and quite commonly some of the main ditches are made much larger and deeper than would be necessary for drainage alone in order to provide more storage.

The size of each drainage ditch must be carefully determined from the duty which it has to perform. The general features are shown in Fig. 25. The side slopes are usually made about 1 on 1½. When excavated with dredges it may be more convenient to leave

Fig. 25. Cross-section of Drainage Ditch

steeper banks and allow additional width with the idea that the banks will cave in and eventually conform approximately to 1 on 1½ slopes. Excavated material should be deposited in spoil banks on either side of the ditch, leaving suitable berms between the ditch and banks.

Excavating Machinery. Levees on firm dry land may be built either with teams and scrapers or with machinery. In marshy land the main canals and levees can usually be built better with floating dredges than by any other means. If the ground is soft and there is nothing to interfere with its use, an orange peel dredge may be used. If the tract contains stumps and fallen timber a dipper dredge will be more serviceable. On account of its longer reach the orange peel type of dredge is preferable where the conditions are favorable for its use. Small open field ditches are frequently excavated by hand after the main body of the land has been drained.

Maintenance of Levees and Ditches. Bushes and other vegetation of rank growth should not be allowed on levee banks since water will follow the roots and increase seepage. After the soft material in a levee has dried sufficiently it should be smoothed off and preferably seeded to Bermuda grass. It may then be mowed with a mowing machine, or the grass may be kept down by allowing stock to graze upon it. A heavy sod will assist in preventing erosion and in keeping out weeds and other objectionable vegetation. Grass and weeds should be cut out of ditches from 1 to 3 times each year. At least once in 2 years the ditches should be cleaned of the accumulated mud and silt.

The Cost of dredging drainage ditches in the United States prior to 1916 varied approximately from 7 to 11 cents per cubic yard. At the same time the cost of building levees with dredges varied from 10 to 19 cents per cubic yard. The cost of clearing right of way, where clearing is necessary, should be added to the above figures. The cost per acre of reclamation by drainage where both levees and interior ditches are required (exclusive of the cost of pumping plants) varies from $15 to $45 per acre. The average cost of excavation on over 50 drainage projects in the Mississippi valley has been approximately $23 per acre. Of this amount the ditches cost about one-third and the levees two-thirds.

20. Inland Marshes

Source of Water. The first step in the investigation, preliminary to deciding upon the plan of reclamation, is to determine the source of the water or the reason that the land is too wet. The water may come from direct rainfall, from visible streams, from the run-off from neighboring hills, or from springs.

The condition may be due largely to the fact that the natural outlet channel is obstructed or of insufficient depth or capacity to properly drain the area.

Main Drainage Channel and Outlet. In order that a swamp area may be properly drained it is necessary that the outlet and main drainage channel should be deep enough and of sufficient capacity to carry the drainage of the swamp and all tributary areas while maintaining an elevation of water surface low enough to provide for effectively draining the area to be reclaimed. The natural drainage channel thru an inland marsh may not be clearly marked or it may be very winding and obstructed with fallen timber and debris. One of the first requirements in such cases is to excavate or straighten and enlarge and deepen such channels and carry them to a natural outlet. If no satisfactory outlet exists, pumping may be resorted to, but inland marshes are usually drained entirely by gravity.

Auxiliary Drainage. The amount of drainage required in addition to that provided by the main channel will depend largely upon the size of the marsh, the natural slope of the ground, the soil formation, and the source of under-

Fig. 26. Reclamation of Inland Marsh

ground water. If the subsoil is sandy and especially if the ground has a fair slope toward the main channel no additional drainage may be necessary. Also if the marsh is small no additional ditches may be required. If the subsoil is of impervious formation auxiliary drainage ditches across the tract may be required at ¼- or ½-mile intervals. When springs occur on the tract they should be cut off by intercepting drains, that is drains which tap the source of supply before it reaches the surface of the ground. This result may usually be accomplished by means of an underground tile drain. If there is much flow on to the tract from surrounding hills a catchwater open ditch at the junction of the high and low land may be advisable. After the main drainage channel and principal auxiliary ditches have been completed, if further drainage is required it may be accomplished by open farm ditches or tile drains. Fig. 26 indicates the different methods of drainage that may be used in reclaiming inland marshes.

The Water Table thruout the tract should not be closer than 3 or preferably 4 ft from the surface of the ground at any point. Marsh lands commonly

settle from 1 to 2 ft after cultivation, the settlement being greater in proportion to the depth of decayed vegetable matter with which the tract is covered. Proper allowance should be made in designing ditches and drains, so that the land will be drained to a sufficient depth after settlement has taken place.

21. Overflowed Lands

Classification. There are two general classes of overflowed lands: tidal marshes which are periodically submerged and uncovered by the rise and fall of tides, and river bottom lands which are temporarily inundated during high stages of the streams. The lower lying marshes in either case may be permanently submerged. Some lands, like those in southern Louisiana, may be subject to overflow from both causes. As regards topography, the area to be reclaimed may either adjoin high land on one side, or be entirely surrounded by overflowed land. In general, a similar plan may be adopted for reclaiming all overflowed lands, the details being changed to suit the particular conditions.

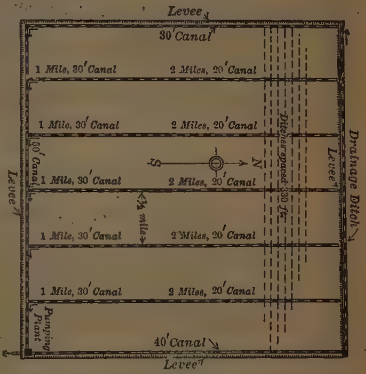

Fig. 27. Reclamation of Overflowed Land

Protection from Overflow is secured by constructing levees around the area to be reclaimed, (Art. 19.) If the tract joins high land on one side, levees will be required on but 3 sides. In general the area of such lands that may be reclaimed by one levee system is limited to that which is included between the main stream or body of water and two of its tributaries. A levee runs along the bank of the main water and return levees follow the tributaries to the high land. Diversion ditches may be constructed near the foot of the slope where the hills join the flat land to deflect the hill waters and prevent their entering the tract. If the area to be reclaimed is surrounded by overflowed lands, levees must be built on all sides. Fig. 27 shows the system of levees and ditches of Area No. 7, Gueydan, Louisiana. Fig. 28 shows the method of reclaiming a tidal marsh near Dorchester, New Jersey.

Drainage. The drainage system consists of one or more main ditches with auxiliary ditches spaced as required, but usually from ¼ to ½ mile apart. Open farm ditches or drain tile may then be used to provide whatever additional drainage may be necessary. Open ditches should preferably be located on property lines or parallel to them, in order that they may interfere as little as possible with farming operations.

The Depth of Ditches should be such that the entire tract may be satisfactorily drained to a depth of 3 to 4 ft. The practice in the lower Mississippi valley, Fig. 27, is to dig farm ditches 4 ft deep. The main ditches must have dimensions and slopes which will provide satisfactory outlets for the smaller ditches.

Marsh lands will frequently settle 1 to 4 ft after reclamation, and this settlement may continue for several years. The probable settlement of the ground should be considered in designing the drainage system.

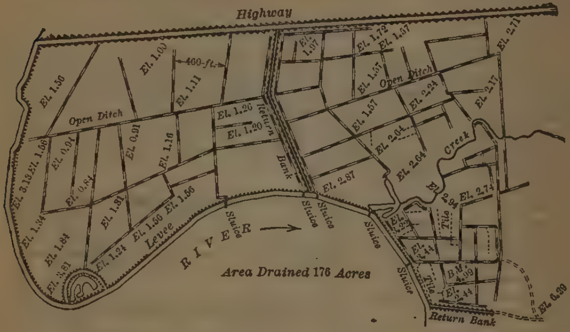

Fig. 28. Reclamation of Tidal Marsh

The Outlet for the drainage system may be provided by gravity or pumping or by a combination of the two. If a natural gravity outlet is relied upon a sluice gate must be provided where the water passes thru the levee. Sluice gates should act automatically and allow the water to pass out when the water surface is higher within than without the tract and close when the opposite condition obtains. A flap valve, hinged at the top, is ordinarily used for this purpose. A hand-operated gate should be installed in conjunction with the automatic gate to be used in case the latter gets out of order. River bottom

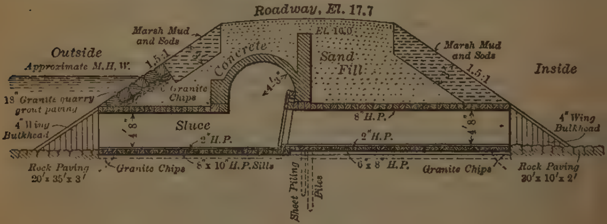

Fig. 29. Longitudinal Section of Levee through Sluice

lands when subject to overflow for only short periods may be drained by gravity outlets if the water surface in the river is normally low enough, otherwise auxiliary pumping will be necessary satisfactorily to drain the tract. Tidal lands may be drained through automatic sluice gates, the gates being opened during low tides and closed during high tides. In localities where the tidal range is small and the elevation of the ground is low, reclamation can be accom-

plished only by pumping. In many instances where tidal lands are drained by gravity the expense of auxiliary pumping would be more than justified by increased returns from the land.

In general, tide lands drained only by gravity lying 1 ft or less above mean low water have no value for agricultural purposes, those between 1 and 2 ft above mean low water will produce hay, and those between 2 and 3 ft above mean low water will produce rye, potatoes, corn and other crops. The best results are obtained from land 3 ft or more above mean low water elevation.

Sluices should be carefully designed and constructed with a view to obtaining both safety and effective service. Cut-off walls and thoroly tamped backfulling will reduce the danger of leakage along the structure. Sluices may be made of either wood or concrete, but the latter is preferable. The gates should be well balanced and fitted so that they will move easily and allow a minimum of leakage and all hardware should be of bronze or some other non-corrosive metal. The tops of sluices should be below ordinary low tides, as they thus afford better drainage and the gates being submerged will operate more easily. The capacity of a sluice should be sufficient to discharge the maximum run-off to be provided for in addition to back leakage. Gates may be set either at the outlet of the sluice or in a chamber within the sluice. Fig. 29 shows a cross-section of a levee and sluice at Wellfleet, Massachusetts.

FARM DRAINAGE

22. General Considerations

Soil Moisture is one of the essentials of plant life, but all water in excess of that required by vegetation is harmful. The only water that is needed by plants is contained in the capillary water (Art. 2) which exists as a thin coating to the soil particles. Gravity water, that is water in excess of the soil's capacity to contain capillary water, is not beneficial. Air within the soil is also essential to healthy plant growth, and this is excluded when the ground contains water in excess of plant requirements. In a soil completely saturated with stagnant water, air is completely excluded and the ground becomes cold and sour and entirely unproductive. The conditions most favorable to plant growth obtain when the gravity water passes freely downward, leaving in the soil only as much water as is beneficial to plants, and allowing a free circulation of air thru the soil.

The Ground-water Level, for ordinary soils and crops, need seldom be at a depth of more than 4 ft, and in some cases less. When too near the surface, water will be continually drawn up by capillary action, the percolation of precipitation will be retarded, and the soil will become cold and improperly aërated.

Lands Requiring Drainage. Three classes of land may be considered: (*a*) That which is entirely unproductive or which cannot be profitably farmed without drainage, (*b*) that which may be profitably farmed without drainage but which with drainage will produce increased returns sufficient to justify the expense of drainage, (*c*) that which cannot be sufficiently improved to justify the expense of drainage. Low lying marshy and springy lands belong to the first class. It is probable that all lands not having a porous subsoil, and especially clay lands, can be benefited by drainage. Whether it will pay to drain such lands depends on the value of the land before drainage as compared to its value after drainage. A fair criterion to apply is whether the increased returns after drainage will exceed the interest on the investment required to drain the land.

Benefits of Drainage. Drainage benefits farm lands in the following ways: (*a*) By removing the surplus water, which is harmful to plants, and aërating the soil; (*b*) by warming the soil and thus decreasing danger from frosts, causing the seeds to germinate earlier, and grow more promptly, permitting earlier cultivation of the land, and increasing the length of the growing season; (*c*) by making the soil more granulated, porous, and friable, and thus increasing its ability to absorb rainfall. In general, the results of farm drainage are to make certain the production of crops each year and to increase the yields and profits.

An Objectionable Feature of drainage is that the ground water in passing down and away carries with it in solution many elements that are valuable as plant food. There appears to be no remedy for this condition in humid regions, since adequate drainage is the first requisite. In irrigated districts the difficulty may be in a large measure overcome by restricting the use of water to the actual requirements of crops.

Preliminary Investigation. Before laying out a plan of drainage for a given area a careful preliminary study should be made and a topographic map should be prepared showing contours and intermediate elevations at controlling points. It is important that natural drainage lines should be distinctly shown. A soil survey of the area should be made and the character of the soil and subsoil at different points may be conveniently marked on the map, supplemented by additional field notes if necessary. The ground water also should be studied, especially if there is evidence that it comes from some source other than precipitation upon the area to be drained. The position of the outlet should be determined from the field investigation and marked upon the map. The map and other data may then be used as a basis for the plan of drainage.

23. Drains and Drain Tile

Principles of Drainage. There are two kinds of drainage: Surface drainage, by which water is conveyed over the surface of the ground; and sub-surface drainage, by which water is conveyed beneath the surface of the ground. Surface drainage removes the water that cannot percolate into the ground as fast as it is supplied by precipitation or melting snow. Sub-surface drainage removes the water which cannot be retained as soil moisture.

Farm lands require surface drainage to remove the excess water resulting from heavy rains, but, in general, it is better to have as much water percolate thru the soil into the sub-surface drainage as possible. If ground slopes are too steep heavy showers will run off the surface before the ground has been wet as deep down as is desirable. Better results will usually be obtained from gently sloping land, where the bulk of the water soaks into the ground and that which is in excess of plant requirements is promptly removed by sub-surface drainage. It is frequently desirable to retard the surface drainage on sloping ground which may be accomplished in a measure by cultivating the land across the slopes. Farm drainage is primarily a problem of supplementing natural sub-surface drainage.

Open Ditches receive water from the surface of the ground and also water that passes thru the soil. They therefore assist in surface drainage, which may be an advantage on very flat areas. In the lower Mississippi, where the rainfall is heavy and the land practically level, open farm ditches are used almost exclusively (Fig. 27). Farm ditches occupy land which might otherwise be cultivated, and make it difficult to move farm machinery from one part of the farm to another. They are expensive to maintain and in clay soils they are apt to become puddled and prevent the free entrance of ground water.

Sub-surface Drains are conduits below the surface of the ground with openings of a size that will permit the ground water to enter freely and exclude the

surrounding earth. Box drains have been used to a limited extent. They are made of four boards nailed together to form a rectangular cross-section with cleats between the top and sides to leave narrow openings for the entrance of water. Blind ditches partially filled with stones or poles were formerly used, but they were not permanent and have been abandoned. Tile drains have been found to provide the most satisfactory drainage, and they are used almost exclusively.

Kinds of Tile. There are two kinds of drain tile in common use: Clay tile and cement tile. Clay tile are sometimes made hexagonal or octagonal, but more commonly they are round. They range from 2 to 36 in in diameter and from 12 in in length for the smaller sizes to 30 in for the largest. Cement tile under 12 in in diameter are more expensive than clay tile, but over this size the cost of production may be less. The following comments on clay and cement tile are contained in Farmers' Bulletin 524 of the U. S. Department of Agriculture:

Clay Tile. Soft, medium, and hard-burned or vitrified clay tile are made. It costs less to make the soft-burned than the hard-burned tile and the selling price is lower, but the quality is not so good. Soft-burned tile have done good service, however, and when put under ground below the frost line have lasted indefinitely. The best tile are burned to a cherry red and when struck by a piece of steel give a sharp metallic ring. In the north, where they are laid above the frost line, only the hard-burned tile should be used. Hard-burned, or vitrified, tile are practically nonporous; thus, they absorb little moisture and unless water stands in them they are not injured by freezing temperatures. A tile that cracks and shatters in winter when lying in the yards unprotected from the weather is not fit to use above the frost line and is not the best under any conditions. Thick tile make the best joints. Those with thin sides, especially in the smaller sizes, are likely to slip out of place and leave openings. Some manufacturers who ship tile make them with thin sides to reduce the weight and the consequent cost of transportation. A 4-in tile should weigh at least 6 lb, a 5-in 8 lb, and a 6-in 11 lb. Some factories make them heavier than this, which is better so far as utility is concerned.

Cement Tile. There are a number of machines on the market for making cement (or concrete) tile that cost from $50 to $100. One part of cement to about 3 parts of aggregate should be used. The largest pieces in the aggregate should not be more than one-half the thickness of the wall. The cement and aggregate should be well mixed and sufficient water should be added to make the mixture moist but not wet. After the tile are taken from the machine they should be placed in the shade. The longer the mold is allowed to remain around the tile the better. After the mold is removed the tile should be sprinkled twice a day for 3 or 4 days, or until thoroly cured. A well-made and well-cured cement tile, like a good clay tile, when struck with a piece of iron will have a sharp metallic ring. Large cement factories are equipped with steam driers, with which the curing can be done to the best advantage.

24. Location of Drains

The General Plan of draining a given area should be determined before any drains are constructed, in order that all parts of the system when completed will work together effectively even tho the construction is to extend over a long period. Details not pertaining to the general scheme of drainage may be worked out as required. When more than one farm will be benefited by the construction of main drains, each party interested should contribute in the investigation in so far as the work affects his property. State laws usually cover the legal points involved

The Outlet is usually the first consideration. On rolling or hilly lands a natural outlet ordinarily exists. On low level land an artificial outlet is usually necessary. The elevation of the water surface in the outlet should be low enough to provide for the effective drainage of the area which it serves. It should be of

sufficient capacity to take care of the requirements of surface and sub-surface drainage. The expense should be assessed against all of the farms using the outlet in proportion to the benefits accruing to each. Outlets may be either open ditches or covered pipes. Tile up to 36 in in diameter have been used for this purpose.

Drainage Systems. There are two general systems of drainage: Partial and complete. Partial drainage systems are used on rolling land when it is desired to drain only isolated portions of a tract, as illustrated in Fig. 30. The complete system is used when all of the land of a comparatively large area is to be drained. Examples of complete drainage systems are shown in Fig. 31 and 32. It will be noticed that certain areas adjacent to the main laterals are double drained, and for maximum economy this double drained area should be as small as practicable. For this reason long parallel field drains are preferable. The system indicated in Fig. 32 requires a smaller amount of tile than that indicated in Fig. 31.

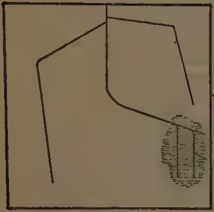

Fig. 30. System of Partial Drainage

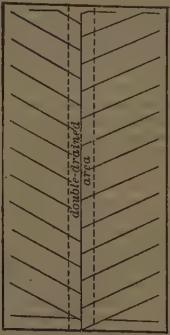

Fig. 31. System of Complete Drainage

Fig. 32. System of Complete Drainage

Field drains should be laid in the direction of the greatest slope. This insures the greatest velocity and capacity. High velocities of water assist in scouring out the drains and in keeping them clean. It is very important that drains in sandy land should have velocities great enough to scour out the sand which filters into the drains between the tile. A 4-in tile drain in sandy land should not be laid on a grade of less than 0.3 ft to 100 ft. The laterals, submains and mains should perferably be located approximately in the lines of natural drainage, since the slope of the ground leads the water in this direction. The drains should be laid as straight as practicable and bends should be made by smooth curves. It usually will be found necessary to deviate somewhat from the natural drainage channel in order to improve the alignment.

The Depth and Frequency of Drains that will produce the most satisfactory results depends largely upon the character of soil. Where deep drainage can be used the drains may be spaced farther apart. The more porous the soil the deeper the drains can be placed. In heavy clay soils of close textures, drains placed to a depth of from 2 to 3 ft have produced good results when deeper drains have failed. In other cases clay soils have been satisfactorily drained at depths of from 3 to 4 ft. A depth of about 4 ft appears to be the best for sandy soils.

Practice also varies widely regarding the proper spacing of drains. In dense clay soils they should probably be placed from 30 to 40 ft apart, and in sand a spacing of 200 ft may be used. For intermediate grades of material distances of from 50 to 150 ft may be selected to suit the conditions.

Before deciding definitely as to the proper depth and frequency of drains for a given area a careful study should be made of all factors likely to affect the problem. Conditions vary widely and results obtained in one locality may not apply to another locality where conditions appear quite similar. Local conditions especially should be studied, and if time is available and other conditions seem to warrant it, experiments with different depths and spacings of drains should be made before the completion of the work as a whole is undertaken.

25. Capacity and Size of Drains

The Required Capacity of a sub-surface drain depends upon the rate at which water will pass from the surface of the ground to the drain. The two principal factors affecting the rate at which water will enter a drain are the porosity of soil and the amount and rate of precipitation.

Drainage Coefficient. The inches depth of water which must be removed in 24 hours to satisfactorily drain any area is called the drainage coefficient of that area. Its value for different soils must be obtained from experiments. An investigation by the U. S. Department of Agriculture of a number of underground drains in Illinois and Iowa that were doing satisfactory service showed maximum discharges in 24 hours of from 0.11 to 0.27 in, most of the results varying from 0.15 to 0.20 in. These results were obtained on areas having fairly porous subsoils. Heavy clay soils and coarse sand soils will have respectively smaller and larger drainage coefficients than the above. It also appears that the drainage coefficient of rolling land is about 20 percent greater than for flat land. The following may be considered average values of drainage coefficients for different soils:

Compact clay soil, flat, 0.12; rolling, 0.14.
Medium porous soil, flat, 0.18; rolling, 0.22.
Porous sandy soil, flat, 0.30; rolling, 0.36.

With the drainage coefficient decided upon, the capacity of drain in cu ft per sec required to drain a given area can be obtained by multiplying the area in square miles or acres by the proper value in the accompanying tables:

Size of Drain. The size of drain required to discharge a given quantity of water can be computed from one of the open channel formulas. The Manning formula for the smallest diameter of circular conduit that will discharge a given quantity of water may be written,

$$d = 12\left(\frac{2Qn}{s^{1/2}}\right)^{3/8},$$

in which d is the diameter of the conduit in inches, Q is the discharge in cu ft per sec, s is the slope or fall per foot, and n is the coefficient of roughness, which is to be given the same value as Kutter's n. Values of n depend upon the degree of roughness of the pipe and the care that is taken in placing the tile to get smooth joints, the extreme range of variation being from about .011 to .017. A value of .014 should be attained from a good grade of tile if proper care is taken in laying them. Values of d from the above formula with $n = 0.14$ given in the table cover the ordinary ranges of Q and s. For other values of n multiply d as given in the table by the following factors:

For n equal to.............	.011	.012	.013	.015	.016	.017
Multiply d in table by......	0.91	0.94	0.97	1.03	1.05	1.08

Formerly 2-in tile were used for farm drains, but modern practice is to use no tile smaller than 3 in in diameter. The size of tile selected for a given case should ordinarily be the commercial size nearest to and larger than the computed size, excepting that no tile smaller than 3 in should be used. The following are diameters in inches of common commercial tile: 2, 2½, 3, 4, 5, 6, 7, 8, 10, 12, 15, 18, 20, 21, 22, 24, 27, 30, 33, and 36. For main drains above 15 in in diameter vitrified sewer pipe is commonly used.

Diameters of Tile Drains in Inches and Decimals of an Inch Required to Discharge Various Quantities of Water at Different Slopes

26. Construction of Tile Drains

Staking Out. Tile drains should be set true to line and accurately to grade. When curves are necessary they should be smooth and regular. Before beginning excavation stakes should be set 50 ft apart parallel to and about 2 or 3 ft from the center line of the drain on the side opposite to that on which the earth will be thrown. Elevations of tops of stakes should be taken with a level and the cut marked on each. These stakes will serve as guides for the rough excavation. After the excavation is approximately to grade, batter boards should be placed across the trench opposite each stake at the same distance, preferably about 6.5 or 7 ft above grade. The center line is then marked on the batter boards and a string connecting these points will be directly above and parallel to the grade line. The center line at any point may then be obtained by dropping a plumb bob from the line, and the grade by measuring down with a pole of proper length.

Fig. 33
Tile Hook

Excavation should be begun at the outlet. The trench may be dug either by hand or with a trenching machine. If much work is to be done the trenching machine will prove more economical. For 6-in. tile or smaller the trench may be made 12 in wide at the top and 7 in at the bottom. The ditch should be finished at the bottom with a drain scoop. It is especially important that the bottom of the ditch be excavated accurately to grade and line before the tile are placed.

Trenching Tools and Machines. The special tools commonly used in digging trenches or drain tile are tile spades, a shovel, pick, drain scoop, and tile hook. There are two kinds of tile spades, solid and open, the latter being used for wet sticky soils. Tile spades are from 16 to 22 in long and from 5 to 6 in wide. A drain scoop is used for finishing the bottom of the trench preparatory to laying the tile. It should be curved to a radius approximately equal to the outer radius of the tile. A tile hook, Fig. 33, is used for placing tile in the trench. It consists of a bent ½-in rod attached to a wooden handle. There are a number of types of trenching machines on the market. They vary from different styles of plows, which loosen the earth so that it may be more readily shoveled, to large machines of the wheel-bucket and endless chain type, which do all the work of excavation. The larger trenching machines vary in cost from $1800 to $6500. Trenching plows may be obtained at $20 to $300.

Laying of Tile, like the excavation of trenches, should begin at the outlet. If the bottom of the trench has been properly prepared the laying of the tile should proceed rapidly. The smaller sizes of tile are usually laid with a tile hook by a man standing at the top of the trench, Care should be taken to see that the tile joints fit tightly, especially at the top. Crooked and imperfect tile should be thrown out and if used at all they should be placed together near the upper end of the drain. Curves are usually made by using crooked tile or by chipping off one edge of the tile. It is easier and better, however, to have special curved shapes, either drain or sewer tile, available for the purpose. Y-junctions should be placed where needed, the open end being plugged up until the connection is made. Before the tile are covered the work should be inspected to see that all joints are properly made and that the tile are laid true to line and grade.

Backfilling. Before the trench is filled the tile may be surrounded by coarse hay, twigs, burlap, small stones, or pieces of brick. This provides for a freer entrance of water and helps to exclude fine sand from the drain. The first earth should be put into the trench carefully so as not to move the tile. The

remainder of the backfilling may be done with shovels, scrapers, or a turn plow.

Outlets. Where a tile drain discharges into an open waterway the outlet should be protected by building a substantial retaining wall around it. The foundation should extend well below the bottom of the channel so that the wall will not be undermined by the current in the waterway or the water discharging from the drain. Only vitrified clay or metal pipe should be used near the outlet, as the softer clay tile which will be satisfactory under ordinary conditions may disintegrate under the alternate conditions of freezing and thawing to which they will be subjected at the outlet.

Surface-Inlets are sometimes constructed at low places to supplement surface drainage. They are commonly made of wood, concrete, or sewer pipe. They consist essentially of a small basin that extends to or below the bottom of the drain to which they are connected, with an opening at the top for the entrance of surface water. The surface opening should be covered with an iron grate which also should be protected by a covering of loose rock to prevent the entrance of dirt and drift.

Silt-Basins or Sand-Traps are basins placed in drains or at the junctions of drains for the collection of silt and sand. They also afford an opportunity for the inspection of drains. The bottoms of the basins should be 2 or 3 ft below the tile to provide a receptacle for the silt, which may be cleaned out as often as is necessary. These structures are not required for clay or loam soils, but are useful where drains are laid in sandy soils.

27. Costs and Profits

Cost of Round Drain Tile f o b Factory

Prices quoted by manufacturers, subject to discount of from 35 to 55%.

Size, in	Length of one tile, ft	Weight per linear ft, lb	Price per 1000 ft	Price of Y's, T's, ells and curves, each	Linear ft per car load of 30 000 lb
2	1	3	$ 12	$0.10	9000
2½	1	4	15	.10	7500
3	1	5	20	.20	6000
4	1	7½	30	.20	4000
5	1	10	40	.30	3000
6	1	13	55	.40	2500
8	2	20	90	.60	1500
10	2	30	135	1.00	1000
12	2	40	180	1.50	750

Amount of Tile per Acre. Where, over a considerable area, field drains are placed parallel and an equal distance apart, the number of linear feet of tile required per acre may be obtained by dividing 43560 by the distance between drains in feet. The following are linear feet for distances commonly used. An allowance of 5 percent should be made for breakage and imperfect tile.

Distance apart....	25	30	33	40	50	66	80	100	150	200
Lin ft per acre....	1742	1452	1320	1089	872	660	545	436	291	218

Cost of Constructing Drains. Under favorable conditions, for 6 in tile or smaller, the cost of digging trenches 3 ft by hand varies from 2 to 3 cts per ft.

On large contracts, trenching machines have done similar work for from 1½ to 2½ cts per ft. About 50 percent should be added to these figures for trenches 4 ft deep. Laying tile and backfilling costs from ¼ to ½ ct per ft. If the ground is rocky or contains many roots the expense of excavation will be greatly increased. Very wet soil and especially quicksand may add to the cost of the work. The cost of laying a 12-in drain will be about twice as great as laying a small drain to the same depth.

The Cost per Acre of drainage will depend upon the distance between drains. If drains are 100 ft apart, 436 lin ft of tile will be required. With the cost of 4-in tile at $20 per thousand delivered to the ground, the cost of tile per acre will be $8.72. If trenching costs 2½ cts per ft and laying tile and backfilling ⅜ cts per ft the total cost of drainage, exclusive of mains and laterals and other accessories, will be $20.25 per acre. Where field drains are spaced from 50 to 120 ft apart the corresponding costs of drainage may range from $45 to $15 per acre. A common cost of tile drainage is about $25 per acre.

Profits from Drainage. The profits to be derived from farm drainage depends largely on the character of the land. The greatest profits usually result from the drainage of lands too wet for cultivation. The following examples are given in the Yearbook of the U. S. Department of Agriculture for 1914 as typical of results obtained from properly draining farm lands in the humid region of the United States:

In the coastal plain of North Carolina about 25 acres that were producing nothing were tile drained for perhaps $250, probably not including costs of teaming and of supervision, and since then have produced a bale of cotton per acre. A field of 6 acres was drained for about $160, and the owner makes good crops on soil worthless without drainage. In the black prairie belt of Alabama, a field that had not been cultivated in years because too wet was drained with tile; then it produced one bale of cotton per acre and repaid the entire cost of drainage the first year. The following year the field yielded 50 bush of corn per acre, twice the rate from other parts of the farm. Another drained field produced one bale of cotton per acre, while the undrained land produced only half a bale. A 10-acre field that yielded practically nothing in 1912 was tile drained, and in 1913 produced 60 bush of oats per acre; in 1914 the rate was again 60 bush of oats, in contrast to 10 bush per acre from the adjoining 15-acre field planted to the same grain. The cost of most of the tile drainage in Alabama has been about $25 per acre, some of it as high as $30 to $35, but increases of 50 to 200 percent in yields and the assurance of good crops every year instead of only in very favorable seasons are very satisfactory returns. The cost of drainage there has usually been repaid in 2 to 3 years by improved crops. In Iowa, a field of 40 acres too wet for planting was tile drained at a cost of $24 per acre, after which it produced 60 bush of corn per acre. Another field was drained for $23 per acre, thereby increasing the yield from 15 bush to 40 and 50 bush of corn per acre. In Arkansas, on one of the State farms, 1 bale of cotton per acre was secured in favorable years, and nothing at all when the early part of the season was wet; the year following the installation of tile the yield was 1½ bales per acre. In Nebraska a tract of more than 700 acres was tile drained at $24.25 per acre, the pumping plant cost $2 per acre, and as part of a larger district the cost of levees to protect from overflow was $9 per acre. The improvement, at a total cost of $35 per acre, immediately increased the crop on about 80 acres of corn 22 bush, and on another part the increase in 2 years was from nothing to more than 30 bush of wheat per acre.

28. Drainage of Irrigated Land

Necessity. More than 10 percent of the area in United States, which has been under irrigation for a considerable period, has become partially or entirely unproductive thru waterlogging or becoming impregnated with harmful mineral salts. These conditions are brought about by over-irrigation and inadequate natural drainage, and the remedy lies in supplementary artificial drainage.

he necessity for artificial drainage or the system of drainage to be employed s not apparent usually until after several seasons of irrigation, but from a study f the topography and soil strata it should be possible to foretell approximately he future drainage requirements of a newly irrigated tract. Some irrigation rojects do not require artificial drainage and others require it only to a limited xtent, but in all cases the matter should be thoroly studied in connection with he investigation and design of an irrigation system.

Alkali is the popular name applied to a number of mineral salts, harmful to vegetation, hich are found in the soils of arid districts. The more common of these are sodium hloride, sodium sulphate, magnesium sulphate, calcium chloride, calcium sulphate and odium carbonate. All of these except the last appear on the ground as a white crust nd are called white alkali. Sodium carbonate, or black alkali, is the most injurious to lants. It is indicated by dark spots on the surface of the ground due to the dissolution f humus and vegetable matter which it causes. These salts are readily soluble in water nd irrigation waters after passing thru the soil become more or less impregnated with hem. When the ground water reaches a sufficiently high elevation, moisture is drawn om it by capillary attraction to the surface of the ground, where the water is evapoated and the alkali is left as a thin deposit. After this action continues long enough ufficient alkali collects on the ground to injure or destroy vegetation. The height to hich water will rise by capillarity varies from about 2 ft for coarse sand to 5 ft for fine lay.

Removal of Alkali. Lands which contain an excess of alkali either from atural causes or from irrigation usually may be cleansed by irrigation after dequate drainage has been provided. The water must be lowered below he limit of capillary action, and then by applying water the salts are dissolved nd carried thru the soil to the ground water. Usually two good irrigations ill reduce the alkali on the surface to a harmless quantity, tho in rare instances wo years or more may be required for reclamation.

Objects of Drainage. The specific results to be accomplished by the drainge of irrigated land may be one or more of the following: (*a*) The lowering f the ground water to a level where it will not interfere with the penetration f plant roots to the required depth; (*b*) the removal of alkali from the surface f the ground; (*c*) the removal of excess soil moisture and the aëration of the oil. The problem differs from that encountered in humid regions in that kaline soils are peculiar to arid districts and the amount of water which the nd receives under irrigation may in a large measure be controlled.

Source of Water. A drainage system cannot be designed successfully until e source of the damaging water is known and its movement understood. The urce of the water may be (*a*) irrigation water applied to the tract itself, (*b*) rigation water applied to an area at a higher elevation, (*c*) a canal or reservoir a higher elevation. In the first case the movement of the water will be downard thru the soil. In the last two cases the water will move laterally either in orous strata near the surface or under pressure beneath an impervious stratum hardpan or clay.

Depth of Drains. The drainage should be such as to keep the ground water vel below the depth which will allow the movement of water to the surface of e ground by capillary action. The depth must be more than 4 ft for fine soils. xperience has shown that the depth of drains should be never less than 5 ft d a depth of 6 to 8 ft will produce more efficient results. Intercepting drains ould be placed at the depth that will most effectively cut off the flow of underound water.

Location of Drains. The location of drains will always depend upon the source d movement of the damaging water, and no general rules can be laid down. arallel drains may be used on flat areas where the water does not come from

some clearly defined outside source. Such drains are usually spaced 300 ft or more apart. Intercepting drains may be used to cut off the ground water flowing from higher areas. They are usually placed near the foot of a hill or where there is an abrupt change of slope. A secondary intercepting drain is sometimes placed below and approximately parallel to the main drain to collect water that passes the upper drain.

The area enclosed by the shaded line, Fig. 34, shows a tract of land near Hyde Park, Utah, which had become waterlogged and alkaline from the irrigation of lands at higher elevations. This land was successfully reclaimed by the system of intercepting drains indicated in the figure. Fig. 35 shows a tract of land near Garland, Utah, that was reclaimed by a combined system of intercepting drains and field drains. Where water is carried from a higher area thru a porous stratum the intercepting drain should extend down to the impervious material, as indicated in Fig. 36, otherwise some of the water will pass below the drain. Fig. 37 shows a method of intercepting water under pressure beneath an impervious stratum. This method may be used when the water is at a great depth.

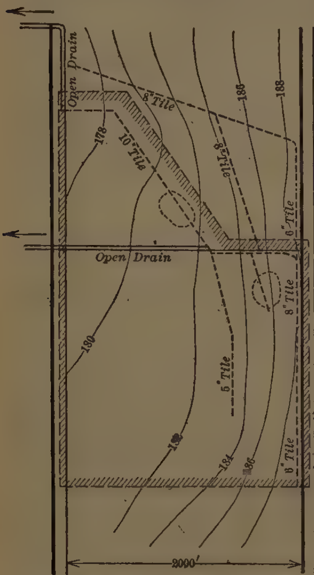

Fig. 34. Drainage of Irrigated Land by Intercepting Drains

Capacity of Drains. The amount of drainage to be provided for will depend upon the source of the water. Where the water comes entirely from the irrigation of the tract being drained it will usually be sufficient to provide for the removal of 0.05 to 0.1 in of water per 24 hours. This is equivalent to 9 to 18 in for a growing period of 6 months. Where the damaging water comes from an outside source, the determination of the proper drain capacity may be very difficult and definite rules cannot be given. If the water comes from other irrigated lands their areas and the amount of water percolating from them should be determined as accurately as possible. If it comes from irrigation canals, the seepage losses in such canals should be investigated. The careful consideration of these matters may assist in a satisfactory solution of the problem.

Drains. Either open ditches or closed drains may be used. The relative advantages and disadvantages of the two types are practically the same as with drains in humid regions. Nothing smaller than 4-in drain tile should be used on irrigated lands. The outlet may be either a natural drainage channel or an irrigation ditch. In the latter case, the drainage water will be available for irrigating areas lower than the one drained. The cost of trenching for tile

drains will be relatively higher than in humid regions owing to the greater depth of drains. If the banks tend to cave, timbering must be resorted to, which will add materially to the cost of the work.

Over-irrigation and Drainage. The necessity for the drainage of irrigated lands is brought about largely thru over-irrigation. If water is applied to the

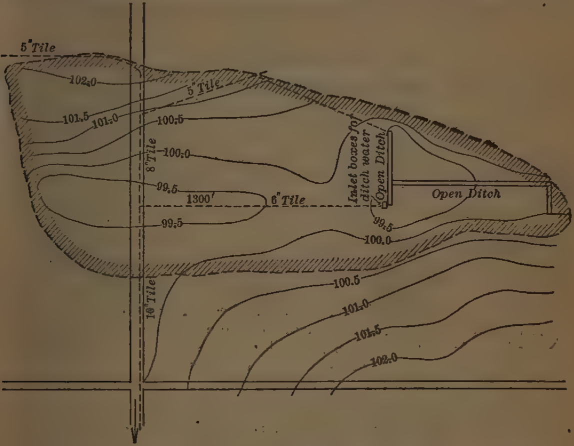

Fig. 35. Drainage of Irrigated Land by Intercepting and Field Drains

land only within its capacity to contain capillary water the needs of vegetation may be provided for and no water will be lost thru deep seepage This ideal condition cannot always be attained, but in general the use of less water will be beneficial in many ways. The injurious effects of waterlogging and alkali

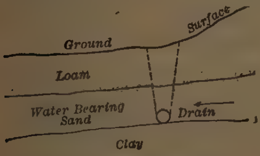

Fig. 36. Intercepting Drain

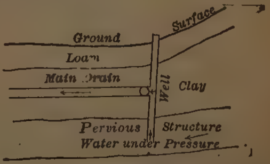

Fig. 37. Intercepting Drain for Water under Pressure

usually can be overcome by drainage, but in the same manner that alkali is removed, various mineral elements of the soil, and humus and nitrogen which are valuable plant foods are washed thru the soil and out of reach of plant roots. In all districts where over-irrigation is practiced, this process of leaching out the soil is in progress and the ground is gradually losing its valuable

elements of plant food. By exercising care in the use of water newly irrigated districts may, while providing adequate moisture for crops, avoid this waste and possibly prevent the necessity of constructing expensive drainage systems in the future.

LEGAL AND ECONOMIC FEATURES

29. Administration of Streams

Early History. During the early colonial period of the United States it was found that domestic legislation could not be enacted immediately to cover all subjects and provide for all contingencies. In order that some supplementary law might be available to govern unusual cases, the states generally accepted the Common Law of England. This was presumed to be a temporary matter and it was believed that statutory law would soon replace this legislation borrowed en bloc during a time of emergency. The states thus introduced, as a part of the Common Law of England, the doctrine of riparian rights.

The Doctrine of Riparian Rights was given its first concrete definition by Lord Ellenborough, in the English House of Lords in 1805. A final definition of the doctrine was given in the House of Lords in 1833 in th ecase of Mason *v.* Hill as follows: " A riparian proprietor can have no larger right than he has by nature against those above and below him. Hence the right to have a stream flow in its natural state without diminution or alteration is an incident to the property in the land thru which it passes." The doctrine as commonly understood and interpreted is: " All persons owing land abutting on a natural stream have the right to demand that the waters of that stream shall pass their lands undefiled in quality and undiminished in quantity."

The doctrine of riparian rights is negative and cannot be supported on arguments dealing with the beneficial use of water or public interests. It came into being before streams were of much importance in England save for navigation, and at a period when public interests were not considered. The English colonies have abrogated the doctrine wherever streams are of importance to the welfare of the people, especially where irrigation is an essential to agriculture. The defects of the doctrine were not soon discovered in the United States. The eastern part of the United States does not differ greatly from England in so far as the use of streams is concerned. Water resources were not appreciated during the early history of the United States. As the waters of streams and lakes were diverted for beneficial use conflicts arose between users, and the courts were appealed to for a definition of the rights concerned. The courts have had an impossible task and the record of their inability to administer a resource which must rest on technical judgment may be found among the archives of nearly every tribunal of justice.

Principle of Prior Appropriation. When gold was discovered in California the miners established rules of their own making. The first man to stake out a claim had the right to the ground. He posted a notice which defined the limiting boundaries of his claim. Since most of the mining industry of California in the early days depended upon the use of water, some rule was necessary to define their rights to the streams. They naturally accepted the same rule that applied to their claims, that is the first to use water had the first right to the stream. This was the birth of the doctrine of priority. This doctrine is now accepted as one of the fundamental principles in the arid districts of the United States.

California Legislation. In 1873 the legislature of California passed an act which recognized the doctrine of prior appropriation and also provided for the posting of a notice at some conspicuous place on the river bank setting forth

the claims of the prospective water user. In 1878 California created the office of State Engineer, who was presumed to have general supervision of the streams. Some time later a contest was waged between the doctrine of appropriation and the doctrine of riparian rights. The leading case, Lux v. Haggin (69 Cal. 255, at 398 et seq., 10 Pac. 674) was decided by the Supreme Court of California in 1884, upholding the common law doctrine. This decision has retarded development in California and prevented the enactment of legislation which might have brought about an effective administration of water resources.

Colorado Legislation. Colorado adopted the best features of the California legislation and was the first state to abrogate the doctrine of riparian rights. The office of State Engineer was created in 1881. Claims to water are made by filing in the office of the county clerk, the courts determining the rights accruing under the claims. This system has resulted in expensive litigation, and unnecessary delay in the settlement of claims. The main features of the Colorado law were adopted by other states and in many cases an attempt was made to enforce its provisions and at the same time accept the doctrine of riparian rights.

The Wyoming Water Laws. Laws very similar to those of Wyoming have been adopted by practically every western state with the exceptions of California, Colorado, Montana and Washington. The Province of Alberta, Canada, has also adopted the principal features of these laws. The Wyoming water laws represent the first attempt to place the control of water in the state. They were drafted by Dr. Elwood Mead, Territorial and later State Engineer. The following clauses were placed in the constitution of Wyoming:

ARTICLE I

"Sec. 31. Water being essential to industrial prosperity, of limited amount, and easy of diversion from its natural channels, its control must be in the state, which, in providing for its use, shall equally guard all the various interests involved."

ARTICLE VIII

"Sec. 1. The water of all natural streams, springs, lakes or other collections of still water, within the boundaries of the state, are hereby declared to be the property of the state."

"Sec. 2. There shall be constituted a board of control, to be composed of the state engineer and the superintendent of the water divisions; which shall, under such regulations as may be prescribed by law, have the supervision of the waters of the state, and of their appropriation, distribution and diversion, and of the various officers connected therewith. Its decisions to be subject to review by the courts of the state."

"Sec 3. Priority of appropriation for beneficial uses shall give the better right. No appropriation shall be denied except when such denial is demanded by the public interests."

"Sec. 4. The legislature shall by law divide the state into four (4) water divisions, and provide for the appointment of superintendents therefor."

"Sec. 5. There shall be a state engineer who shall be appointed by the governor of the state and confirmed by the senate; he shall hold his office for a term of six (6) years or until his successor shall have been appointed and shall have qualified. He shall be president of the board of control, and shall have general supervision of the waters of the state and of the officers connected with its distribution. No person shall be appointed to this position who has not such theoretical knowledge and practical experience and skill as shall fit him for the position."

Under the law which was enacted by the first legislature of Wyoming, the board of control determines all rights to the use of water. Litigation has practically disappeared. Every water user knows the limits of his rights and the state takes the initiative in their determination and protection. But few appeals have been taken from the board and it has been upheld in practically every case. To initiate a right, an application for permit is filed with the state engineer. If approved, this becomes a permit and the date of the

priority is fixed by the time of filing the application in the office of the state engineer. When the irrigation or other works are completed the proper division superintendent takes proof of the water user and a certificate of appropriation is issued. This is the final guarantee of the right by the state. The state requires complete plans to be filed showing the details of all construction that is contemplated. Where dams over 5 ft in height are to be built across the channels of running streams or over 10 ft in height elsewhere, the state may appoint an engineer to supervise construction—the builder paying the cost of this work. Some of the fundamental principles embraced in the law are contained in the sections which follow:

"Sec. 724. A water right is the right to use the water of the state, when such use has been acquired by the beneficial application of water under the laws of the state relating thereto, and in conformity with the rules and regulations dependent thereon. Beneficial use shall be the basis, the measure and the limit of the right to use water at all times, not exceeding in any case, the statutory limit of volume. Water being always the property of the state, rights to use shall attach to the lands for irrigation, or to such other purpose or object for which acquired in accordance with the beneficial use made and for which the right receives public recognition, under the law and the administration provided thereby. Water rights cannot be detached from the lands, place or purpose for which they are acquired, without loss of priority."

"Sec. 725. Water rights are hereby defined as follows according to use: Preferred uses shall include rights for domestic and transportation purposes; existing rights not preferred, may be condemned to supply water for such preferred uses in accordance with the provisions of the law relating to the condemnation of property for public and semi-public purposes. Such domestic and transportation purposes shall include the following: First—water for drinking purposes for both man and beast. Second—water for municipal purposes. Third—water for the use of steam engines and for general railway use. Fourth—water for culinary, laundry, bathing, refrigerating (including the manufacture of ice), and for steam and hot water heating plants. The use of water for irrigation shall be superior and preferred to any use except where turbine or impulse water wheels are installed for power purposes."

The four water divisions are further subdivided into water districts. In these smaller areas water commissioners have charge of the diversion and division of water, under the supervision of the division superintendent. The water commissioners have police powers.

30. Irrigation and Drainage Development Acts

State and National Laws have been enacted for the purpose of encouraging or assisting irrigation development in the United States. There has been no national drainage legislation, but drainage statutes have been enacted by most of the states. Under certain conditions more effective results could doubtless be obtained thru government legislation, especially for the reclamation of river bottom lands along interstate streams where drainage is incidental to flood prevention and the problem becomes a matter of national as well as local importance.

The Desert Land Act, approved in 1877, represents the first legislation enacted for the purpose of stimulating irrigation development. Like all development acts of this class, it provides a method of securing title to public lands, making their reclamation thru irrigation, one of the requisites for patent. The entryman, under this act, must comply with the water laws of the state and proof of irrigation in compliance with such laws must be submitted. The desert land act originally permitted an entryman to secure 640 acres by irrigating at least 5 acres in each legal subdivision of 40 acres. Since lands have become more valuable, Congress has limited the entry to 160 acres and the entryman is required to reclaim all of the irrigible lands of the entry.

The Irrigation District Law originated in California in 1887. A certain district or area is defined by the people interested in irrigation development and under the law an organization is effected which has some of the power and

authority of a municipality. Bonds are issued for the purpose of financing the construction of irrigation works. The lands of the district are held as security for the bonds. The officers of the district comply with the laws of the state with regard to water rights. The state exercises no supervision beyond this point.

The Carey Act was authorized by Congress in 1894. Under its provisions lands are donated to the states under the condition that the states provide for their reclamation. In the first measure passed by Congress, one million acres of land were donated to each arid state which elected to accept the imposed responsibility by legislative enactment. The states are authorized to contract with companies which perform the construction that is required, and then dispose of interests in the same (commonly referred to as water rights) to settlers in accordance with the area irrigated by each freeholder. At a certain stage in development, usually when the irrigation works are completed, the lands are patented to the state and as settlement takes place, and freeholders pay their installments to the constructing company and water is beneficially applied, the state patents the land to the settler.

The United States Reclamation Act was authorized by Congress in 1902. It provides that all revenues derived from the sale and rental of public lands shall be employed in the construction of irrigation works designed for the reclamation of arid lands. The United States Reclamation Service was organized gradually to take charge of the work. Projects are carefully studied and the irrigation works are then designed and laid out. When the works are finished settlement is invited. Settlers acquire lands in areas that are estimated to support a family comfortably. Under some projects the farm areas are as small as forty acres. These are entered under the homestead act and the settler is given 20 years to complete his payments toward a proportionate interest in the irrigation works. Water users' associations are formed under each project and as the settlers make their payments they become active participants in the management of the irrigation works. Finally, the government withdraws and leaves all responsibility in the hands of the local organizations.

The earliest drainage law enacted in the United States was by the colony of New Jersey in 1772. Statute books of all the states have subsequently been filled with similar legislation. In 1850 the Swamp Land Act of the Federal Government patented to the Public Land States swamp land now aggregating over 63 000 000 acres. The Act contemplated the reclamation of this land by the states as an incident to the perfection of good title. In the interval the states have parted with most of this land to railways, corporations, and individuals, and little or nothing has been undertaken toward its reclamation.

District Drainage Laws enacted in various states are generally based on the following fundamental principles of self-government, namely, (1) the consent of the majority of the interested landowners is necessary before a drainage district can be organized; (2) the drainage district cannot be organized unless it is clearly shown that the benefits to be derived will exceed the cost; (3) no drainage district can be organized unless it is shown that the work will be conducive to public health or general welfare. In general, the state laws require presentation of a petition by interested land owners setting forth the necessity and nature of the improvement accompanied by a bond. This petition is in some states presented to the county commissioner; in others to county supervisors or judges of the county court.

The drainage laws of some states provide for the appointment of county drainage commissioners and surveyors, in others for the appointment of a competent engineer. In some states the laws are based primarily on the idea of drainage for sanitation and the appointment of a sanitary or drainage commissioner for the counties. In others, drainage districts are created from time to time by statute, and provide for drainage commissions and for boards of assessors.

31. Cost and Value of Project

Cost Estimates. A preliminary estimate is usually prepared for the purpose of studying the feasibility of an undertaking. The final estimate which is used as a basis for letting construction contracts and other negotiations should be based upon a thoro investigation of the project and should consider all costs and expenses from the inception of the project to the time when it becomes a going concern. Cost estimates for land reclamation projects may be divided into four divisions: preliminary costs, the cost of construction, interest on investment, and the cost of colonization.

Estimates of Preliminary Costs include preliminary surveys and investigation, financing, rights of way, water rights, damages, legal fees, and all expenses incurred in perfecting rights and titles so that nothing will arise later to interfere with the progress of the work or the rights of settlers. Bond discounts may properly be considered a part of the expense of financing. Legal complication or expenses likely to be incurred from the diversion of waters, deflecting the course or modifying the flow of natural channels, should be investigated with particular care.

Estimates of Cost of Construction include the costs of all labor, supplies and equipment required for building the project. They should be liberal and make proper allowance for unforeseen contingencies such as unusual floods, and possible rise in the price of labor and cost of materials. Estimates of the cost of structures and excavation should be based upon a reasonable knowledge of foundation conditions and the character of material to be excavated. Unexpected difficulties are usually encountered in excavating under water, and these should be allowed for in making estimates. The cost of engineering, which includes final surveys, plans and supervision will usually range from 5 to 10 percent of the construction cost.

Interest on Investment, which begins with the first expenditures, increases in amount until the project is completed, and remains a charge against the cost of construction until it can be carried by revenues received from the project. As each tract of land is settled it carries its proportionate share of the interest charge. In order to reduce this expense to a minimum the construction work should be carried forward without undue delay and an active campaign for colonizing the land should be undertaken at as early a date as practicable.

The Colonization of a reclaimed area is an important feature of its development and an independent advertising and selling organization is usually advisable. Frequently the colonizing of a project is given out by contract, at a stipulated price per acre, to a colonization company, the commission being deducted from the revenues received from sales. No matter how attractive a newly reclaimed project may be, its advantages must be advertised and opportunities for showing the land must be provided. Frequently free railroad transportation from long distances is furnished by colonizing agencies to prospective settlers. It is important that a project should be settled and put under cultivation with as little delay as possible, in order to reduce interest charges and secure prompt returns on the investment. For this reason a vigorous colonizing campaign, with a view to settling the greater part of the project in a comparatively short time is generally advisable even tho it may require a larger expenditure than would be necessary if the settlement were extended over a longer period of time. The cost of colonization may vary from \$5 to \$25 per acre, depending upon the desirability, location, accessibility, and price of the land as well as the efficiency of the organization and general business conditions.

The above comments refer more particularly to projects developed by private capital, but in general the same principles apply to government reclamation work. Under

the terms of the U. S Reclamation Act, the reclamation fund is available without interest and the expenses resulting from delays in construction and colonization, tho just as real, are not so readily apparent. The government has provided no method of effectively advertising and colonizing its projects, and much of the available reclaimed area has not been settled.

The Value of Raw Land after reclamation will depend upon the fertility of soil, the kind of crops to which it is adapted, market conditions, transportation facilities, the efficiency of reclamation works, temperature, precipitation, length of growing season, and general business conditions. The safest basis for estimating the value of land is the market price of similar lands in the same or neighboring localities, making proper allowance if necessary for the expense of subjugating wild land.

The Cost of Reducing Raw Land from its wild state to the condition where it can be profitably cultivated may be considered as a part of the total cost of reclamation. If, as is usually the case, the farmer bears the expense of preparing his land for cultivation, the cost of this work in addition to the difference between the value of crops that might be expected from the land if thoroly subjugated, and those actually obtained while the land is being brought to a condition of profitable cultivation, should be deducted from the market price of similar cultivated lands in the locality to obtain the approximate value of the raw land. The three principal items of cost are: Clearing the land of native vegetation, grading, and putting in and successfully growing the first crops.

The Value of a project before reclamation may be estimated by deducting the estimated investment required for development from the estimated value of the land after reclamation. This difference may also be considered as the estimated profit from the investment.

Reclamation Projects as Security for Investment. After a reclamation project is completed and colonized and in successful operation it furnishes ideal security for investment. It is permanent and continually increases in value as improvements are made and the land is brought to a higher state of cultivation. Such security is comparable to a farm mortgage. A proposed or partially completed project, however, has a market value equal only to the value of the raw land which it embraces, and it is only within this limit that it provides safe security for an investment. The securities usually issued for the development of land reclamation projects are common and preferred stocks and bonds.

Projects may be financed with stock alone, with bonds alone, or with stock and bonds. If only stock is issued, the stock represents the actual investment, and the risk of the venture is shared by all of the stockholders. If only bonds are used for obtaining funds it is usual to issue common stock to the amount of the bond issue, the former representing the speculative feature of the investment. A large part of this stock is then distributed with the bond buyers as a bonus, the remainder being used in promoting the enterprise. Financing with stock and bonds requires an actual investment in stock which places the bonds on a sounder basis.

Failure of Reclamation Projects may result from improper engineering or poor business management. Engineering failure may result from under estimating construction costs, improper designs, or, in the case of irrigation projects, over-estimating the available water supply. From the business standpoint, failure may be caused by extravagance in the use of funds, inefficient management, inadequate arrangements for financing, colonization difficulties, or the short-sighted policy of putting an exorbitant price on land. The revenue from every project is dependent upon its successful colonization, and this not only requires that the project be settled with a good class of people, but that they be maintained in a prosperous and contented condition. Reclaimed lands are usually sold on the partial payment plan, the initial payment being frequently 25 percent of the selling price, with equal annual payments

and interest on deferred payments until the total amount is paid. It is a common experience on newly reclaimed areas that the settlers do not appreciate the expense or time required to subjugate raw land and having invested too much of their capital, either because of paying an exorbitant price for their land or buying too large an acreage, they do not have enough money left to develop their land, and as a result they are not able to make deferred payments and the land goes back to the original owners.

32. Operation and Maintenance

Organization. The right to participate in the benefits of an irrigation or drainage system is inherent with every tract of land which it embraces. This implies that every land owner within a project is entitled to a voice in its management. In some instances reclamation works are owned and operated by companies who contract with land owners to provide the benefits of the system at a fixed annual rate. More commonly the ownership of reclamation works ultimately passes to an organization composed of the land owners each of whom participates in the operation of the system proportionately to the area of land which he owns. This may be accomplished by forming a stock company in which 1 share of stock is issued for each acre of land. Such an organization has general direction of the operation of the system.

Water Users' Associations are formed by the water users of the projects of the U. S. Reclamation Service as soon as it appears probable that a project is to be constructed. The object of these associations is to facilitate dealings with the Department of the Interior and, after the construction work is completed, to participate in the operation of the project. The ownership, and operation of storage works remains in the hands of the Government while the distribution of water is left to the management of the Water Users' Associations.

The Operation of a reclamation system may be divided into three general divisions: (*a*) The operation proper, which includes the operation of pumps and other machinery, and for irrigation projects the delivery and distribution of water; (*b*) maintenance; and (*c*) clerical work. The force necessary will depend upon the size of the project. The organization should be such as to provide for effective and efficient service from the system, to keep the project maintained in a satisfactory operating condition, and to keep all records and accounts in a proper manner. General supervision will rest with the board of directors, or its equivalent, who determine the general policies of the system. Direct supervision is under a general manager, who is the responsible head.

The Head of the Operating Department of a drainage project may be the chief engineer of the pumping plant. On irrigation projects he is the water superintendent, and has charge of the distribution of the irrigation water. Under the superintendent are ditch riders who apportion the water among the various users. One ditch rider can oversee the distribution of water for 2000 to 3000 acres, where water is controlled at the farmers' headgates. If delivered to lateral headgates he serves from 5000 to 10 000 acres. The water superintendent should be thoroly versed in the principles of water measurement and the ditch riders should be sufficiently skilled to be able to make an equitable distribution of the water.

Maintenance as applied to reclamation projects includes the repairs, and labor necessary to keep the system in successful operation. Repairs to canals or structures damaged by floods, cleaning canals, replacement of broken parts of machines and similar work belong properly to maintenance, and it may also include minor extensions and betterments and the replacement of inexpensive structures. A regular maintenance force should be employed to keep the system

in satisfactory operating condition, except in case of unusual accidents, in order that the expense of maintenence for different years may, as nearly as practicable, be uniformly distributed.

Depreciation. There is a natural limit to the life of many of the parts of a reclamation system. Canals, levees, earth and rock dams and similar structures if properly maintained, and not accidentally destroyed should last indefinitely. Also it cannot be said that there is any limit to the life of many properly constructed concrete or masonry structures. Wooden and steel structures, however, will eventually deteriorate to such a state that they can no longer be maintained in a satisfactory working condition. The depreciation of the different parts of a reclamation system should be estimated in advance and provisions for replacements should be made by an amortization fund created by equal annual contributions, which are included as a part of the operating expense.

The Average Life, in years, of various parts of reclamation systems is approximately as follows:

Wooden flumes, redwood	15 to 20
Wooden flumes, fir	12 to 15
Wooden flumes, pine	8 to 10
Wooden stave pipe, fir, uncoated	12 to 20
Wooden stave pipe, fir, wellcoated	20 to 25
Wooden stave pipe, redwood, uncoated	20 to 25
Wooden stave pipe, redwood, wellcoated	25 to 30
Miscellaneous small wooden structures	10 to 20
Steel riveted pipes, uncoated	20 to 30
Steel riveted pipes, wellcoated	30 to 40
Centrifugal pumps	12 to 20
Steam engines	15 to 25
Boilers	12 to 20
Crude-oil engines	10 to 15
Pole lines for telephones or transmission	10 to 15
Electric motors	15 to 20
Buildings and improvements	25 to 75

The life of a structure depends largely upon the care that is taken to preserve it and the conditions of use to which it is subjected. Wood that is alternately wet and dry will deteriorate more rapidly than if kept continually wet. Structures above water may be preserved by keeping them well painted. Wood or steel buried in the ground or submerged or in contact with water for considerable periods will last longer if well coated with asphaltum or tar. The following, relative to the life of wood stave pipe (by D. C. Henny, Reclamation Record, August, 1915), was collected from a large number of installations:

(*a*) Under favorable conditions of complete saturation, fir well coated may have the same life as redwood uncoated.

(*b*) Either kind of pipe will have a longer life if well buried in tight soil than if exposed to the atmosphere. Such life may be very long, 30 years or over, if a steady pressure is maintained.

(*c*) Either kind of pipe will have a longer life if exposed to the atmosphere than if buried in open soil, such as sand and gravel and volcanic ash, provided in a hot or dry climate it be shaded from the sun.

(*d*) Under questionable conditions, such as light pressure or partially filled pipe, fir, even if well coated, may have only one-third to one-half the life of redwood.

(*e*) Under light pressure the use of bastard staves should be avoided.

(*f*) The use of wooden sleeves in connection with wire wound pipe is objectionable and has caused endless trouble and expense.

(*g*) If wooden sleeves are employed they should be provided at least for sizes from 10 in up with individual bands to permit taking up leaks.

Annual Cost of Operation includes all expenditures required to secure the benefits from the reclamation works and maintain them in working condition.

There is a wide variation in costs for different projects. The following represent the annual range of costs on a large number of projects:

Cost per acre of distributing water	$0.40 to $1.00
Cost per acre of maintenance	.50 to 1.20
Cost per mile of canal of maintenance	50.00 to 125.00
Cost per acre of general expense	.40 to .80
Cost of pumping water. (See Art. 18.)	
Cost of depreciation; each part of system must be considered separately.	
Total cost per acre of operation	2.00 to 4.00

Other costs are taxes, insurance, interest on investment and sinking fund, any or all of which may be included as a part of the annual expense.

The following is an estimate of the annual cost of irrigating 40 000 acres of land in southern Texas by pumping. It is based upon a total yearly water consumption of 120 000 acre-feet pumped against an average head of 20 ft. It does not include taxes, insurance, interest on investment or sinking fund:

Pumping Plant			
Depreciation, 7½ percent of $145 000		$10 875	
Labor			
3 enginemen	$4 200		
10 firemen	3 650		
Day labor	2 400		
		10 250	
Fuel, 40 000 bbls oil at $1.50		60 000	
Incidental supplies and repairs		3 000	
			$84 125
Canal System			
Depreciation of flumes, 7½ percent of $40 000		$3 000	
10 ditch riders at $900		9 000	
1 superintendent (civil engineer)		2 400	
1 assistant		1 500	
Cleaning canal system		25 000	
Renewals and maintenance, structures		8 000	
Miscellaneous		3 000	
			51 900
General			
Office rent		$1 200	
General manager		6 000	
Assistant		1 800	
2 clerks		2 400	
2 automobiles, operation and depreciation		2 000	
Miscellaneous expense		5 000	
			18 400
Total annual expense			$154 425

33. Engineering Reports

Purpose. A report on a land reclamation project should set forth, in clear and concise form, the essential characteristics of the enterprise. All data on which conclusions are based should be given, in order that the report will withstand a critical inspection by other engineers, but the controlling features, on which the feasibility of the project depends, should be intelligible to any good business man. Voluminous details, such as run-off, temperature, and pre-

cipitation records may be included in an appendix. Reports are always required in connection with the financing of reclamation projects, and their value in this regard may depend, in a large measure, on the standing and reputation of the engineer who makes them. In order to bring a project properly before investors, the promoters of the enterprise should have the report of a reputable engineer. Financial concerns, before investing, ordinarily require an independent report from their own engineer. Frequently several reports are made before a project is financed. Reports may be made at intervals during construction to determine whether work is progressing satisfactorily and in case of failure the creditors may require a report to determine the status of their securities.

An Investigation must precede the preparation of a report. This includes a field examination and a search for all data bearing on the development or success of the project. Ordinarily all surveys and other data of the field engineers will be available and these should be scrutinized with sufficient care to justify conclusions as to their reliability. Information relative to land values, crops, market conditions and similar matters may frequently be obtained from interviews with reliable persons, but data obtained from such sources should be accepted with caution. Government reports should be used if possible for securing temperature, precipitation, and stream flow data. Information obtained from investigating other projects in the locality is always valuable. Frequently additional surveys, test pits or other work will be required, but these should not be of extensive character. If data sufficient for an intelligent report are not available, this fact may be stated in the report, or the investigation may be postponed until full and complete data are secured. The field investigation ordinarily should not require more than one or at the most two weeks.

The Contents of a Report should be such as will set forth clearly the feasibility of the project from both engineering and business standpoints. In general, the main points to be shown are: (*a*) the efficiency of the reclamation system, (*b*) the cost of reclamation, and (*c*) the value of the project after reclamation or the net profit to result from the development of the project. The material should be presented in logical order and each subject should be discussed under an appropriate heading. The following are headings, with outlines of subject matter to be treated under each. They will have to be modified to suit the particular conditions of different projects:

(1) **Introduction.** There should be a few introductory statements leading up to the main body of the report. These may include the authority for making the report, the data on which the report is based, the engineer's opinion of the reliability of such data, the period covered by the investigation, and other general information of a similar nature.

(2) **Location.** It is important that the general location of the project should be described. Principal boundaries, railway and water transportation facilities, and distances to the more important markets should be given. A small scale general map showing this and other information will be valuable.

(3) **General Description.** A general description of the project should be given before entering into details. This may include important topographical features, the area of the project, and a comprehensive outline of the scheme of reclamation. A map of the project showing the general plan of reclamation should be included with the report and referred to in the discussion.

(4) **Climate.** Since the growth and time of marketing crops depends in a large measure on climate, this subject may be discussed in considerable detail. Tables may be prepared from government records showing maximum, minimum, and mean temperatures and amounts of precipitation for the different months of the year. Dates of last killing frosts in the spring and first killing frosts in fall should be given.

(5) **Soil.** The soil formation of the project from the standpoints of texture, fertility, adaptability to particular crops, and drainage conditions should be discussed. If the

soil formation varies greatly a soil map may be included. Government and state publications give valuable data relative to soils for many localities.

(6) **Crops.** Information as to the kinds, yields, and values of crops to which the lands of the project are particularly adapted should be included in the report. The costs of growing, the times of marketing, and the net returns to be expected from producing different crops may also be given. Information of this kind may frequently be shown to advantage in tables.

(7) **Markets.** The market for crops is usually an important consideration, and this should be discussed. Transportation facilities and freight rates should be given consideration in this connection.

(8) **Water Supply.** The success of an irrigation project depends in a large measure upon the adequacy of its water supply and this subject should be treated with considerable detail. The two things to be determined are the water supply available and the water supply required, and the analysis of the problem should show the data used and the steps taken in arriving at conclusions in regard to these matters. The discussion may be incorporated under the following headings.

(8*a*) **Period of Irrigation** showing the time when different crops will ordinarily be irrigated and the number of irrigations for different crops, with conclusions as to the approximate distribution in the use of water.

(8*b*) **Water Requirements** for crops or duty of water based upon a study of the needs for irrigation of the crops likely to be grown on the project.

(8*c*) **Water Supply Necessary** for the project determined from considerations of plant requirements, actual area to be irrigated, and seepage and evaporation losses in canals and reservoirs:

(8*d*) **Water Supply Available,** determined from a study of stream flow and other hydrological data, with proper deductions for prior rights to water. This phase of the problem will require careful investigation and all conclusions should be supported by as many records as practicable. If such records are too voluminous to be incorporated in the body of the report they should be put in the appendix.

(9) **Run-off.** The run-off from an area to be reclaimed by drainage should be discussed in detail and all precipitation records and other data necessary to support conclusions should be given. If pumps are to be used at the outlet the reasons for selecting a pumping plant of a certain capacity should be fully explained.

(10) **Cost of Project.** An estimate of the cost of developing a project, up to the point where it will become a going concern, should be included in the report and the main elements entering into the cost should be discussed. Estimates of this class should be made on a liberal basis so that ample allowance will be made for all contingencies.

(11) **Annual Cost.** An estimate of the annual cost of operating the project should be submitted. This, like the estimate of cost, should be on a liberal basis.

(12) **Value of Land.** The various conditions affecting the value of lands after reclamation should be discussed and an estimate of values should be submitted. It is important to distinguish between the value of raw lands after reclamation and the value of cultivated lands.

(13) **Net Returns.** An estimate of net returns on the investment may be submitted. This will be obtained by deducting the total expense of reclamation from the estimated value of land.

(14) **General Conclusions.** A few short, clear-cut paragraphs summarizing the main points brought out in the investigation should be given at the beginning or at the end of the report. The conclusions should contain definite statements of opinion regarding the value of crops, the adequacy of water supply for irrigation projects, the estimated cost of reclamation, the cost of operation, the value of land, estimated returns from the investment, and other important features. In some instances the report may be concluded with the engineer's recommendations.
